Preface

Natural Language Processing (NLP) has benefited from promising recent advances including the employment of latest deep learning technology amongst a host of other solutions. The current pandemic has prevented the in-person exchange of ideas and networking of NLP researchers and students, but virtual communication opportunities have enabled continued collaboration and provided alternative communication channels. While eagerly awaiting the return of normality, the international conference RANLP’2021 is offering an opportunity to promote the latest advances in the field, exchange ideas, learn from each other and interact virtually.

The conference in 2021 features nine keynote speakers:

- Tim Baldwin (The University of Melbourne, Australia),
- Josef van Genabith and Nico Herbig (DFKI and Saarland University, Germany),
- He He (New York University, USA),
- Eduard Hovy (Carnegie Mellon University, USA),
- Jing Jiang (Singapore Management University, Singapore),
- Alessandro Moschitti (Amazon Alexa, USA),
- Hwee Tou Ng (National University of Singapore, Singapore),
- Constantin Orasan (University of Surrey, UK),
- Sebastian Riedel (University College London and Facebook AI Research, UK).

This year 257 papers were submitted to the event. The good news is that most of them were of very good quality: 50 regular papers, 66 short papers, 68 posters, and 2 demos were accepted for presentation at the conference. The higher acceptance rate translates into better research quality in 2021 (with numerous papers presented in parallel made possible due to the online mode of communication).

The proceedings cover a wide variety of NLP topics, including but not limited to: deep learning; machine translation; opinion mining and sentiment analysis; author profiling, offensive language detection, fact checking; semantics and discourse; topic modelling; named entity recognition; coreference resolution; word-sense disambiguation; knowledge discovery and language models; corpora and ontologies; syntax; text summarisation; text categorisation, information extraction, question answering; multilinguality; language tools; NLP for biomedical domain; and NLP for low-resource languages.

In 2021 RANLP will host two post-conference workshops on popular NLP topics: the 14th Workshop on Building and Using Comparable Corpora (BUCC) and the First Workshop on Multimodal Machine Translation for Low Resource Languages (MMTLLRL-2021). The First International CLaDA-BG Conference, to be held on 6-7 September 2021, will present the achievements of the Bulgarian Interdisciplinary Research e-Infrastructure CLADA-BG for resources and technologies for the Bulgarian linguistic and cultural heritage, integrated within the EU Research Infrastructures CLARIN and DARIAH.

In addition to thanking the keynote speakers who accepted our invitation, we would like to thank all members of the Programme Committee and all additional reviewers. They ensured that the best papers were included in the Proceedings and provided invaluable comments to the authors.

We would like to use this paragraph to acknowledge the members of the Organising Committee, who worked very hard during the last few months and whose dedication and efforts made the organisation
of this event possible. All members of the Organising Committee (listed in alphabetical order below) carried out numerous organisational tasks and were eager to step in and support the organisation of the conference whenever needed: Dinara Akmurzina, Isuri Anuradha, Lucía Bellés-Calvera, Sol Berges, Maria Carmela Cariello, Rocío Caro Quintana, Ana Isabel Cespedosa Vázquez, Parthena Charalampidou, Anna Beatriz Dimas Furtado, Souhila Djabri, Anne Eschenbrücher, Marie Escribe, Darya Filippova, René Alberto García Taboada, Diana Geneva, Dinara Gimadi, Zara Kancheva, Alfiya Khabibullina, Lilis Kharatian, Shaifali Khulbe, Aida Kostikova, Sonia Kropiowska, Lydia Körber, Maria Kunilovskaya, Anastasia Laktionova, Ljubica Leone, Gabriela Llull, Jessica López Espejel, Ana Isabel Martínez-Hernández, Laura Mejías Climent, Alistair Plum, Kateryna Poltorak, Ivaylo Radev, Branislava Sandrih, Georgi Shopov, Nikola Spasovski, Natalia Sugrobova, Marina Tonkopeeva and Cecilia Valdenea. A big THANK YOU to all of you, this challenging in terms of organisation event could not have been taken place so smoothly without you!

Finally, many thanks go to the University of Wolverhampton, the Institute of Information and Communication Technologies at the Bulgarian Academy of Sciences, and Sirma AI for their generous support of RANLP.

Welcome to this year’s virtual event RANLP-2021 and we hope that you enjoy the conference!

The RANLP 2021 Organisers
The International Conference RANLP–2021 is organised by:

Research Group in Computational Linguistics,
University of Wolverhampton, UK

Department of Artificial Intelligence and Language Technologies,
Institute of Information and Communication Technologies,
Bulgarian Academy of Sciences, Bulgaria

RANLP–2021 is partially supported by:
Sirma AI

Programme Committee Chair:
Ruslan Mitkov, University of Wolverhampton, UK

Organising Committee Chair:
Galia Angelova, Bulgarian Academy of Sciences, Bulgaria

Workshop Coordinator:
Kiril Simov, Bulgarian Academy of Sciences, Bulgaria

Publishing Team:
Ivelina Nikolova-Koleva, Bulgarian Academy of Sciences and Sirma AI, Bulgaria
Georgi Shopov, Bulgarian Academy of Sciences, Bulgaria
Diana Geneva, Bulgarian Academy of Sciences, Bulgaria
Nikolai Nikolov, INCOMA Ltd., Shoumen, Bulgaria

Programme Committee Coordinators:
Ivelina Nikolova-Koleva, Bulgarian Academy of Sciences and Sirma AI, Bulgaria
Maria Kunilovskaya, University of Wolverhampton, UK
Rocío Caro, University of Wolverhampton, UK
Anne Eschenbrucher, University of Wolverhampton, UK
Maria Carmela Cariello, University of Wolverhampton, UK

The team behind RANLP-2021:
Galia Angelova, Bulgarian Academy of Sciences, Bulgaria
Ruslan Mitkov, University of Wolverhampton, UK
Preslav Nakov, Qatar Computing Research Institute, HBKU, Qatar
Nikolai Nikolov, INCOMA Ltd., Shoumen, Bulgaria
Ivelina Nikolova, Bulgarian Academy of Sciences, Bulgaria
Petya Osenova, Bulgarian Academy of Sciences, Bulgaria
Kiril Simov, Bulgarian Academy of Sciences, Bulgaria
Programme Committee:

Cengiz Acarturk (Middle East Technical University, Turkey)
Hassina Aliane (Research Centre on Scientific and Technical Information, Algeria)
Pascal Amsili (New Sorbonne University - Paris 3, France)
Le An Ha (University of Wolverhampton, United Kingdom)
Verginica Barbu Mititelu (Romanian Academy Research Institute for Artificial Intelligence, Romania)
Alberto Barrón-Cedeño (University of Bologna, Italy)
Riza Batista-Navarro (University of Manchester, United Kingdom)
Leonor Becerra (Aix-Marseille University, France)
Andrea Bellandi (National Research Council, Italy)
Victoria Bobicev (Technical University of Moldova, Moldova)
Svetla Boytcheva (Bulgarian Academy of Sciences, Bulgaria)
António Branco (University of Lisbon, Portugal)
Chris Brew (LivePerson, United States of America)
Erik Cambria (Nanyang Technological University, Singapore)
Burcu Can (University of Wolverhampton, United Kingdom)
María Carmela Cariello (University of Pisa, Italy)
Sheila Castilho (Dublin City University, Ireland)
Yue Chen (Indiana University, United States of America)
Parthena Charalampidou (Aristotle University of Thessaloniki, Greece)
Kenneth Church (Baidu, United States of America)
Kevin Cohen (University of Colorado, United States of America)
Orphee De Clercq (Ghent University, Belgium)
Radina Dobreva (University of Edinburgh, United Kingdom)
Anne Eschenbrücher (University of Wolverhampton, United Kingdom)
Antonio Ferrández Rodríguez (University of Alicante, Spain)
Alexander Gelbukh (National Polytechnic Institute, Mexico)
Tracy Holloway King (Adobe Inc., United States of America)
Veronique Hoste (Ghent University, Belgium)
Diana Inkpen (University of Ottawa, Canada)
Elena Irimia (The Romanian Academy, Romania)
Hitoshi Isahara (Otemon Gakuin University, Japan)
Udo Kruschwitz (University of Regensburg, Germany)
Sandra Kübler (Indiana University, United States of America)
Maria Kunilovskaya (University of Wolverhampton, United Kingdom)
Ladislav Lenc (University of West Bohemia, Czech Republic)
Natalia Loukachevitch (Lomonosov Moscow State University, Russia)
Stefano Marchesin (University of Padua, Italy)
Eugenio Martínez-Cámara (University of Granada, Spain)
Ricardo Muñoz Martín (University of Bologna, Italy)
Antonio Valerio Miceli Barone (University of Edinburgh, United Kingdom)
Johanna Monti (University of Naples “L’Orientale”, Italy)
Andrés Montoyo (University of Alicante, Spain)
Rafael Muñoz-Guillena (University of Alicante, Spain)
Preslav Nakov (Qatar Computing Research Institute, Qatar)
Roberto Navigli (Sapienza University of Rome, Italy)
Ivelina Nikolova-Koleva (Bulgarian Academy of Sciences and Sirma AI, Bulgaria)
Maciej Ogrodniczuk (Polish Academy of Sciences, Poland)
Constantin Orasan (University of Surrey, United Kingdom)
Petya Osenova (Sofia University and Bulgarian Academy of Sciences, Bulgaria)
Vasile Pais (The Romanian Academy, Romania)
Pavel Pecina (Charles University, Czech Republic)
Maciej Piasecki (Wroclaw University of Science and Technology, Poland)
Jakub Piskorski (Polish Academy of Sciences, Poland)
Alistair Plum (University of Wolverhampton, United Kingdom)
Gábor Prószéký (Hungarian Research Centre for Linguistics and Pázmány Péter Catholic University, Hungary)
Tharindu Ranasinghe (University of Wolverhampton, United Kingdom)
Omid Rohanian (University of Oxford, United Kingdom)
Paolo Rosso (Polytechnic University of Valencia, Spain)
Raheem Sarwar (University of Wolverhampton, United Kingdom)
Nasredine Semmar (Laboratory for Integration of Systems and Technology, France)
Vilelmini Sosoni (Ionian University, Greece)
Yoshimi Suzuki (University of Yamanashi, Japan)
Stan Szpakowicz (University of Ottawa, Canada)
Hristo Tanev (Joint Research Centre, European Commission, Italy)
Dan Tufis (Romanian Academy, Romania)
Luis Alfonso Ureña López (University of Jaén, Spain)
Marcos Zampieri (Rochester Institute of Technology, United States of America)
Michael Zock (National Centre for Scientific Research, France)

Reviewers:
Noor Abo Mokh (Indiana University, United States of America)
Ahmed AbuRa’ed (Pompeu Fabra University, Spain)
Itziar Aldabe (University of the Basque Country, Spain)
Ahmed Amine Aliane (Research Centre on Scientific and Technical Information, Algeria)
Ekaterina Artemova (Higher School of Economics University, Russian Federation)
Iana Atanassova (University of Bourgogne Franche-Comte, France)
Eduard Barbu (Institute of Computer Science, Estonia)
Antonina Bondarenko (University of Paris, France)
Aurélien Bossard (Paris 8 University, France)
Boryana Bratanova (St. Cyril and St. Methodius University of Veliko Tarnovo, Bulgaria)
Aljoscha Burchardt (German Research Centre for Artificial Intelligence, Germany)
Lindsay Bywood (University of Westminster, United Kingdom)
Oliver Cakebread-Andrews (University of Wolverhampton, United Kingdom)
Pablo Calleja (Universidad Politécnica de Madrid, Spain)
Hiram Calvo (Centre for Computing Research, Mexico)
Rocío Caro Quintana (University of Wolverhampton, United Kingdom)
Thiago Castro Ferreira (Federal University of Minas Gerais, Brazil)
Daniel Dakota (Indiana University, United States of America)
Kareem Darwish (Qatar Computing Research Institute, HBKU, Qatar)
Angelo Mario Del Grosso (National Research Council, Italy)
Mattia A. Di Gangi (AppTek GmbH, Germany)
Asma Djaidri (University of Science and Technology Houari Boumediene, Algeria)
Kevin Deturck (ERTIM & Viseo Technologies, France)
Sobha Lalitha Devi (Anna University, India)
Marie Escribe (University of Wolverhampton, United Kingdom)
Richard Evans (University of Wolverhampton, United Kingdom)
Mariano Felice (University of Cambridge, United Kingdom)
Vasiliki Foufi (University of Geneva, Switzerland)
Thomas François (Université catholique de Louvain, Belgium)
Emma Franklin (University of Wolverhampton, United Kingdom)
Larissa Freitas (Federal University of Pelotas, Brazil)
Björn Gambäck (Norwegian University of Science and Technology, Norway)
Aina Garí Soler (University of Paris-Saclay, France)
Federico Gaspari (Dublin City University, Ireland)
Darina Gold (University of Duisburg-Essen, Germany)
Momchil Hardalov (Sofia University "St. Climent Ohridski", Bulgaria)
Ali Hatami (University of Wolverhampton, United Kingdom)
Tomáš Hercig (University of West Bohemia, Czech Republic)
Diliara Iakubova (Kazan Federal University, Russian Federation)
Adrian Iftene ("Alexandru Ioan Cuza” University of Iași, Romania)
Camelia Ignat (Joint Research Centre, European Commission, Italy)
Milica Ikonić Nešić (University of Belgrade, Serbia)
Dmitry Ilvovsky (National Research University Higher School of Economics, Russia)
Radu Ion (Research Institute for Artificial Intelligence, Romanian Academy, Romania)
Tomoya Iwakura (Fujitsu, Japan)
Rubén Izquierdo Bevia (Nuance Communications, Spain)
Héctor Jiménez-Salazar (Metropolitan Autonomous University, Mexico)
Danka Jokić (University of Belgrade, Serbia)
Olga Kanishcheva (National Technical University, Ukraine)
Georgi Karadzhov (University of Cambridge, United Kingdom)
Aleksandar Kartelj (University of Belgrade, Serbia)
Dimitar Kazakov (University of York, United Kingdom)
Payal Khullar (International Institute of Information Technology, India)
Yasen Kiprov (Sofia University "St. Kliment Ohridski", Bulgaria)
Olga Kolesnikova (National Polytechnic Institute, Mexico)
Yannis Korkontzelos (Edge Hill University, United Kingdom)
Venelin Kovatchev (University of Birmingham, United Kingdom)
Cvetana Krstev (University of Belgrade, Serbia)
Todor Lazarov (New Bulgarian University, Bulgaria)
Tommaso Lo Sterzo (National Research Council, Italy)
Elpida Loupaki (Aristotle University of Thessaloniki, Greece)
Mireille Makary (Lebanese International University, Lebanon, and University of Wolverhampton, United Kingdom)
Suresh Manandhar (Wiseyak, United States of America)
Michał Marcińczuk (Wrocław University of Science and Technology, Poland)
Patricia Martín-Chozas (Universidad Politécnica de Madrid, Spain)
Halyna Maslak (University of Wolverhampton, United Kingdom)
Irina Matveeva (Reveal, Unites States of America)
Lesly Miculicich (Microsoft, United States of America)
Todor Mihaylov (Facebook, United States of America)
Cristina Vertan (University of Hamburg, Germany)
Veronika Vincze (University of Szeged, Hungary)
Victoria Yaneva (University of Wolverhampton, United Kingdom)
Sevinj Yolchuyeva (Budapest University of Technology and Economics, Hungary)
Kristina Yordanova (University of Rostock, Germany)
Wajdi Zaghouani (Hamad Bin Khalifa University, Qatar)
Mai Zaki (American University of Sharjah, United Arab Emirates)
Carlos Mario Zapata Jaramillo (Universidad Nacional de Colombia, Colombia)
Alisa Zhila (Amazon, United States of America)
He Zhou (Indiana University, United States of America)
Inès Zribi (University of Sfax, Tunisia)

Operational Team Leaders:
Rocío Caro Quintana, University of Wolverhampton, UK (Website content)
Ana Isabel Cespedosa Vázquez, University of Malaga, Spain (Correspondence)
Aida Kostikova, New Bulgarian University, Bulgaria (Session chairs)
Lydia Körber, University of Potsdam, Germany (Zoom hosting)
Maria Kunilovskaya, University of Wolverhampton, UK (Conference programme)
Gabriela Llull, Argentine Catholic University, Argentina (Final paper check-up)
Ana-Isabel Martínez-Hernández, University Jaume I, Castellón, Spain (Conference documentation)
Alistair Plum, University of Wolverhampton, UK (Website maintenance)
Organising Committee:

Dinara Akmurzina, New Bulgarian University, Bulgaria
Isuri Anuradha, University of Wolverhampton, UK
Lucía Bellés-Calvera, University Jaume I, Castellón, Spain
Sol Berges, University of Buenos Aires, Argentina
Maria Carmela Cariello, University of Wolverhampton, UK
Parthena Charalampidou, Aristotle University of Thessaloniki, Greece
Anna Beatrix Dimas Furtado, University of Malaga, Spain
Souhila Djabri, University of Alicante, Spain
Anne Eschenbrücher, University of Wolverhampton, UK
Marie Escribe, University of Wolverhampton, UK
Darya Filipova, University of Wolverhampton, UK
René A. García Taboada, University of Wolverhampton, UK
Diana Geneva, Bulgarian Academy of Sciences, Bulgaria
Dinara Gimadi, University of Wolverhampton, UK
Zara Kancheva, Bulgarian Academy of Sciences, Bulgaria
Alfiya Khabibullina, Ghent University, Belgium
Lilit Kharatian, University of Wolverhampton, UK
Shaifali Khulbe, University of Wolverhampton, UK
Sonia Kropiowska, University of Wolverhamton, UK
Anastasia Laktionova, University of Wolverhamton, UK
Ljubica Leone, Lancaster University, UK
Jessica López Espejel, Université Sorbonne Paris Nord, France
Ana Isabel Martínez Hernández, University Jaume I, Castellón, Spain
Laura Mejías Climent, University Jaume I, Castellón, Spain
Kateryna Poltorak, University of Wolverhampton, UK
Ivaylo Radev, Bulgarian Academy of Sciences, Bulgaria
Branislava Sandrih, Belgrade University, Serbia and University of Wolverhampton, UK
Georgi Shopov, Bulgarian Academy of Sciences, Bulgaria
Nikola Spasovski, University of Wolverhampton, UK
Natalia Sugrobova, Ghent University, Belgium
Marina Tonkopeeva, University of Wolverhampton, UK
Cecilia Valdenea, University of Wolverhampton, UK
# Table of Contents

**BPoMP: The Benchmark of Poetic Minimal Pairs – Limericks, Rhyme, and Narrative Coherence**  
Almas Abdibayev, Allen Riddell and Daniel Rockmore ......................................................... 1

**Ontology Population Reusing Resources for Dialogue Intent Detection: Generic and Multilingual Approach**  
Cristina Aceta, Izaskun Fernández and Aitor Soroa ................................................................. 10

**Efficient Multilingual Text Classification for Indian Languages**  
Salil Aggarwal, Sourav Kumar and Radhika Mamidi ............................................................. 19

**A New Quality Estimation Approach to Machine Translation**  
Benyamin Ahmadnia and Bonnie Dorr ..................................................................................... 26

**Domain Adaptation for Hindi-Telugu Machine Translation Using Domain Specific Back Translation**  
Hema Ala, Vandan Mujadia and Dipti Sharma ....................................................................... 31

**ArabGlossBERT: Fine-Tuning BERT on Context-Gloss Pairs for WSD**  
Moustafa Al-Hajj and Mustafa Jarrar ....................................................................................... 40

**English-Arabic Cross-language Plagiarism Detection**  
Naif Alotaibi and Mike Joy ........................................................................................................ 49

**Towards a Better Understanding of Noise in Natural Language Processing**  
Khetam Al Sharou, Zhenhao Li and Lucia Specia .................................................................... 58

**Comparing Supervised Machine Learning Techniques for Genre Analysis in Software Engineering Research Articles**  
Felipe Araújo de Britto, Thiago Castro Ferreira, Leonardo Pereira Nunes and Fernando Silva Parreiras .......................................................................................................................... 68

**Enriching the Transformer with Linguistic Factors for Low-Resource Machine Translation**  
Jordi Armengol-Estapé, Marta R. Costa-jussà and Carlos Escolano ......................................... 78

**A Multi-Pass Sieve Coreference Resolution for Indonesian**  
Valentina Kania Prameswara Artari, Rahmad Mahendra, Meganingrum Arista Jiwanggi, Adityo Anggraquito and Indra Budi ................................................................................................... 84

**Solving SCAN Tasks with Data Augmentation and Input Embeddings**  
Michal Auersperger and Pavel Pecina ....................................................................................... 91

**PyEuroVoc: A Tool for Multilingual Legal Document Classification with EuroVoc Descriptors**  
Andrei-Marius Avram, Vasile Pais and Dan Ioan Tufis ................................................................ 97

**TEASER: Towards Efficient Aspect-based SEntiment Analysis and Recognition**  
Vaibhav Bajaj, Kartikey Pant, Ishan Upadhyay, Srinath Nair and Radhika Mamidi ................. 107

**Interactive Learning Approach for Arabic Target-Based Sentiment Analysis**  
Husamelddin Balla, Marisa Llorens Salvador and Sarah Jane Delany ....................................... 116

**Litescale: A Lightweight Tool for Best-worst Scaling Annotation**  
Valerio Basile and Christian Cagnazzo ..................................................................................... 126
Character-based Thai Word Segmentation with Multiple Attentions
Thodsaporn Chay-intr, Hidetaka Kamigaito and Manabu Okumura ........................................ 269

Are Language-Agnostic Sentence Representations Actually Language-Agnostic?
Yu Chen and Tania Avgustinova ................................................................. 279

Investigating Dominant Word Order on Universal Dependencies with Graph Rewriting
Hee-Soo Choi, Bruno Guillaume, Karën Fort and Guy Perrier .......................... 286

RED: A Novel Dataset for Romanian Emotion Detection from Tweets
Alexandra Ciobotaru and Liviu P. Dinu ..................................................... 296

Assessing the Eligibility of Backtranslated Samples Based on Semantic Similarity for the Paraphrase Identification Task
Jean-Philippe Corbeil and Hadi Abdi Ghavidel ........................................... 306

Fine-tuning Neural Language Models for Multidimensional Opinion Mining of English-Maltese Social Data
Keith Cortis, Kanishk Verma and Brian Davis .......................................... 314

Towards an Etymological Map of Romanian
Alina Maria Cristea, Anca Dinu, Liviu P. Dinu, Simona Georgescu, Ana Sabina Uban and Laurentiu Zoicas ........................................................... 320

A Syntax-Aware Edit-based System for Text Simplification
Oscar M. Cumbicus-Pineda, Itziar Gonzalez-Dios and Aitor Soroa ................. 329

On Generating Fact-Infused Question Variations
Arthur Deschamps, Sujatha Das Gollapalli and See-Kiong Ng ............................ 340

Event Prominence Extraction Combining a Knowledge-Based Syntactic Parser and a BERT Classifier for Dutch
Thierry Desot, Orphee De Clercq and Veronique Hoste .................................. 351

Automatic Detection and Classification of Mental Illnesses from General Social Media Texts
Anca Dinu and Andreea-Codrina Moldovan ................................................. 363

A Pre-trained Transformer and CNN Model with Joint Language ID and Part-of-Speech Tagging for Code-Mixed Social-Media Text
Suman Dowlagar and Radhika Mamidi ...................................................... 372

Tracing Source Language Interference in Translation with Graph-Isomorphism Measures
Koel Dutta Chowdhury, Cristina España-Bonet and Josef van Genabith ............. 380

Decoupled Transformer for Scalable Inference in Open-domain Question Answering
Haytham Elfdaeel and Stanislav Peshterliev .................................................. 391

Towards Task-Agnostic Privacy- and Utility-Preserving Models
Yaroslav Emelyanov ................................................................................... 399

Knowledge Discovery in COVID-19 Research Literature
Ernesto L. Estevanell-Valladares, Suilan Estevez-Velarde, Alejandro Piad-Morffis, Yoan Gutierrez, Andres Montoyo, Rafael Muñoz and Yudivian Almeida Cruz ................................. 407

Online Learning over Time in Adaptive Neural Machine Translation
Thierry Etchegoyhen, David Ponce, Harritxu Gete and Victor Ruiz ..................... 416
Application of Deep Learning Methods to SNOMED CT Encoding of Clinical Texts: From Data Collection to Extreme Multi-Label Text-Based Classification
Anton Hristov, Aleksandar Tahchiev, Hristo Papazov, Nikola Tulechki, Todor Primov and Svetla Boytcheva .................................................................562

Syntax Matters! Syntax-Controlled in Text Style Transfer
Zhiqiang Hu, Roy Ka-Wei Lee and Charu C. Aggarwal ........................................571

Transfer Learning for Czech Historical Named Entity Recognition
Helena Hubkrová and Pavel Kral ................................................................. 581

Personality Trait Identification Using the Russian Feature Extraction Toolkit
James R. Hull, Valerie Novak, C. Anton Rytting, Paul Rodrigues, Victor M. Frank and Matthew Swahn ................................................................. 588

Semi-Supervised Learning Based on Auto-generated Lexicon Using XAI in Sentiment Analysis
Hohyun Hwang and Younghoon Lee ............................................................ 598

Multiple Teacher Distillation for Robust and Greener Models
Artur Ilichev, Nikita Sorokin, Irina Piontkovskaya and Valentin Malykh .............. 606

BERT Embeddings for Automatic Readability Assessment
Joseph Marvin Imperial ................................................................. 616

Semantic-Based Opinion Summarization
Marcio Inácio and Thiago Pardo .............................................................. 624

Using Collaborative Filtering to Model Argument Selection
Sagar Indurkhya ................................................................. 634

Domain-Specific Japanese ELECTRA Model Using a Small Corpus
Youki Itoh and Hiroyuki Shinnou ............................................................. 645

BERT-PersNER: A New Model for Persian Named Entity Recognition
Farane Jalali Farahani and Gholamreza Ghasem-Sani ..................................... 652

Cross-lingual Fine-tuning for Abstractive Arabic Text Summarization
Mram Kahla, Zijian Győző Yang and Attila Novák ....................................... 660

Behavior of Modern Pre-trained Language Models Using the Example of Probing Tasks
Ekaterina Kalyaeva, Oleg Durandin and Alexey Malafeev ................................ 669

Towards Quantifying Magnitude of Political Bias in News Articles Using a Novel Annotation Schema
Lalitha Kameswari and Radhika Mamidi .......................................................... 676

Application of Mix-Up Method in Document Classification Task Using BERT
Naoki Kikuta and Hiroyuki Shinnou ............................................................. 684

Translation Memory Retrieval Using Lucene
Kwang-hyok Kim, Myong-ho Cho, Chol-ho Ryang, Ju-song Im, Song-yong Cho and Yong-jun Han 689

Now, It’s Personal: The Need for Personalized Word Sense Disambiguation
Milton King and Paul Cook ................................................................. 697
Multilingual Image Corpus: Annotation Protocol  
Svetla Koeva ......................................................... 706

ELERRANT: Automatic Grammatical Error Type Classification for Greek  
Katerina Korre, Marita Chatzipanagiotou and John Pavlopoulos .................. 713

Neural Machine Translation for Sinhala-English Code-Mixed Text  
Archchana Kugathasan and Sagara Sumathipala ...................................... 723

Multilingual Multi-Domain NMT for Indian Languages  
Sourav Kumar, Salil Aggarwal and Dipti Sharma .................................. 732

Fiction in Russian Translation: A Translationese Study  
Maria Kunilovskaya, Ekaterina Lapshinova-Koltunski and Ruslan Mitkov ....... 739

Corpus Creation and Language Identification in Low-Resource Code-Mixed Telugu-English Text  
Siva Subrahmanyam Varma Kusampudi, Anudeep Chaluvadi and Radhika Mamidi .......... 749

Sentiment Analysis in Code-Mixed Telugu-English Text with Unsupervised Data Normalization  
Siva Subrahmanyam Varma Kusampudi, Preetham Sathineni and Radhika Mamidi .......... 758

From Constituency to UD-Style Dependency: Building the First Conversion Tool of Turkish  
Aslı Kuzgun, Öğuz Kerem Yıldız, Neslihan Cesur, Büşra Marşan, Arifete Betül Yenice, Ezgi Sanryar, Oğuzhan Kuyrukçu, Bilge Nas Arçan and Olcay Taner Yıldız .................. 766

Making Your Tweets More Fancy: Emoji Insertion to Texts  
Jingun Kwon, Naoki Kobayashi, Hidetaka Kamigaito, Hiroya Takamura and Manabu Okumura775

Addressing Slot-Value Changes in Task-oriented Dialogue Systems through Dialogue Domain Adaptation  
Tiziano Labruna and Bernardo Magnini .............................................. 785

Developing a Clinical Language Model for Swedish: Continued Pretraining of Generic BERT with In-Domain Data  
Anastasios Lamproudis, Aron Henriksson and Hercules Dalianis .................... 795

Text Retrieval for Language Learners: Graded Vocabulary vs. Open Learner Model  
John Lee and Chak Yan Yeung ......................................................... 803

Transforming Multi-Conditioned Generation from Meaning Representation  
Joosung Lee ................................................................................. 810

Frustration Level Annotation in Latvian Tweets with Non-Lexical Means of Expression  
Viktorija Leonova and Janis Zuters ................................................ 819

System Combination for Grammatical Error Correction Based on Integer Programming  
Ruixi Lin and Hwee Tou Ng .......................................................... 829

Multilingual Learning for Mild Cognitive Impairment Screening from a Clinical Speech Task  
Hali Lindsay, Philipp Müller, Insa Kröger, Johannes Tröger, Nicklas Linz, Alexandra Konig, Radia Zeghari, Frans RJ Verhey and Inez HGB Ramakers ........................................ 835

Naturalness Evaluation of Natural Language Generation in Task-oriented Dialogues Using BERT  
Ye Liu, Wolfgang Maier, Wolfgang Minker and Stefan Ultes .......................... 844
Towards the Application of Calibrated Transformers to the Unsupervised Estimation of Question Difficulty from Text
Ekaterina Loginova, Luca Benedetto, Dries Benoit and Paolo Cremonesi ........................................... 851

GeSERA: General-domain Summary Evaluation by Relevance Analysis
Jessica López Espejel, Gaël de Chalendar, Jorge Garcia Flores, Thierry Charnois and Ivan Vladimir Meza Ruiz ................................................................. 861

On the Interaction between Annotation Quality and Classifier Performance in Abusive Language Detection
Holly Lopez Long, Alexandra O’Neil and Sandra Kübler ................................................................. 872

NEREL: A Russian Dataset with Nested Named Entities, Relations and Events
Natalia Loukachevitch, Ekaterina Artemova, Tatiana Batura, Pavel Braslavskii, Ilia Denisov, Vladimir Ivanov, Suresh Manandhar, Alexander Pugachev and Elena Tutubalina .................................................. 880

Active Learning for Interactive Relation Extraction in a French Newspaper’s Articles
Cyrielle Mallart, Michel Le Nouy, Guillaume Gravier and Pascale Sébillot ........................................ 890

ROFF - A Romanian Twitter Dataset for Offensive Language
Mihai Manolescu and Çağrı Çöltekin .................................................................................................. 899

Monitoring Fact Preservation, Grammatical Consistency and Ethical Behavior of Abstractive Summarization Neural Models
Iva Marinova, Yolina Petrova, Milena Slavcheva, Petya Osenova, Ivaylo Radev and Kiril Simov ......................................................................... 905

Cultural Topic Modelling over Novel Wikipedia Corpora for South-Slavic Languages
Filip Markoski, Elena Markoska, Nikola Ljubešić, Eftim Zdravevski and Ljupco Kocarev ........... 914

Discovery of Multiword Expressions with Loanwords and Their Equivalents in the Persian Language
Katarzyna Marszalek-Kowalewska ........................................................................................................ 922

The Impact of Text Normalization on Multiword Expressions Discovery in Persian
Katarzyna Marszalek-Kowalewska ........................................................................................................ 933

Improving Neural Language Processing with Named Entities
Kyoumoto Matsushita, Takuya Makino and Tomoya Iwakura ................................................................ 944

TREMoLo-Tweets: A Multi-Label Corpus of French Tweets for Language Register Characterization
Jade Mekki, Gwénot Lecorvé, Delphine Battistelli and Nicolas Béchet ........................................................................ 954

Ranking Online Reviews Based on Their Helpfulness: An Unsupervised Approach
Alimuddin Melleng, Anna Jurek-Loughrey and Deepak P ....................................................................... 963

incom.py 2.0 - Calculating Linguistic Distances and Asymmetries in Auditory Perception of Closely Related Languages
Marius Mosbach, Irina Stenger, Tania Avgustinova, Bernd Möbius and Dietrich Klakow .......... 972

Not All Linearizations Are Equally Data-Hungry in Sequence Labeling Parsing
Alberto Muñoz-Ortiz, Michalina Strzyz and David Vilares ........................................................................ 982

Pre-training a BERT with Curriculum Learning by Increasing Block-Size of Input Text
Koichi Nagatsuoka, Clifford Broni-Bediako and Masayasu Atsumi ................................................... 993

COVID-19 in Bulgarian Social Media: Factuality, Harmfulness, Propaganda, and Framing
Preslav Nakov, Firoj Alam, Shaden Shaar, Giovanni Da San Martino and Yifan Zhang ................ 1001

xix
Siamese Networks for Inference in Malayalam Language Texts
Sara Renjit and Sumam Mary Idicula ................................................................. 1171

A Call for Clarity in Contemporary Authorship Attribution Evaluation
Allen Riddell, Haining Wang and Patrick Juola .................................................. 1178

Varieties of Plain Language
Allen Riddell and Yohei Igarashi ................................................................. 1184

Word Discriminations for Vocabulary Inventory Prediction
Frankie Robertson .................................................................................. 1192

FrenLyS: A Tool for the Automatic Simplification of French General Language Texts
Eva Rolin, Quentin Langlois, Patrick Watrin and Thomas François .................. 1200

Spelling Correction for Russian: A Comparative Study of Datasets and Methods
Alla Rozovskaya ............................................................................. 1210

Sentiment-Aware Measure (SAM) for Evaluating Sentiment Transfer by Machine Translation Systems
Hadeel Saadany, Constantin Orăsan, Emad Mohamed and Ashraf Tantavy .............. 1221

Multilingual Epidemic Event Extraction: From Simple Classification Methods to Open Information Extraction (OIE) and Ontology
Sihem Sahnoun and Gaël Lejeune ............................................................... 1231

Exploiting Domain-Specific Knowledge for Judgment Prediction Is No Panacea
Olivier Salaün, Philippe Langlais and Karim Benyekhlef .................................. 1238

Abstract

We adapt BLiMP (Benchmark of Linguistic Minimal Pairs) language model evaluation framework to the context of poetry, introducing the first of a series of tasks titled Benchmark of Poetic Minimal Pairs (BPoMP). The tasks presented herein use one genre of English-language poetry, the limerick (five-lines, rhyme scheme AABBA). Following the BLiMP schema, the BPoMP tasks use 10,000 minimal pairs of limerick/corrupted limerick. The latter is created by (1) shuffling two rhyming end-of-the-line words, (2) shuffling two rhyming lines, (3) replacing end-of-the-line word by a non-rhyming synonym. Our general task is detection of the original limerick, which we believe tests a language model’s capacity to utilize “end rhymes”, a common feature of poetry. We evaluate Transformer-based models by checking if they assign a higher probability to the non-corrupted limerick in each minimal pair. We find that the models identify the original limerick at rates better than chance, but with a nontrivial gap relative to human accuracy (average of 98.3% across tasks). The publicly available curated set of limericks accompanying this paper is an additional contribution. In general, we see this as a first step to create a community of NLP activity around the rigorous computational study of poetry.

1 Introduction

Machines — i.e., artificial intelligence — continue to make great progress toward the challenges of machine-assisted and machine-written literature. Examples range from word auto-completion algorithms to deep learning-based methods that (sometimes) produce Turing Test-passing text (Elkins and Chun, 2020) and even credible sonnets (Ghazvininejad et al., 2016). Evaluating such work uses a range of techniques, including automatic metrics such as BLEU as well as – rightly or wrongly – Turing Test-inspired human evaluation.

This paper focuses on testing if large models pretrained on gigabytes of text, such as GPT-2 (Radford et al., 2019) and Transformer-XL (Dai et al., 2019)), are capable of “discovering” the rhyming and basic narrative information inherently present within a simple poetic form, the limerick, a five-line poem, usually humorous, with rhyme scheme AABBA and regular – albeit not fixed – metrical structure. In particular, we test Transformer models on various (suitably contextualized) forms of the line completion problem for the limerick as well as a fundamental narrative-oriented task. These tests should be viewed as a first step toward a broader goal of framing the rigorous interrogation of the poetic (or more broadly, literary) capabilities of language models. Given their formulaic structure (e.g., AABBA rhyming scheme) and the relatively small size of each unit, limericks present a good testing ground as compared to longer or more complex poems, such as Shakespearean sonnets (see e.g., (Ghazvininejad et al., 2016)), or most broadly, “literature”.

To this end we gathered a small data set of 99,000 limericks (filtered down further for quality purposes), which we use to test three poetic feature: understanding the concept of a rhyme framed as two kinds of line completion test, and one test of narrative structure, framed as a line ordering test, given the full limerick. The primary contri-
butions of this paper are the instantiations of these tests as “minimal pair” tasks and a curated and publicly available dataset of limericks. The former are designed in the spirit of the BLiMP (Benchmark of Linguistic Minimal Pairs) tests (Warstadt et al., 2020) that are used to interrogate more general linguistic capabilities of language models. Our limerick-based test is a first construction that will be part of a larger collection of tests of machine poetry capabilities, given the title BPoMP, or Benchmark of Poetic Minimal Pairs. As for the latter contribution we hope that the availability of this curated data set inspires other computational studies of this and other poetic forms.

Recognizing the basic ingredients of a limerick (or any poetic form) are also part of being able to produce a limerick and thus, we also see this as a first step toward another larger goal: machine composition of high-quality limericks, or any prescribed poetic form.

2 Related Work

This paper is a part of the growing body of literature devoted to the formulation and execution of tasks for probing language models, including the “BERTology” literature that focuses on BERT (see e.g., (Tenney et al., 2019; Michel et al., 2019; Clark et al., 2019; Hewitt and Manning, 2019). In formulation, it is directly modeled on the BLiMP framework (Warstadt et al., 2020), wherein the machine is given a pair of instances, one correct, and another “minimally” modified (i.e., “corrupted” in some very minor, but systematic way) and the language model then outputs probabilities (or some derivative thereof) signifying which is the most likely. Our line completion tasks produce line completion-based metrics, and thus are related to the large body of work already devoted to the sentence completion task (see e.g., (Mirowski and Vlachos, 2015)). Our simple exploration of narrative structure, interrogated through the minimal pair of limericks, one an original and the other with two rhyming lines swapped, is related to, but different from work on next sentence prediction (Cui et al., 2018), which presents two sentences of text in original and swapped orders (but without the fuller context that our minimal pair of limericks provides) and produces probabilities for both occurrences.

Our work also drew partial inspiration from poetry generation literature (Ghazvininejad et al., 2016; Li et al., 2018; Liu et al., 2019; Lau et al., 2018). However, in this work we do not aim to create machine poetry, but rather show the way in which poetry can be used as a prism to evaluate models which purport to be accurate models of a wide variety of human-produced texts, i.e. texts written in a variety of genres and registers.

3 Problem Statement

In the spirit of BLiMP (Warstadt et al., 2020), we present the language model with a five-line limerick and its corrupted counterpart and compare the probabilities the model assigns to each of these text blocks. Note that for each test we always include a full limerick and full limerick with corruption (which thus may or may not still be a limerick). The corrupted limerick differs from its source in several possible ways (in the order of increasing difficulty): (1) two rhyming words swap places, (2) two rhyming lines swap places, (3) one word is changed, always an end-of-the-line rhyming word which has been replaced by a synonym (see below for details) that removes rhyming information. Each of the three defines its own task. The difficulty ordering is based on the amount of corruption introduced into the limerick—from somewhat obvious to more subtle. Note however, that this doesn’t necessarily correspond to empirical human rating of difficulty. We mostly focus on causal models, which allows us to infer the probability of sequence (i.e. limerick), by multiplying estimated probabilities of each token using previously seen tokens as context (in practice we sum log-probabilities) (Bengio et al., 2003):

$$P(S) = \prod_{i=0}^{|[S]|} P(w_i|w_{<i})$$

where $S$ is the limerick sequence and $w_i$ is the token at the position $i$.

In some cases (i.e. BERT) we use a modified pseudo-likelihood formulation we adapted from (Lau et al., 2020), to compute “probabilities” using bidirectional context:

$$P(S) = \prod_{i=0}^{|[S]|} P(w_i|w_{<i}, w_{>i})$$

This produces a simple experiment (and 3 tasks): given two sequences, a limerick and its corrupted
version, the model must correctly “guess” the original by assigning a higher probability to it. Each limerick pair then serves as a single test point. However, the source limerick may appear more than once within the dataset, since we may have generated several corrupted versions.

4 Experimental Setup

4.1 Dataset

We did not source published books of limericks, as they lacked machine-readable editions and tended to use dated language. Instead, we worked from the website The Omnificent English Dictionary In Limerick Form (OEDILF). OEDILF\(^1\), established in 2004, publishes user-submitted limericks subject to approval by moderators. The topics are generated by users and moderators. Our scrape of OEDILF contains limericks by 1624 different authors. The distribution of limericks by author is not uniform, with the top 10 authors responsible for ca. 40 % of all limericks. We first filtered limericks based on simple criteria: limericks must have 5 lines and must use words (as opposed to symbols, such as emojis or formulae). This excludes a range of unorthodox limericks such as ASCII art limericks. The result was a corpus of 98,454 limericks (dated 1998–present). For our experiment we further require all “limericks” satisfy some simple machine-identifiable limerick criteria: (a) end-of-the-line words must be in our rhyming dictionary, (b) 2nd and 3rd lines must have fewer syllables than other lines. Our first criterion is there to ensure all our limericks can be identified as following the AABBA rhyme scheme. Our second follows from the conventional definition of a limerick (and is tied to metrical structure). Verification uses CMUdict\(^2\) and a custom character-level RNN model used to predict the number of syllables in the words, trained on CMUdict and syllable count information from Wiktionary\(^3\). The details of this model can be found in the Appendix. This second stage filtering leaves us with 29,853 limericks to build the set of minimal pairs. This clean subset contains 52,316 unique words, and a total of 879,653 tokens. Next, we discuss the corruption process of the limericks for all of our tasks. Note that in every case, we sample a limerick from the clean subset and pair it up with its corrupted version using procedures described below.

4.2 “Shuffled” Test Sets

Two of our tasks shuffle the contents of the original limerick, by either swapping two words, or swapping two lines. We generated these as follows.

Our first shuffled dataset, samples a limerick and randomly swaps end-of-the-line two rhyming words (as defined by AABBA scheme) within it. Doing so, we aim to preserve rhyming information but also to distort the semantics. Swapped words are checked to belong to the same part of speech during the replacement process. In certain instances, rhyming words can in fact repeat within the same limerick, but we found that these account for only 0.05% of all altered limericks.

Our second shuffled dataset randomly swaps two lines in a sampled original limerick. In this case, we are trying to remove longer-horizon semantic information, as well as to disturb the meter. As previously, they must belong to the same part of rhyme scheme, A or B. We make sure to remove any obvious datapoints, such as lines that start a quotation, or corrupted limericks that now end with a non-line ending symbol, such as comma, as a result of the swap.

For both of these test sets, we sample 10,000 test

\(^1\)http://www.oedilf.com/db/Lim.php

\(^2\)http://www.speech.cs.cmu.edu/cgi-bin/cmudict

\(^3\)https://en.wiktionary.org/wiki/Wiktionary:Main_Page
pairs of original and altered limerick.

4.3 Corrupted Rhyme Test Set

The corrupted rhyming word limerick dataset was auto-generated using the following procedure. For each limerick we replace the $i$th end-of-the-line rhyming word, $i \in \{1, 2, 3, 4, 5\}$ with a non-rhyming synonym. To generate high-quality synonyms we used Merriam-Webster’s Collegiate Thesaurus API.\footnote{https://dictionaryapi.com/products/api-collegiate-thesaurus. We publish a static version of the set of minimal pairs so that all results reported here can be verified easily.} We were able to retrieve synonyms for 34,699 unique end-of-the-line words. Synonyms were then filtered by part of speech (Merriam-Webster provides different synonyms for each POS the query word potentially belongs to and it has in its database\footnote{For example eye returns ‘noun’: [‘ring’, ‘navel’, ‘scrutiny’, ‘...’, ‘consciousness’, ‘vision’, ‘loop’], ‘verb’: [‘deliberate’, ‘sight’, ‘ponder’, ‘meditate’, ‘perceive’, ‘...’, ‘watch’, ‘wrestle (with)’]}). We utilize spaCy (Honnibal et al., 2020) as our POS tagger. Once the set of synonyms is found, we choose the synonym with the closest contextualized representation (within the limerick) to the representation of an original word provided by BERT\textsubscript{LARGE} (Devlin et al., 2018). Separately, we score each synonym using a different scheme: we replace each end-of-the-line word with a synonym using the same process described above, and then use GPT-2 to score total limerick probability of each potential corrupted limerick. We then choose the highest probability replacement and see if it agrees with the BERT replacement. In case of agreement, we add the corrupted limerick to the pool. We want to stress that at no point are we comparing the corrupted limerick to the original in terms of total sequence probability as this would interfere with our experimental goals. In other words, all comparisons are made between candidate synonym replacements. This GPT-2 filtering ensures that most of our replacements are of high quality. Finally, we exclude all limericks whose tokens are not in any of the models’ vocabularies, and then sample 10,000 limerick pairs for the final test set.

4.4 Models

We assess a family of Transformer-based (Vaswani et al., 2017) language models. Transformer is a neural network that consists of several layers of attention (Bahdanau et al., 2014) interspersed with fully connected layers. For all Transformer models we utilize Hugging Face’s transformers (Wolf et al., 2020) library.

GPT-2 (Radford et al., 2019) is a causal language model, meaning that it predicts a word based only on preceding words. Thus, for line 3, the model uses all words from lines 1 and 2, and potentially uses rhyming information contained within the last word of line 1. We use GPT-2–Medium that has equivalent number of parameters (345 million) as all other Transformer models we test. GPT-2 was pretrained on a custom, 40 GB size dataset called WebText, which includes various HTML pages from around the web filtered so as not to include Wikipedia text.

BERT (Devlin et al., 2018) uses bidirectional self-attention, which in addition to looking behind, also looks ahead in sequence. BERT is trained on a masked language task, where in a given sequence (a sentence, a paragraph) certain words are masked at random and are then predicted given the surrounding context. We use uncased BERT in the generation of corrupted synonyms, and cased model in our experiments. In both cases we use 340M model. BERT is trained on a 3,300 million word combined corpus of regular prose (BookCorpus, (Zhu et al., 2015)) and an English Wikipedia dump scraped by the authors.

Transformer-XL (Dai et al., 2019) is another causal language model that differs through the addition of a recurrence mechanism: hidden states from previous segments (a fixed-length context window that the model uses to predict the next word) are carried over to the next segment, which theoretically extends the context length that Transformer-XL can utilize. In addition to support this recurrence mechanism the authors propose a novel position embedding scheme. Transformer-XL was pretrained on Wikitext-103 (Merity et al., 2016), a dataset of 103M tokens scraped from English Wikipedia. We use the 340 million parameter version of Transformer-XL.

XLNet (Yang et al., 2019) differs from other models in the optimization objective: the model is trained using a novel permutation language model objective, where instead of a fixed-order (left to right) context, the model is exposed to a randomly permuted sequence, while predicting the last word.
(or last few words) of this sequence. Since the new context includes tokens both from the left and right of the original context of the target word, the model is bidirectional. At the same time it is also causal as the generation is still left to right. In addition, XLNet reuses segment level recurrence as introduced in (Dai et al., 2019) to increase potential context length. XLNet, is trained on BookCorpus, English Wikipedia, but adds heavily filtered versions of datasets Giga5, ClueWeb 2012-B, and Common Crawl\(^6\) (Parker et al., 2011; Callan et al., 2009), resulting in 33 billion subword-piece dataset. The model we test has 340 million parameters.

5 Results

Our general experimental framework is as follows: we ask if the models assign higher probability to the uncorrupted limerick of the pair. Again, in each test the “minimal pair” is a pair of five-line texts, one the original limerick, the other a corruption, which may or may not still be a limerick. We compare our models using simple count-based accuracy: total number of correctly guessed pairs (i.e., pairs where the higher probability is assigned to the uncorrupted limerick) versus total number of (minimal) pairs.

Table 2 summarizes our results. For the task of differentiating between the original limerick and its twin with shuffled rhyming words, GPT-2 wins by a small margin over other Transformer models. The differences are very small, with the exception of Transformer-XL, which performed poorly (a pattern that appears in other tasks). Overall, the models were easily able to distinguish semantically inconsistent corrupted limericks.

Next we take a look at the task of swapping lines that rhyme. Since the semantic issues here are not as apparent, we expected performance of all models to dip compared to our first task. This largely has proven to be true, as accuracy drops by an average of 11% across all models. Here, as well, GPT-2 emerges to be superior in terms of performance.

Finally, we assess results on the most difficult task, where we preserve the semantic information but diminish rhyming information, by replacing one word with a non-rhyming synonym. The accuracy drops significantly, compared to first two tasks, and the gap between human and model performance is considerable. Here, BERT is the clear “winner” is that it outperforms the favorite GPT-2 by almost 5 percentage points. We theorize that the better performance comes from BERT’s increased bidirectional context. Based on these three experiments, rhyming information seems to matter to a non-trivial extent for these models.

5.1 Human Baseline

All models perform worse than human judges. Human readers correctly identify the original limerick with probability 1 in shuffled rhyming words and corrupted rhyming word tasks. The subjects emphasized that they identified corrupted limericks after scanning end-of-the-line words to find the non-rhyming word. On the shuffled line task they get 95% accuracy. The human experiments were performed with 11 test subjects in corrupted rhyming word task and 2 test subjects in the remaining two tasks. All test subjects were native English speakers and none poetry experts. Each test subject was presented with 20 randomly sampled pairs of limericks presented in randomized order. Arguably, in the shuffled line test, for both test subjects the mislabeled limerick was still syntactically - and metrically and rhyme scheme correct. We suspect that a similar test performed with a larger sample of human annotators would produce identical results.

5.2 GPT-2 Error Analysis: Synonym Corruption Case Study

For a more detailed error analysis we focus on the GPT-2 results within the corrupted rhyme task as the model is the clearest in terms of optimization task (next-word prediction) and performs well in most tasks. To analyze the GPT-2 errors we considered the distribution of log-probability differences between original and corrupted limericks, identifying tail cases with largest difference.\(^7\) This is a proxy for a measure of model prediction “confidence.”

We hypothesize that difference in the n-grams counts\(^8\) \(n \in \{2, 3, 4\}\) used in the last tokens of the corrupted line is strongly correlated with the log probability (the one model assigns to the entire limerick) difference between the limerick pair.

First we consider examples where the model assigned relatively high probability to the correct (original) limerick. We expect to see that the original bi-gram\(^9\) occurs with much higher frequency

\(\text{https://commoncrawl.org/}\)

\(\text{https://books.google.com/ngrams}\)

\(\text{We start with bi-grams, and in some cases used 3- and}\)
Transformer-based models succeed at a rate better than chance, but much worse than the perfect and near-perfect human baseline. The limerick dataset is made publicly available.

Future near-term contributions to the BPoMP framework include meter, assonance, and alliteration tested in more complex short poetry. While the limerick may appear to be a “simple” textual form, it is in that way a perfect kind of “model organism” for a more general study of poetry and even literature. A five-line poem of this form can still articulate a range of narrative structure and sophisticated literary devices, but is of a size that admits relatively easy modification and interrogation – e.g., through the minimal pairs framework. We hope that this paper and the concomitant data set release inspire such future work.

6 Conclusion

In this paper we have introduced a first instance of a Benchmark of Poetic Minimal Pairs (BPoMP), a framework for the testing of the poetic “knowledge” of a language model. Using a curated set of limericks we interrogate the abilities of four Transformer-based language models on three poetry-based tasks (end-of-the-line rhyme replacement, rhyming word swapping, and rhymed line swapping) framed as distinguishing a limerick from a minimally corrupted version. In each case the

Table 2: Accuracy in all 3 tasks in which we stress test Transformer models, with last line showing the average (2 subjects) human performance. In shuffled rhyming word task, corrupted limerick has two rhyming end-of-the-line words switch places. Shuffled rhyming lines, as the name implies, switches the position of two lines, e.g. line 1 and 5 trade places and corrupted limerick is rearranged in the line form 5,2,3,4,1. Lastly, in corrupted rhyming word task we choose one end-of-the-line word at random and replace it with a non-rhyming synonym found in Merriam-Webster dictionary.

than the corrupted bi-gram, which would translate to higher difference in bi-gram counts. The Pearson correlation for seven tail end cases was 0.71. This suggests that bi-gram frequency difference is a moderately good predictor of the log-probability difference. Next, we considered examples in which the model was very confident and wrong. In all such cases the GPT-2 output could be explained by bi-gram counts, with correlation of 0.89 for five extreme tail cases. In other words, the corrupted bi-grams displayed much higher frequency than their correct (original) counterparts. Note however, that this proxy falls apart as correlation reduces to $-0.39$ once we include more cases where the model isn’t as confident. Thus, for high confidence scenarios bi-gram statistics explain the differences in probabilities the model assigns to either original or a fake.

Appendix

A.1 Compute Resources

For most of the model testing and synonym generation work we used 2 NVidia Titan X graphics cards with 12GB of VRAM, running CUDA 11.2. In parallel, we also used Google Colab with T4 instances that sport 16GB of VRAM and also run CUDA 11.2.

A.2 OEDILF Description

The limericks are organized according to two categories: (a) included words contained and (b) topics. The latter are tags provided by both the managers of the website and the people who submitted the limericks. The dictionary part of the website refers to these words that could be found within a limerick, that is for any word in this dictionary there is a corresponding limerick that contains this word.

A.3 Identifying Number Of Syllables

Not all words in the vocabulary of our dataset are present in CMUdict, which only includes 133,779 examples. The full 98,454 limerick dataset (recall that there were two filtering steps to get us from this full set to the set used in the experiments) produces a vocabulary of 110,650 words, of which 55% are not present in CMUdict. To estimate the number of syllables in the vocabulary we trained a small (∼ 9800 parameters) character-level RNN\(^\text{12}\). The model consists of an embedding layer, a one-layer LSTM, with hidden size of 30, and a final linear layer that outputs back to characters. We train our charLSTM to be a classifier over 20 classes where each class determines the number of syllables in a word. The number 20 was set as an upper bound of number syllables based on the fact that the longest syllable word known in dictionaries has 19 syllables. A simple regression model did not work, nor did it optimize very well, displaying mode collapse-like behavior (i.e., consistent prediction of the average value, which is not useful for our discrete scenario).

\(^{12}\)We based the code from https://github.com/spro/char-rnn-pytorch

Table 3: Example of bigrams we captured for the analysis. Bigrams are highlighted in color. The limerick comes from a tail case when the model is correctly very confident.

Initially, we trained using pure CMUdict and around 15,000 words were used as a validation set, with another 118,000 used as as a training set. For our test set we decided to predict the number of syllables within lines of 21 limericks (which we labeled manually), as it emulates our scenario more closely than pure prediction of syllables in unseen words. We removed all of the words present in limericks from the training set. After analysis we determined that CMUdict did not contain many words with more than 11 syllables, so we supplemented it with another source: Wiktionary, an open source dictionary with user-submitted definitions of words. Wiktionary contains statistics with regards to number of syllables per word\(^\text{13}\) that can be scraped quite easily. We were able to obtain training examples with up to 19 syllables. In total that gave us additional 40789 training examples. We trained the model using ADAM optimizer, setting learning rate to 0.001 until validation loss went below 0.2 (around 10-12 epochs depending on the optimization curve).

A.4 GPT-2 Analysis And Bi-gram Outliers

In this section we present various supporting materials we used in our analysis of cases where the model assigned high probability to a limerick within a test pair. Table 3 presents an example limerick pair from our test set, in which GPT-2 correctly guessed the original with high confidence.

\(^{13}\)https://en.wiktionary.org/wiki/Category:English_words_by_number_of_syllables
Table 4: Outliers: target end-of-the-line word and its preceding neighbor taken from original and corrupted limericks which GPT-2 labelled correctly, but whose bi-gram frequency is higher for the corrupted limerick. This violates our hypothesis that bi-gram frequency would be higher for the original limerick. Upon closer examination we realize that 3- and 4-grams still fit our hypothesis. If frequency is listed as NA then it was not found in enough documents within Google Ngram corpora. Bigger n-grams (compared across rows) are bolded. The outliers were found when analyzing set of log-probabilities farther from the tail of empirical distribution.

Abstract

This work presents a generic semi-automatic strategy to populate the domain ontology of an ontology-driven task-oriented dialogue system, with the aim of performing successful intent detection in the dialogue process, reusing already existing multilingual resources. This semi-automatic approach allows ontology engineers to exploit available resources so as to associate the potential situations in the use case to FrameNet frames and obtain the relevant lexical units associated to them in the target language, following lexical and semantic criteria, without linguistic expert knowledge. This strategy has been validated and evaluated in two use cases, from industrial scenarios, for interaction in Spanish with a guide robot and with a Computerized Maintenance Management System (CMMS). In both cases, this method has allowed the ontology engineer to instantiate the domain ontology with the intent-relevant information with quality data in a simple and low-resource-consuming manner.

1 Introduction

Nowadays, the arrival of new technologies and virtual assistants (e.g., Siri, Alexa) prove that naturally interacting with different devices and applications is a reality that is constantly improving through time. In many contexts, such as industrial scenarios, this fact has contributed to an increasing demand of technologies that allow workers to naturally communicate (i.e., without relying on specific constructions or keywords) with industrial systems such as robots, machines or information systems so as to increase productivity and security (González-Docasal et al., 2020), among other aspects.

A common approach to support natural communication between humans and machines are dialogue systems. When the goal is for the system to perform a specific action requested by the user, task-based dialogue systems are used (Jurafsky and Martin, 2020). As stated in Jurafsky and Martin (2020), a wide range of modern commercial task-oriented dialogue systems are to some extent inspired in the Genial Understannder System (GUS) architecture in Bobrow et al. (1977). This architecture consists of frame structures, that model the situations to be invoked by the user –the intents– and the required slots –arguments– to be provided for each frame. To determine the frame to be selected for a specific request, an intent detection step is needed.

The main research goal is to develop a generic semantic-based task-oriented dialogue system inspired by GUS, in which both the dialogue process and the domain modelling are conceptualized in a generic manner by making use of ontologies\(^1\). The focus in this paper is the population process of the domain ontology to efficiently perform intent detection, minimizing human intervention and linguistic knowledge when adapting the dialogue system to specific use cases.

Communication based on natural language can use a variety of words and expressions to convey the same meaning. Therefore, a dialogue system that interacts with users must be able to recognize different words that evoke the same situation or refer to the same entity to perform successful intent detection\(^2\). In an ontology-based approach, to populate the domain ontology with this information, it is very important that the maximum number of these possibilities is considered. Doing so manually would be a high time- and resource-consuming task, and the tendency is to apply semi-automatic or automatic techniques (Makki, 2017; Benabbas et al., 2018). According to this tendency, this work presents a generic strategy that aims to overcome

\(^1\)The former is usually called dialogue ontology, and the latter domain ontology.

\(^2\)For the previous example, besides inform, the verb tell may also elicit the give information intent.
the challenge of instantiating the domain ontology with intents and their trigger words by semi-automatically exploiting existing lexical resources, without reducing the quality of the results and decreasing time and costs in the adaptation to different scenarios and applications. The result, thus, is a semi-automatic process which leverages existing Semantic Frames (Fillmore et al., 1976) and obtains the maximum number of words that trigger them in different languages —i.e., their translation equivalents—, so as to instantiate the domain ontology of the dialogue system approach previously described. This process has been validated in two use cases from industrial scenarios.

The rest of the paper is organised as follows: Section 2 will provide relevant Related Work. Section 3 will describe the ontology population strategy. Section 4 will present the validation and evaluation of the strategy through 2 use cases, and Section 5 will provide Conclusions and Further Work.

2 Related Work

There is a wide range of works in the literature that deal with intent detection, as it is one of the core tasks in the interpretation component in task-oriented dialogue systems (Gupta et al., 2019). In this sense, two main approaches to perform intent detection can be distinguished: on the one hand, approaches that rely on machine learning (ML) methods and, on the other hand, approaches that make use of ontologies. For both methodologies, a fair amount of data is needed and, thus, cannot cope with scenarios with limited or nonexistent labeled data, which implies the necessity of performing manual work, which is resource-consuming (Chen et al., 2017).

For machine-learning-based methods, several approaches can be observed in the literature that make use of traditional ML algorithms such as Support Vector Machines (Cortes and Vapnik, 1995) or logistic regression (Bishop, 2006). However, modern approaches employ deep learning (DL) methods (Louvan and Magnini, 2020; Chen et al., 2019). As mentioned previously, ML-based approaches require a large volume of data to perform training tasks, especially DL models.

For ontology-based methods, the population of the domain ontology to perform intent detection is generally based on patterns, which can be obtained automatically or semi-automatically. The formalization in Cassier et al. (2019), who have designed an intent detection system for emails in French, is inspired in semantic frames and the population of the domain ontology is based on a set of mainly automatically-generated patterns that allow to determine the words that trigger the intents. However, to obtain these patterns, a large amount of data was collected and processed. On the other hand, Quamar et al. (2020) present a dialogue system in which intent detection in health-related texts is performed. As in the previous case, the authors also rely on patterns to determine Key and Dependent concepts, which are considered to determine the intent in a sentence. Also, the information related to patterns is obtained combining expert knowledge and automatic methods.

Considering the previous remarks, intent detection seems to require either a large volume of data or manual work. In ontology-based approaches, for the former, the task of instantiating the domain ontology in low-resourced scenarios is severely limited and, for the latter, the use of manual expert knowledge is time and resource consuming. In this sense, a well-known challenge to the Semantic Web community is how to reduce the amount of manual work in the ontology population task. As noted by Kontopoulos et al. (2017), most approaches for ontology population make use of textual input and rely on natural language processing techniques to obtain the necessary knowledge to populate the ontology (Corcoglioniti et al., 2016; Makki, 2017), whereas approaches that rely on data that is structured at some degree—which are of interest for this work— are less common (Leshcheva et al., 2017; Kontopoulos et al., 2017). Considering this, the authors in Kontopoulos et al. (2017) use structured knowledge in Linked Data for ontology population.

The approach presented in this paper aims to overcome these challenges providing a methodology that could be used in scenarios with a lack of data with a relative minimal effort, without depending of expert linguistic work, and by making use of already available structured knowledge.

2.1 Resources

The concept of FrameNet originates from Frame Semantics (Fillmore et al., 1976), which is the linguistic theory that asserts that specific words evoke specific frames. In a nutshell, FrameNet constitutes a multilingual predicate resource that aims
to model situations (frames) and the words that elicit them (lexical units) in a comprehensive way, and also provides with the necessary actors that take part on them (Frame Elements) as a sort of a slot-modelling approach. In FrameNet, frames are not language-specific, and therefore are common in all language versions. That said, the data that varies across languages are, for each frame, the corresponding lexical units in the target language.

FrameNet, however, is not the only resource that provides predicate-related information in the literature. Other examples are VerbNet (Schuler, 2006) or PropBank (Kingsbury and Palmer, 2003). Each of these resources present characteristics that the rest of alternatives do not offer which, in the end, has generated the need to integrate them into a single repository. The result of this integration is Predicate Matrix (PM) (De Lacalle et al., 2014), in which data from different predicate (e.g. English FrameNet), lexical (e.g., WordNet (Miller, 1995)) and semantic (e.g. Suggested Upper Merged Ontology - SUMO (Pease et al., 2002)) resources is mapped, providing a “multilingual interoperable predicate lexicon” (De Lacalle et al., 2016).

Regarding the data integrated in PM, one of the lexical resources included is WordNet. WordNet (Miller, 1995) is a lexical knowledge base that stores nouns, verbs, adjectives and adverbs –and their corresponding senses– and groups them semantically into what are called synsets, which are described in Miller (1995) as “sets of cognitive synonyms”. In this sense, words are interlinked in semantic terms, considering each word’s senses. WordNet has been adapted to many languages and even some wordnets have been integrated into single resources, such as the Multilingual Central Repository –MCR–(Atserias et al., 2004). The MCR, which at the time of writing this paper is on version 3.0, aims to provide a powerful and rich multilingual lexical knowledge base (Atserias et al., 2004). This lexical knowledge base integrates data from multiple resources, including WordNet –in its 3.0 version– in six different language versions (English, Spanish, Catalan, Basque, Galician and Portuguese). Moreover, following the EuroWordNet architecture (Atserias et al., 2004), the MCR interconnects these wordnets using interlingual indices (ILI), also based in WordNet 3.0, for equivalent synsets in different languages. Furthermore, the repository has been enriched with ontological knowledge coming from semantic resources such as Base Level Concepts (Rosch, 1977), WordNet domains (Bentivogli et al., 2004) and SUMO\(^3\) (Pease et al., 2002; Guinovart et al., 2021). MCR synsets are also mapped in PM.

In terms of semantic data, among others, PM includes SUMO. SUMO is intended as an upper level ontology to serve as a “foundation for more specific domain ontologies” (Niles and Pease, 2001) by including a wide range of general-purpose terms that comprehensively cover different fields, such as Linguistics, Computer Science or Artificial Intelligence. Also, these terms are formally defined through axioms, which makes SUMO a specially enriched resource. Thus, the aim of SUMO is to provide a comprehensive, precisely defined term ontology. The mapping of SUMO tags with the rest of the elements in PM allows to establish a categorization between the different terms in it.

It is worth noting that PM is centred in verbal information. Thus, for resources that account for multiple parts of speech (such as nouns or adjectives in WordNet or frames that have nominal lexical units in FrameNet), only verbal data is integrated, so as to be able to properly map the data from all the resources involved.

3 Generic Strategy for Ontology Population for Intent Detection

The aim of the generic strategy is to support ontologists in the process of task-oriented dialogue system domain ontology population, minimizing the manual work, reusing linguistic resources, but without expert knowledge of the linguistic field.

The core linguistic resource used for collecting the necessary information for the ontology population process is PM, since it integrates and maps, among others, the information contained in FrameNet, SUMO and the MCR—the resources that include most of the relevant data for this work.

The strategy will guide the ontologist through the selection of the relevant information within PM, and will gather, semi-automatically, the relevant intents (through frames), the associated trigger words (through lexical units) and their corresponding synonyms for a specific use case in which the dialogue will take place. Considering this, the main steps of the strategy are the following:

0. **Use Case Characterization.** The identification of the different situations (associated

---

3Equivalence (“=”), subsumption (“+”) and instantiation (“@”) mapping relations (Alvez et al., 2019).
that surround the use case is performed. For example, for a guide robot, the situations involved may be to be taken to a given place or just to present information.

1. **Linguistic-resource-driven data selection.**
   For the given situations identified for the use case, a data selection from linguistic resources is performed, following three phases: **frame selection, lexical unit selection** and **semantic extension and filtering**.

2. **Automatic data gathering for intents.** Considering the selected data, the relevant knowledge to the intents is automatically gathered and structured in terms of the intents, their corresponding frames and the words that evoke them that are relevant to the use case. **Up to this point, the gathered information is agnostic to the structure of the target domain ontology.**

3. **Query generation and ontology population.** Once the relevant intent-related information is automatically obtained, the query for the final population of the target domain ontology will be generated.

The following sections will detail the aforementioned steps.

### 3.1 Linguistic-resource-driven data selection

This first step is aimed to obtain the necessary information that will serve as input for the automatic data gathering step. This data will be selected according to the situations identified for the use case.

#### 3.1.1 Frame Selection

The first stage in the process is to select the most suitable frames for the previously defined events in the use case. For this step, the ontology engineer will choose the relevant frames for the use case from the list of available FrameNet frames in PM.

For example, in a guide robot scenario – described in more detail in Section 4.1-- – one frame to be chosen would be **Motion**.

#### 3.1.2 Lexical Unit Selection

For each selected frame, a set of lexical units in English are automatically extracted from PM and presented to the ontology engineer, who will select the relevant lexical units according to the use case. This step is necessary because it is not evident that all lexical units are suitable to all the cases the chosen frame may apply to.

To illustrate this with an example, the frame chosen in the previous section, **Motion**, applied to the guide robot use case, in which a robot may be asked to guide the user to some final destination, has the lexical units *fn:blow.v, fn:fly.v, fn:go.v, fn:move.v,* etc., associated in PM. Within the use case, some lexical units such as *fn:fly.v* do not apply, and must therefore not be selected. In this case, the relevant lexical units to be selected are *go.v* and *move.v*.

#### 3.1.3 Semantic Extension and Filtering

The objective of this step is to extend semantically the previously selected lexical units by exploiting MCR synsets and SUMO tags.

For that, firstly, an automatic semantic extension is performed through the links from lexical units to MCR synsets in PM, collecting all the synsets related to given lexical units. However, not all the synsets in MCR for a lexical unit may apply to the use case, because polysemous words may acquire different meanings in a same frame, so a selection is required. For example, *go* may imply movement from one place to another or to pass away.

In PM, synsets are mapped to SUMO tags, which aim to group different synsets into single concepts. Since SUMO tags are more human-readable than synsets and the amount of tags is considerably lower without losing significance, the selection of synsets is proposed to be performed through SUMO tags. For that, the associated SUMO tags for the whole synset list are automatically extracted from PM and presented to the ontology engineer for the final selection.

To continue with the previous example, for *fn:go.v,* the **mcr:SubjectiveAssessmentAttribute, mcr:OccupationalRole; duration, mcr:Motion** and **mcr:Death** SUMO tags are presented to the ontology engineer, from which they will select the most relevant ones for the use case (all except **mcr:Death**).

### 3.2 Automatic Data Gathering for Intents

The objective of this step is to obtain the final words in the target language that evoke the desired intents. For this, the translation equivalents corresponding to the set of synsets obtained through the data in the previous steps will be retrieved automatically.
Taking as input the set of selected frames, lexical units and SUMO tags, the corresponding synsets will be automatically retrieved from PM. After that, the words in the target language that belong to these synsets will be obtained from the MCR, also automatically. As a result of this step, a set of synonyms in the target language(s) for each lexical unit will be obtained.

In the example used previously, for the frame *Motion* and the relevant synsets for the lexical unit *go.v*, the resulting synonyms in Spanish are the following: *acudir, desplazarse, ir, mover, moverse, viajar* and *partir*.\(^5\)

At this point, all the necessary data to support intent detection has been obtained.

### 3.3 Query Generation and Ontology Population

In this step, the SPARQL query necessary to populate the ontology with the gathered data is created according to the modelling of the target ontology. To summarise, Figure 1 represents the complete process, including the example use case shown in the previous sections, which is described in more detail in Section 4.1.

### 4 Validation and Evaluation

The process has been implemented as an API REST and has been tested in two use cases: a guide robot scenario and a Computerized Maintenance Management System (CMMS), both for the Spanish language. The domain ontology used is the Domain Module for Task-Oriented Dialogue management Ontology (TODO) –TODODom–\(^6\), as it is an ontology that provides a top model for domain modelling for task-based dialogue systems. The implementation of the methodology to instantiate the ontology described in this work applied to these use cases will be detailed in the following lines.

#### 4.1 Use case #1: Interacting with a Guide Robot in Spanish

In this use case, the user needs to communicate to a guide robot in Spanish. This robot is able to guide the user to their destination of choice and to offer information from specific elements (a room, a machine, etc.). The situations that may be identified from this use case, thus, are: to move from one point to another, and to ask for information or details about something. After checking the FrameNet frames in PM, the ones deemed more relevant in this use case are the following: *Motion, Taking* and *Arriving*\(^7\).

The next step is to select the appropriate lexical units for each frame in PM. In this case, the total number of lexical units for all the frames selected in the previous step are 34. Although many of the lexical units do cover the use case, such as *move* and *arrive*, there are others, such as *fly* or *blow*, that are too specific and do not apply to the use case and must not be selected.

After this selection, the number of lexical units in English is reduced to 12: *go, move (Motion); take (Taking); approach, arrive, come, enter, get, make, reach, return, visit (Arriving)*.

So as to semantically filter the synsets associated to each lexical unit, SUMO tags are used. In this case, the number of available SUMO tags is 34. In this use case, the application of semantic filtering is specially relevant, since from the initial 34 available tags, only two are applicable to the use case and have been selected: *BodyMotion* and *Motion*. The rest of tags were related to situations that were not considered in the use case, such as *Death or Cooking* and, thus, were not part of the final selection. This considerable reduction of tags reinforces the importance of this filtering step.

Finally, after having selected the frames, lexical units in English and SUMO tags, this information is used to automatically extract the applicable synsets and their translation equivalents in Spanish which, in this case, make a total of 32. The vast majority of the synonyms are relevant to the use case (e.g., *moverse, acudir, desplazarse, regresar*\(^8\)), although a very small portion of them are not entirely appropriate (e.g., *estar_ activo – to be active*).

#### 4.2 Use case #2: Interacting with a CMMS in Spanish

In this use case, the target system is a Computerized Maintenance Management System (CMMS), in which the user should be able to ask about problem solving protocols, request blueprints and similar tasks. As the previous use case, the language used is Spanish. Considering the previous remarks, the

---

5*Attend, move, go, move, travel and leave*

6*https://w3id.org/todo/tododom*

7Although the original FrameNet includes the frame *Information*, which would suit this use case, it is not included in PM due to the fact that it only has nominal lexical units. In the context of this work, this frame will remain out of the evaluation experiments carried out in Section 4.3.

8*move, go, move and return, respectively.*
Figure 1: Diagram representing the ontology population process presented in this work in a guide robot scenario.

</tr>
</tbody>
</table>

Identifiable situations in this use case are showing information and reporting and solving problems. The applicable frames are, thus, Resolve problem, Evidence, Reporting and Communication.

Regarding the lexical units, a total of 30 results have been obtained from the previously selected frames. After discarding some lexical units that were not applicable to the current use case, such as contradict or deal, the selected lexical units are the following: solve, resolve (Resolve проблем); indicate, reveal, show (Evidence and Communication); inform, report, tell (Reporting).

In this next step, the number of remaining SUMO tags is 9, which are reduced to Communication, VisualAttribute and IntentionalPsychologicalProcess. Given this selection, the total number of automatically obtained word synonyms in Spanish for this use case is 39, being most of them appropriate to the use case (e.g. solucionar, informar, presentar). However, other results are not applicable to the use case, such as denunciar (report, in the legal sense of the word).

4.3 Evaluation

The results obtained in the 2 use cases above have been evaluated to determine the suitability of the strategy described in this work. For this, a gold standard has been created using expert knowledge, by considering the synonyms in the target language (in this case, Spanish) for all the lexical units corresponding to the selected frames for each use case.

For this evaluation, different combinations of the manual selection steps in Section 3 have been applied, and their corresponding synonyms have been obtained through the resulting synsets. The combinations evaluated are the following:

- **Frame selection (F).** All lexical units for the selected frames and their associated synonyms.
- **Frame + lexical unit selection (F+LU).** Selection of lexical units for the selected frames.
- **Frame selection + SUMO filtering (F+SUMO).** All lexical units for the selected frames, plus SUMO filtering.
- **Frame+lexical unit selection+SUMO filtering (F+LU+SUMO).** Selection of lexical units for the selected frames, plus SUMO filtering. It is the strategy defined in this work.

Table 1 shows the number of synonyms obtained in each combination\(^\text{10}\). For each of the configurations, precision-recall-F1 evaluations have been performed, the results of which can be seen in Table 2. These evaluations show that the less filtering, the more recall, as the more synonyms obtained, the more possibility they will include the gold ones. In terms of F1, on average, unique filtering configurations (F+LU and F+SUMO) obtain practically the same results. It is especially relevant that SUMO filtering is able to obtain on average better precision.

results than LU selection --+0.07 points--, which emphasises the importance of a semantic filtering step in this type of task. Nevertheless, it is important to point out that both configurations help improve the results. In this sense, both processes combined are complementary, since their combination allows to significantly improve the base results obtained with F.

All in all, these results show that manual filtering is necessary in this type of task, as it has been proved that improves up to 0.3 points the F1 measure on average. Also, the figures obtained allow to determine that this is a complex task that deserves further investigation.

### 4.4 Other remarks

The information gathered in the use cases considered in this work allows to instantiate the domain ontology with intent-detection-relevant data reducing effort and potential intent identification errors. As it can be seen from the data reported in Sections 4.1 and 4.2, the incremental filtering through the defined steps allows to drastically reduce options, and semantic filtering allows to fine-tune the lexical units to be associated to an intent.

As a side note, and regarding both use cases, manual selection is not always a straight-forward process. Regarding frames, the online version of FrameNet\(^1\) --with the corresponding description of each frame in human-friendly terms-- may be used to be able to differentiate ambiguous frames.

### 5 Conclusions

This work focuses on the intent detection step in an ontology-based task-oriented dialogue system, which requires a modelling of the intents into the domain ontology. Since the intents and the words that trigger them vary depending on the use case, the task of instantiating the domain ontology with such information every time a new use case is needed is time and cost consuming.

The paper has presented a generic, semi-automatic strategy that reuses existing multilingual lexical resources to assist ontology engineers in modelling the specific intents and the words that elicit them for a given use case. This method consists of a preliminary characterization of the use case, a selection of relevant FrameNet frames, lexical units in English and SUMO tags and an automatic data gathering for intents given the previously selected data. The result is a structured set of intents, their corresponding frames and the words that evoke them. Finally, and depending on the modelling of the target domain ontology, a SPARQL query is generated, to be used to instantiate it.

To prove the generality of the approach, this strategy has been validated in 2 different industrial use cases: interaction in Spanish with a guide robot and with a CMMS. Moreover, an evaluation in terms of precision, recall and F1 has been performed. This evaluation validates the steps described in this work and their positive contribution to instantiate valid intent-related information with a lower resource consumption than doing so manually.

Further work includes research oriented to the improvement of the quality of the data extracted. As stated previously, PM only includes frames that have verbs as lexical units, leaving out other frames, such as Information, that have nominal or adjectival lexical units. In this line, it may be interesting to explore other sources of information that allow to obtain information about these missing frames and in different languages, in a similar manner that PM does with frames with verbal lexical units.

Abstract

India is one of the richest language hubs on the earth and is very diverse and multilingual. But apart from a few Indian languages, most of them are still considered to be resource poor. Since most of the NLP techniques either require linguistic knowledge that can only be developed by experts and native speakers of that language or they require a lot of labelled data which is again expensive to generate, the task of text classification becomes challenging for most of the Indian languages. The main objective of this paper is to see how one can benefit from the lexical similarity found in Indian languages in a multilingual scenario. Can a classification model trained on one Indian language be reused for other Indian languages? So, we performed zero-shot text classification via exploiting lexical similarity and we observed that our model performs best in those cases where the vocabulary overlap between the language datasets is maximum. Our experiments also confirm that a single multilingual model trained via exploiting language relatedness outperforms the baselines by significant margins.

1 Introduction

Text classification is the task of assigning pre-defined categories to free-text documents with the use of natural language processing (NLP). Here, the classifier is fed a text and it returns a category based on the content. For the purpose of this paper, the task is to classify whether a piece of news article is regarding sports or not. This process of assigning tags or categories to text according to its content helps businesses automatically structure and analyze text quickly and cost-effectively to automate processes and enhance data-driven decisions. With the growth of the Internet around the world, users write comments in different languages. But the majority of current classification systems still address only a single language, mainly English (Dashtipour et al., 2016). This increases the risks of missing essential information in texts written in other languages. Also, training these systems require substantial amounts of annotated datasets, which is again an arduous task for many languages. Same is the case with Indian languages. Despite having a very large number of native speakers, most of the Indian languages are still considered to be resource poor. There are not enough datasets available in most of the domains. Therefore, the task of text categorization becomes challenging for Indian languages.

Therefore, in order to classify data in different languages, multilingual text classification techniques are the need of the hour. Training a multilingual model would refrain us from training a separate model for different languages and it also helps the system in better learning by means of parameter sharing. This approach mainly works by combining all the data in hand and studies in machine translation (MT) have shown that multilingual learning is not much efficient in case of unrelated languages (Kudugunta et al., 2019; Kunchukuttan and Bhattacharyya, 2020). But this is not the case with Indian languages. Underlying the vast diversity in Indian languages are many commonalities. Because of contact over thousands of years, most of the Indian languages have undergone convergence to a large extent (Sridhar, 1981). These languages share many common words which have the same root word and meaning. However, they use different scripts derived from the ancient Brahmi script (Kunchukuttan and Bhattacharyya, 2020), but correspondences can be established between equivalent characters across different scripts. So, the main question arises whether we can benefit
from the relatedness found in between Indian languages? By relatedness, we refer to languages that exhibit lexical and structural similarities on account of sharing a common ancestry.

Thus, in this work, we put our efforts in exploring the zero-shot as well as multilingual text classification via exploiting lexical similarity of Indian languages. For zero-shot classification, we are proposing the efficient way of reusing a classification model trained on one language on some other Indian language. In addition to this, we also tackled the problem of deciding which language model to use for zero-shot classification for a particular test language. Our results confirm that maximum accuracy is achieved in those cases where the vocabulary overlap between the two language datasets is maximum. For efficient multilingual text classification, we are exploiting the lexical similarity via two techniques namely unified transliteration and subword segmentation. Our experiments also confirm that in case of low resource related languages, multilingual models achieve better accuracy than the baseline models.

This paper is further divided into 5 sections. Section 2 discusses related work in this area. Section 3 elaborated the methodology behind the different techniques and experiments. Section 4 elaborates the experimental details including the dataset preparation, dataset pre-processing and the experimental setup for training our models. All the results and analysis have been discussed in Section 5. Section 6 talks about conclusion and possible future work.

2 Related Work

One of the main problems in multilingual classification is the significant lack of resources (Balahur and Turchi, 2012). Thus, analysis in multiple languages is often addressed by transferring knowledge from resource-rich to resource-poor languages (Denecke, 2008), because there are no resources available in other languages. Much of the work in subjectivity analysis has been applied to English data, though work on other languages is growing: e.g., Japanese data are used in (Kobayashi et al., 2004; Suzuki et al., 2006; Kanayama and Nasukawa, 2006), German data are used by Kim and Hovy (2006b). Lexical approaches for sentiment analysis necessitate language specific lexical and linguistic resources. Generating these resources is very time consuming and often requires a lot of manual work. Methods have been developed for the mapping of subjectivity lexicons to other languages. To this aim, Kim and Hovy (2006a) use a machine translation system and subsequently use a subjectivity analysis system that was developed for English to create subjectivity analysis resources in other languages.

Another approach in obtaining subjectivity lexicons for other languages than English was explored by Banea et al. (2008b). In this work, authors attempt to leverage on the resources available for English and, by employing machine translation, generate resources for subjectivity analysis in other languages. This paper introduces a method for creating a subjectivity lexicon for languages with scarce resources. Further on, another approach to building lexicons for languages with scarce resources is presented by Banea et al. (2008a). This method is able to build a subjectivity lexicon by using a small seed set of subjective words, an online dictionary, and a small raw corpus, coupled with a bootstrapping process that ranks new candidate words based on a similarity measure. Machine translation for multilingual text classification has also seen attention from researchers. The approach is to use a machine translation system to translate texts in other languages into English: the text is translated from the original language into English, and then English-language resources such as SentiWordNet are employed (Denecke, 2008). Kanayama et al. (2004) translated only sentiment units with a pattern based approach. Balahur and Turchi (2014) used uni-grams, bi-grams and tf-idf features for building support vector machines on translated text. Boyd-Graber and Resnik (2010) built Latent Dirichlet allocation models to investigate how multilingual concepts are clustered into topics. Translation systems, however, have various problems, such as sparseness and noise in the data (Balahur and Turchi, 2012). Sometimes, the translation system does not translate essential parts of a text, which can cause serious problems, possibly reducing well-formed sentences to fragments. Therefore, we put our efforts for training a multilingual classifier without
India is known as the land of many tongues (Kunchukuttan and Bhattacharyya, 2020). There is no single language called “Indian”. India speaks hundreds of languages and dialects (Sengupta and Saha, 2015). Some are extinct, while some are still in use with considerable speakers. Despite having a lot of different scripts, most of the Indian languages still share a lot of lexical features and common words which have the same root and meaning which can be utilized to help improve the quality of zero-shot as well as text classification systems trained on them. So, in this paper we propose our technique of performing zero-shot classification via exploiting the language relatedness. Also, we investigate how multilingual classification models perform in case of Indian languages. To do this efficiently, we exploited the lexical similarity via two techniques namely unified transliteration and subword segmentation.

3.1 Exploiting Lexical similarity

Unlike the original multilingual text classification techniques which mostly aim at transfer learning via parameter initialisation i.e. learning from one high resource language and then transferring knowledge to some low resource language, we are exploiting lexical similarity between related Indian languages via parameter sharing. For this, we combined the two different approaches namely unified transliteration and subword segmentation to ensure that there is sufficient overlap between the vocabularies of the related Indian languages datasets.

3.1.1 Unified Transliteration

Since the languages involved in the models have different scripts, the data processing should help to map them into a common single script. So here, we transliterate all the Indian languages into a common Devanagari script (which in our case is script for Hindi) to share the same surface form (Kunchukuttan and Bhattacharyya, 2020). This unified transliteration is a string homomorphism, replacing characters in all the languages mentioned above with Hindi characters (script conversion to Devanagari) or consonant clusters independent of context.

3.1.2 Subword Segmentation

Despite sharing a lot of cognates, Indian languages do not share many words at their non-root level. Therefore, the more efficient approach is to exploit Indian languages at their sub-word level which will ensure more vocabulary overlap. Therefore, we are converting every word to sub-word level using the very well known technique Byte Pair Encoding (BPE) (Sennrich et al., 2015). This technique is applied after the unified transliteration in order to ensure that languages share same surface form (script). BPE units are variable length units which provide appropriate context for translation systems involving related languages. Since their vocabularies are much smaller than the morpheme and word level models, data sparsity is also not a problem. In a multilingual scenario, learning BPE merge rules will not only find the common sub-words between multiple languages but it also ensures consistency of segmentation among each considered language pair.

3.2 Zero-Shot Text Classification

There are many languages in India and one can not expect annotated data available in all of the domains for all of the languages. So in zero-shot text classification, the model can classify any text between given labels without any prior training data. For performing it efficiently for Indian languages, we are using the vocabulary overlap technique as discussed in Section 3.2.1. From our experiments, we noticed that the zero-shot classification performs best in those cases where the vocabulary overlap is maximum between the different language datasets. That model will perform best on that language, which is most similar to the

training language dataset using vocabulary overlap technique. The method of calculating vocabulary overlap matrix is explained in the further subsection.

3.2.1 Vocabulary Overlap

We calculated similarity scores for each language based on vocabulary overlap by considering other language training data as monolingual data. Vocabulary Overlap provides a crude measure of surface form similarity between two languages. It is efficient to calculate, and is often quite effective, especially for low-resource languages. Here, we use the number of tokens that two languages share to measure the similarity between them. First, we transliterated each language to a common script, in our case it is Devanagari script and then all the tokens were converted into their respective subwords. After that score was calculated using the percentage of the common tokens in the two languages as:

\[
\text{vocab}_{l1-l2} = \frac{|\text{Token}_{l1} \cap \text{Token}_{l2}|}{|\text{Token}_{l1}|} \times 100
\]

The details of the vocabulary overlap matrix is shown in Table 1.

3.3 Multilingual Text Classification

We trained a Multilingual model, which is a single model that can handle multiple languages simultaneously. This would circumvent having to train a monolingual model for every single Indian language. One example in our case would be to classify whether a piece of news article is regarding sports or not. Using a regular Machine learning or Deep learning model, we would be able to classify only Punjabi language sports articles but not articles written in other Indian languages say Marathi. But if we use a multilingual model, we would be able to classify news articles in Punjabi, Marathi and multiple other Indian languages. Our results also prove that multilingual models achieve better performance than monolingual models, especially for low-resource languages. This could be the ability to learn not just from the training data of the language in question, but also from other language datasets.

But we noticed that this learning is not much efficient in case of the languages that don’t show any kind of relatedness. But on the other hand, Indian languages exhibit a lot of lexical and structural similarities on account of sharing a common ancestry. It is therefore important to utilize the lexical similarity of these languages to build systems by combining all the related languages. For the scope of this paper, we have trained 2 kinds of multilingual models. One with the training data of all the languages combined in their respective scripts and the other in which all the languages are first transliterated into one common script, in our case in Devanagari and then they are combined. To the best of our knowledge, this is the first time when someone has exploited the lexical similarity found in between Indian languages by using the techniques of unified transliteration and subword segmentation for the task of text classification. The pipeline is shown in Figure 1.

4 Experiments

4.1 Dataset

We have used IndicNLP News Article Classification Dataset (Kunchukuttan, 2020) for performing our experiments. This classification dataset comprises news articles and their categories for 9 different Indian languages. The dataset is balanced.

4.2 Dataset Preprocessing

We noticed that the dataset contains a lot of punctuation, so we used manually created regex for cleaning the entire corpora. For all of our experiments, we have taken an equal number of training sentences from all the languages in order to maintain uniformity while training multilingual models. We have used the Indic NLP library (Kunchukuttan, 2020) for tokenization and normalization as our pre-processing steps. Also, to make sure that all the languages share the same surface form and have sufficient vocab overlap, we again used Indic NLP library (Kunchukuttan, 2020) for unified transliteration and subword segmentation.

4.3 Training Details

The dataset was split into a ratio of 4:1 for the purpose of training and testing. All of our experiments were performed using 5-fold cross-validation. We used an embedding layer followed by a Bidirectional LSTM layer followed by a dense layer. The embedding size was set to 128 and 128 hidden units were used in the LSTM layer. All the models were trained for 20 epochs with a batch size of 64. All of the experiments were performed using Keras library (Chollet et al., 2015) with Tensorflow (Abadi et al., 2015) as its backend.

5 Results and Analysis

Table 2 shows the results of zero-shot text classification on various languages. We can see that the maximum accuracy is achieved in those cases where the vocabulary overlap between the training and the monolingual dataset is maximum. For eg, Marathi model will perform best on the Punjabi test set due to maximum overlap. This can be confirmed from our vocabulary overlap matrix shown in Table 1. The reason is that most of the Indian languages share a lot of common sentiment bearing words and we exploit this using converting everything into same script and every word to its component subwords.
Table 3 shows the results of baselines as well as our multilingual models. We can see from the table that both the multilingual models outperform the baseline models. The reason is the ability to learn not only from its own dataset, but also from the other related languages present in the dataset. The best accuracy is achieved in the case where we apply the technique of unified transliteration and subword segmentation. The reason as explained above is the increase in vocabulary overlap which further increases the accuracy as compared to the first case. So, we can observe that in both the cases, we have benefitted from the lexical similarity found in Indian languages.

6 Conclusions and Future Work

In this work, we explored effective methods to exploit lexical similarity between related Indian languages in order to improve the quality of classification systems on low resource Indian languages. Our results confirm that a model trained on one Indian language can be reused for another Indian language and will provide good results if there is a significant vocabulary overlap between the two datasets. We also proved that for low resource Indian languages, multilingual models outperform the baseline models. The reason is the ability to learn not just from the training data of the language in question, but also from the other language datasets. Unified Transliteration and Subword Segmentation further increase the accuracy by increasing the vocab overlap among the datasets. Also, to get more increase in accuracy, one can try with large size datasets. For future work, we will try to apply this technique to other NLP related tasks for Indian languages.

Abstract

Procedures that perform the task of Machine Translation (MT) quality estimation are typically trained with text from the same distribution on which their performance is later evaluated. In most cases, additional human-scored source-target sentence pairs are provided for training. In this paper, we investigate an MT quality estimation setting where the algorithm has no access whatsoever to the test distribution of text or to an annotated training set with human judgment scores. Our method is based on a new notion of sentence cohesiveness. Our experiments on standard competition datasets for various language pairs show that the performance of our system is comparable to the baseline system.

1 Introduction

Procedures that perform the task of Machine Translation (MT) quality estimation are typically trained with texts from the same distribution on which their performance is later evaluated. In most cases, additional human scored source-target sentence pairs are provided for training. One flavor of the MT quality estimation task is to provide an MT metric like BLEU (Papineni et al., 2002) but without using reference translations.

The typical setting is a supervised learning one (Kreutzer et al., 2015; Martins et al., 2016, 2017), to mention a few. The algorithm is trained with a large corpus of source-target pairs, along with human judgment scores. The test set is typically sampled from the same distribution of the train. The algorithm is evaluated by comparing, for example, the scores that it assigns to the test sentence pairs with human judgment scores. When only text is provided for training, but no human judgment scores, then it is referred to as an unsupervised learning setting. Examples of unsupervised algorithms include Moreau and Vogel (2012); Banchs and Li (2011); Yankovskaya et al. (2019); Xu et al. (2020). This still does not preclude training on the same distribution of text as the test. Thus, the algorithm can use valuable features such as n-gram statistics or word embedding, tailored to that specific distribution.

Currently, there is no formal name or distinction from the scenario where the algorithm has no access whatsoever to the text distribution on which its performance is being tested and in particular no human judgment scores are provided. In this paper, we make this distinction and define the latter one as our learning setting. This setting makes sense in cases where access to the text’s distribution is impossible or too expensive. Furthermore, our learning setting can serve as a benchmark to test the robustness of an MT quality estimation algorithm to various degrees of noise in the training step.

The contribution of this paper is making formal the distinction between unsupervised and our proposed MT quality estimation, and providing a new quality estimation algorithm inspired by physical systems of particles. We view a sentence as a small system of interacting components (the words, represented using word embedding). For each sentence, we compute a cohesiveness factor, $N$, which reflects the extent to which the meaning of the entire system is a function of the meanings of its constituents. In fact, we take the difference in cohesiveness between source and target sentences as the measure for translation quality. The difference in cohesiveness is some aspect of adequacy, which is commonly understood as the amount of information (meaning) preserved between the reference and the candidate translation.

The proposed method is compatible with the learning setting as it can use word embedding that were trained on a generic text from the relevant source-target language pair. Furthermore, this
method utilizes only monolingual data that makes the method attractive in cases where cross-lingual parallel corpora is scarce or non-existent.

This paper is organized as follows; Section 2 details the proposed methodology. Section 3 outlines the experimental design and describes the results. Section 4 concludes the paper.

2 Methodology

An instance of the MT quality estimation problem is a pair of sentences $S$ (source) and $T$ (target). The output is a score that the algorithm assigns for the quality of the translation from $S$ to $T$ ($S \rightarrow T$). The words of $S$ are represented by word embedding, obtained e.g. via word2vec. These words are stacked into a sentence matrix $M_S$, whose rows are the $d$-dimensional vectors of the words.

To measure the extent to which the meaning of a sentence is a function of its words, we need to represent a sentence. The standard possibility is to train a system to represent all the words in a corpus as vectors. The purpose of the Skip-Gram Architecture is to train a Phrase-Based Statistical MT (PBSMT) decoder.

The $i$th row of $M_S$ (the $i$th word) can be written as:

$$W_i = \sum_{n=1}^{m} U_{in} \sigma_n v_n = U_{i1} \sigma_1 v_1 + \text{err}$$

(1)

That is, the vector of each word in the sentence is composed of the semantic contribution from $v_1$ (the main direction of the sentence) plus an error term, $\text{err}$. Thus, we can derive cohesiveness as the ratio:

$$n(M) = \frac{\sigma_1}{\sum_{i=1}^{m} \sigma_i}$$

(2)

For illustration consider the following three 5-word sentences: Dear dear dear dear dear (same word), Breakfast, dinner, lunch, milk, egg (same theme), and Monster, factory, gym, lake, chair (random themes). Using the vectors of Mikolov et al. (2013) we computed the sentence matrix and cohesiveness factor of each sentence. The first sentence scored $N = 1$, the second $N_2 = 0.46$ (nearly 50%) and the third merely $N_3 = 0.22$, which is roughly the expected approximation rate had $v_1$ been a random vector. In fact, the meaning of the first and second sentences is the “sum of their parts” (large cohesiveness) while the meaning of the third sentence is not (small cohesiveness).

Mathematically, the procedure receives as input the source sentence $S$, the target $T$, word embedding $w_S$ in the source language and $w_T$ in the target one, and an error $L : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$, the better the translation. For the evaluation, we use:

$$L(x, y) = \max \{x, y\} / \min \{x, y\}$$

(3)

Algorithm 1 Proposed quality estimation

Procedure: quality estimation ($S$, $T$, $w_S$, $w_T$, $L$)

1: Embed $S$ and $T$ using the word-embedding $w_S$ and $w_T$ respectively
2: $M_S \leftarrow$ sentence matrix of $S$
3: $M_T \leftarrow$ sentence matrix of $T$
4: return $L(N(M_S), N(M_T))$

For the task of document-level quality estimation, the algorithm is applied iteratively on the sentences, and the final score is computed as the average of the $L$-values.

3 Evaluation

In our experiments, we employ “Google’s word2vec” (Mikolov et al., 2013) for English, and “Wikipedia-trained vectors” for non-English. All vectors are 300-dimensional, and also are trained using the skip-gram architecture with negative sampling.

The first batch of tests compares the performance of our proposed quality estimation algorithm (at sentence-level) against various supervised algorithms. As seen in Table 1, the first four columns show the results along with information about the baseline and best and supervised systems in that competition. As evident from Table 1, the performance of the supervised baseline which having access to human-judgment annotated data from the same distribution of they estimation algorithm train) is on average by merely 25% better.

The WMT’12 quality estimation task dataset (Callison-Burch et al., 2012) consists of 442 English-Spanish news texts produced by Moses4

4https://github.com/Kyuhong/wordvectors

4The purpose of the Skip-Gram Architecture is to train a system to represent all the words in a corpus as vectors.

4A Phrase-Based Statistical MT (PBSMT) decoder.
were manually annotated for quality in terms of post-editing effort (1-5 scores).

The WMT’17 quality estimation task dataset contains English sentences that are translated to German by various MT-systems, and ranked by correlation with HTER labels that are computed using TERCOM. We took 479 sentences translated by SYSTRAN4847. This system had the largest number of human scored sentence pairs.

The Japanese-English and Japanese-Chinese sentence pairs are taken from Fujita and Sumita (2017). The dataset contains 1676 sentences in Japanese that are obtained from role-play dialogues of healthcare providers. The sentences are translated into English and Chinese using their in-house MT system and quality is graded on a 1–5 scale, reflecting post-edit effort.

The baseline in the third share task of WMT’19 (Fonseca et al., 2019), LASER, is an unsupervised algorithm (Artetxe and Schwenk, 2019), but also supervised-learning algorithms competed in that task. The last two columns of Table 1 show how our approach compares on that data. The results that we reported are on a sample from the train set that was published by the organizers. We sampled about 200 sentences, which is roughly the size of the test set in that same competition (the test set, along with human-judgment scores, was not released). As evident, the proposed quality estimation outperforms LASER.

In the second batch of tests, we compared our method against BLEU at the document-level using two datasets sampled from two very different distributions. The first set consists of 100 online news pieces in English from websites like CNN, NBCNews and NYTimes. The second contains 100 English poems by more than 30 different poets written in the 19th century. The average number of words per poem is 130 and 196 for a news piece. For each text we performed forward translation into each of German and French and then back to English using three MT systems: Bing, Google and SDL. All texts and translations are provided as supplementary data.

We evaluated each pair using the proposed quality estimation and BLEU, the original text serving as a reference for BLEU. For each of the 200 pairs, we recorded the winning MT system according to BLEU and the proposed quality estimation. Tables 2 and 3 contain the ranking of the three MT systems. It shows that BLEU and the proposed quality estimation are aligned in their ranking: Bing > Google > SDL for German, French, and both distributions. The Spearman rank correlation between BLEU and the proposed quality estimation is around 0.4 for poetry (across languages), 0.27 for news via German and 0.16 for news via French.

We checked how sensitive are our results to the choice of text that was used to train the word embedding, and to the parameters of the training (specifically, with or without negative sampling). To this end, we repeat the tests with various combinations of pre-trained vectors, using either Google news text or Wikipedia. For English text, we replaced Google’s word2vec with WikiNeg\(^5\) and for non-English we replaced WikiNeg with WikiNorm.

Table 4 summarizes the correlation with human judgment scores when our proposed quality estimation was parameterized with the various com-

\(^5\)It means without negative sampling

4 Conclusion

In this work, we defined a new MT quality estimation setting where the proposed algorithm has no access whatsoever to the test text’s distribution or to an annotated training set with human judgment scores. In fact, we proposed an MT quality estimation system based on a new notion of sentence cohesiveness that we introduced. We tested our system on standard competition datasets for various language pairs. Our experimental results suggest that reasonable MT quality estimation can be carried out even in the restrictive setting.

Abstract  

In this paper, we present a novel approach for domain adaptation in Neural Machine Translation which aims to improve the translation quality over a new domain. Adapting new domains is a highly challenging task for Neural Machine Translation on limited data, it becomes even more difficult for technical domains such as Chemistry and Artificial Intelligence due to specific terminology, etc. We propose Domain Specific Back Translation method which uses available monolingual data and generates synthetic data in a different way. This approach uses Out Of Domain words. The approach is very generic and can be applied to any language pair for any domain. We conduct our experiments on Chemistry and Artificial Intelligence domains for Hindi and Telugu in both directions. It has been observed that the usage of synthetic data created by the proposed algorithm improves the BLEU scores significantly.

1 Introduction  

Neural Machine Translation (NMT) systems achieved a breakthrough in translation quality recently, by learning an end-to-end system (Bahdanau et al., 2014)(Sutskever et al., 2014). These systems perform well on the general domain on which they trained, but they fail to produce good translations for a new domain the model is unaware of.  

Adapting to a new domain is highly challenging task for NMT systems, it becomes even more challenging when it comes to technical domains like Chemistry, Artificial Intelligence etc, as they contain many domain specific words. In a typical domain adaptation scenario like ours, we have a tremendous amount of general data on which we train an NMT model, we can assume this as a baseline model, now provided a new domain data, the challenge is to improve the translation quality of that domain using available little amount of parallel domain data. We adopted two technical domains namely, Chemistry and Artificial Intelligence for Hindi -> Telugu and Telugu -> Hindi experiments.

The parallel data for the mentioned technical domains is very less, hence we used back translation to create synthetic data. Instead of using synthetic data directly which may contain lots of noise we used domain monolingual data to create synthetic data in a different way (see section 3.4) and used such that translation of domain terms and context around them is accurate.

2 Background & Motivation  

As noted by Chu and Wang (2018) there are two important distinctions to make in domain adaptation methods for Machine Translation(MT). The first is based on data requirements, supervised adaptation relies on in-domain parallel data, and unsupervised adaptation has no such requirement. There is also a difference between model-based and data-based methods. Model-based methods make explicit modifications to the model architecture such as jointly learning domain discrimination and translation (Britz et al., 2017), interpolation of language modeling and translation (Gulcehre et al., 2015; Domhan and Hieber, 2017) and domain control by adding tags and word features (Kobus et al., 2016). Zeng et al. (2019) proposed iterative dual domain adaptation framework for NMT, which continuously fully exploits the mutual complementarity between in domain and out domain corpora for translation knowledge transfer. Apart from this Freitag and Al-Onaizan (2016) proposed two approaches,
one is to continue the training of the baseline model (general model) only on the in-domain data (domain data) and the other is to ensemble the continue model with the baseline model at decoding time. Coming to the data-based methods for domain adaptation, it can be done in two ways, combining in-domain and out-of-domain parallel corpora for supervised adaptation (Luong et al., 2015) or by generating pseudo-parallel corpora from in-domain monolingual data for unsupervised adaptation (Sennrich et al., 2015a; Currey et al., 2017).

Our approach follows a combination of both supervised and unsupervised approaches. where we first combine domain data (Chemistry and Artificial Intelligence) with general data, train a domain adaptation model. Then, as an unsupervised approach we use available domain monolingual data to back translate and use to create domain adaptation model. Burlot and Yvon (2019) explained how we can use monolingual data effectively in our MT systems, inspired from Burlot and Yvon (2019), instead of just adding domain parallel data which is very small in amount to general data we used available domain monolingual data to generate synthetic parallel data.

In Burlot and Yvon (2019) there have analyzed various ways to integrate monolingual data in an NMT framework, focusing on their impact on quality and domain adaptation. A simple way to use monolingual data in MT is to turn it into synthetic parallel data and let the training procedure run as usual (Bojar and Tammyna, 2011), but this kind of synthetic data may contain huge noise which leads to performance degradation of domain data. Therefore, we present an approach which generates synthetic data in a way such that it is more reliable and improves the translation. In the context of phrase-based statistical machine translation Daume III and Jagarlamudi (2011) has noted that unseen (OOV) words account for a large portion of translation errors when switching to new domains, however this problem is still exist even in NMT as well. Considering this issue, inspired from Huck et al. (2019) we proposed a novel approach called domain specific back translation which uses Out Of Domain (OOD) words to create synthetic data from monolingual data which will be discussed in detail in section 3.4. Huck et al. (2019) also created synthetic data using OOV in a different way, whereas we used OOD words to create synthetic data.

3 Methodology

As discussed in section 2 there are many approaches for domain adaptation mainly divided into model-based and data-based methods. However our approach falls under data-based method, we discuss this in detail in section 3.3. Though, there exists many domain adaptation works in MT, to the best of our knowledge there is no such work for Indian languages especially which considers technical domains like Chemistry, Artificial Intelligence etc. Hence there is a huge need to work on Indian languages where most of them are morphologically rich and these type of domains (technical domains) to improve the translation of domain specific text that contain many domain terms etc.

We conducted all our experiments for Hindi and Telugu in both directions for Chemistry and Artificial Intelligence. The language pair (Hindi-Telugu) considered in our experiments are morphologically rich therefore, there exists many post positions, inflections etc. In order to handle all these morphological inflections we used Byte Pair Encoding (BPE), we can see detail explanation about BPE in section 3.2.

3.1 Neural Machine Translation

NMT system attempts to find the conditional probability of the target sentence with the given source sentence. There exist several techniques to parameterize these conditional probabilities. Kalchbrenner and Blunsom (2013) used combination of a convolution neural network and a recurrent neural network, Sutskever et al. (2014) used a deep Long Short Term Memory (LSTM) model, Cho et al. (2014) used an architecture similar to the LSTM, and Bahdanau et al. (2014) used a more elaborate neural network architecture that uses an attention mechanism over the input sequence. However all these approaches are based on RNN’s and LSTM’s etc, but because of the characteristics of RNN, it is not conducive to training data in parallel so that
the model training time is often longer, by addressing this issue Vaswani et al. (2017) proposed Transformer framework based on a self-attention mechanism. Inspired from Vaswani et al. (2017) we used Transformer architecture in all our experiments.

3.2 Byte Pair Encoding
BPE (Gage, 1994) is a data compression technique that substitutes the most frequent pair of bytes in a sequence with a byte that does not occur within that data. Using this we can acquire the vocabulary of desired size and can handle rare and unknown words as well (Sennrich et al., 2015b). As Telugu and Hindi are morphologically rich languages, particularly Telugu being more Agglutinative language, there is a need to handle post positions and compound words, etc. BPE helps the same by separating suffix, prefix, and compound words. NMT with BPE made significant improvements in translation quality for low resource morphologically rich languages (Pinnis et al., 2017). We also adopted the same for our experiments and got the best results with a vocabulary size of 30000.

3.3 Domain Adaptation
Domain adaptation aims to improve the translation performance of a model (trained on general data) on a new domain by leveraging the available domain parallel data. As discussed in section 2 there are multiple approaches to do it broadly divided into model-based and data-based however, our approach falls under data-based methods, where one can combine the available little amount of domain parallel data to general data. In this paper we show how usage of domain specific synthetic data improves the translation performance significantly. The main goal of this method is to use domain-specific synthetic parallel data using the approach mentioned in section (3.4) along with little amount of domain parallel data.

3.4 Domain Specific Back Translation
In our experiments we followed data-based approach, we combined domain data with general data and trained a new model as a domain adaptation model.

Due to the fact that the domain data is very less we can use available monolingual data to

end
generate synthetic parallel data. Leveraging monolingual data attained significant improvements in NMT (Domhan and Hieber, 2017; Burlot and Yvon, 2019; Bojar and Tamechna, 2011; Gulcehre et al., 2015). Using back translation we can generate synthetic parallel data but that might be very noisy which will decrease the domain specific translation performance. Hence we need an approach which extracts only useful sentences and creates synthetic data. Our approach addresses the same by creating domain specific back translated data using the algorithm mentioned in 1.

Domain-specific Back Translation tries to improve overall translation quality, particularly translation of domain terms and domain-specific context implicitly. The generic algorithm for domain-specific back translation is described in Algorithm 1. The algorithm is very generic and can be applied to any language pair for any domain. In our experiments, we adopted two domains namely Chemistry and Artificial Intelligence, one language pair Hindi and Telugu in both directions. Let us consider the mentioned languages in terms of algorithm mentioned in Algorithm 1 where L1 as Hindi and L2 as Telugu, domains are Chemistry and Artificial Intelligence. Now, each step of the algorithm can be interpreted as follows. step 1. The training corpus is general data mentioned in Table 1. step 2. We train 2 models using the training corpus from above step. One from Hindi to Telugu and the other is from Telugu to Hindi. These models can be treated as base models. step 3. This step is to find out OOD words, this can be done as follows, In Algorithm 1 this step explained in detail at the last. step 3.1 Get Unique words from general corpus, say Gen-Unique for both the languages step 3.2 Get Unique words from Chemistry corpus, Chem-Unique for both the languages step 3.3 Get Unique words from AI corpus, AI-Unique for both languages step 3.4 Now, take each word from Chem-Unique and check that word in Gen-Unique If it not found then that can be considered as Chemistry OOD words. We get OOD Hindi and OOD Telugu with respect to Chemistry. step 3.5 take each word from AI-Unique and check that word in Gen-Unique If it not found then that can be considered as AI OOD words. We get OOD words Hindi and OOD words Telugu with respect to AI. step 4. Take monolingual data for both languages mentioned in 2. step 5. Extract sentences from Hindi monolingual data where Hindi OOD words w.r.t Chemistry are present[Chem-Mono-Hindi]. step 5.1 Extract sentences from Telugu monolingual data where Telugu OOD words w.r.t Chemistry are present[Chem-Mono-Telugu]. step 5.2 Extract sentences from Hindi monolingual data where Hindi OOD words w.r.t AI are present[AI-Mono-Hindi]. step 5.3 Extract sentences from Telugu monolingual data where Telugu OOD words w.r.t AI are present[AI-Mono-Telugu]. step 6. Run Hindi -> Telugu model from step 2 on Chem-mono-Hindi to get Back Translated data [BT-Chem-Hindi-Telugu] step 6.1 Run Telugu -> Hindi model from step 2 on Chem-mono-Telugu to get Back Translated data [BT-Chem-Telugu-Hindi] step

Table 3: Selected monolingual data for domain specific back translation
6.2 Run Hindi -> Telugu model from step 2 on AI-mono-Hindi to get Back Translated data [BT-AI-Hindi-Telugu] step 6.3 Run Telugu -> Hindi model from step 2 on AI-mono-Telugu to get Back Translated data [BT-AI-Telugu-Hindi].

The data we get from step 6 is the one produced by our proposed algorithm. This domain specific synthetic data can be used to improve the domain adaptation performance. The way of extracting sentences where OOD words are present ensure that we only select sentences where domain terms/domain specific terms were present instead of all sentences which may produce lots of noise.

In our experiments we compare four models in each domain, the general model is common for both the domains. The first model is general or baseline model which trains on only general data, then we add very less amount of parallel domain data for each domain separately which is called domain adaptation model. Then comes our domain specific synthetic data, we combine this in two ways. The third model is adding domain specific synthetic data to the general data and the fourth model is the proposed one which adds domain specific back translated data to the training data used for basic domain adaptation model(general+domain, model2). Therefore we have seven models in total, one is general and three models for Chemistry and AI independently.

4 Experimental Setup

4.1 Data

Based on the above mentioned approaches, we carried out our experiments on datasets mentioned in Tables 1, 2, 3 of parallel data, monolingual data, selected monolingual data for domain specific back translation respectively. we got general parallel data from OPUS corpus (Tiedemann, 2012) and the ILCI (Indian Languages Corpora Initiative) corpus (Jha, 2010), similarly domain data from ICON Adap-MT 2020 shared task 1 for Chemistry and AI. We can see statistics of overlapping tokens and Out of Vocabulary (OOV) tokens (we can assume these as Out Of Domain words) in Tables 4, 5.

We extracted Chemistry and AI monolingual data from Wikipedia and combined for respective language(see Table 2). In absence of domain monolingual data for any domains one can do same experiments with general monolingual data as well. As Hindi and Telugu are morphologically rich languages, Telugu being more inflected language we apply approximate matching to allow for some morphological variations in the terms for mining the sentences from monolingual data using OOD words we got for respective languages and respective domains (see Table 3). If we observe Table 2 and 3 the Chemistry-Hindi got 28672 sentences but the actual monolingual data for Hindi is 16345 which is less than selected monolingual data. This happened because when we have two OOD words present in a sentence then we select that sentence two times for each word one time.

4.2 Training Details

We used OpenNMT-py toolkit (Klein et al., 2018) for all our experiments. We used Transformer model with 6 layers in both encoder and decoder each with 512 hidden units. The word embedding size is set to 512 with 8 heads and dropout is set to 0.3 to avoid over fitting of the model. We used perplexity as an early stopping criteria.
5 Results & Discussion

When we say back chem or back AI in this paper, that means they are the domain specific back translated data. After getting domain specific synthetic data from algorithm 1, we combined that in two ways and trained models. One is directly adding the domain specific back translated data to general parallel data without any actual domain data, second is to add domain specific back translated to the general parallel data along with actual domain parallel data.

We evaluate our models on test data set provided by ICON Adap-MT 2020 shared task using widely used automatic MT evaluation metric called BLEU (Papineni et al., 2002). The models presented in 6 are trained based on data-based approach only. However, the model which used the domain specific synthetic parallel data along with actual domain parallel data outperformed other models.

The first model is M1-Gen which is trained on only general parallel data this is same for both the domains(Chemistry and Artificial Intelligence) it performed well on general data but not on chemistry and AI data for both directions Telugu->Hindi and Hindi->Telugu. Then the second model is a domain adaption model where we combine the available little amount of domain parallel data with general data(M2-gen+chem and M2-gen+AI). These models outperformed the general model on Chemistry(9.5 to 11.8) and AI(8.7 to 10.3) domains though there is a decrease of BLEU score on general data for Telugu->Hindi, this pattern is same for Hindi->Telugu as well. Third model is adding domain specific synthetic data directly to the general data(M3-Gen+Back Chem and M3-Gen+Back AI) which decreased the BLEU score compared to domain adaptation model(M2 for both the domains) but it’s improved little bit from general model. For Chemistry domain in Telugu->Hindi the BLEU score decreased from 11.8 to 9.9, but it increased from general model(9.5 to 9.9). Now the fourth model is the proposed approach which adds domain specific back translated data to the data used in initial domain adaptation model(gen+domain data) for both the domains(M4-Gen+Chem+back Chem and M4-Gen+AI+back AI). M4 model in both domains outperformed all other models. There is an increase 3.4 BLEU points in Chemistry for Telugu->Hindi from general model to proposed model which uses domain specific synthetic data.

The thought behind the domain-specific back translation is selecting sentences where the unseen words (most of them are domain terms) are present. By doing this, the model implicitly learns the translation of domain terms and context around them accurately.
address this point we present two examples below which shows an overall improvement of domain specific text translation including domain terms.

Table 7 represents an example from Telugu to Hindi NMT system for Chemistry domain. This example contains a domain specific term రైబోనూయ్కుల్యేజ్ (raibōnyūkkyēj) which was wrongly translated by other models except our model which uses domain specific back translated text (Gen+Chem+back Chem). If we consider another example in Table 8 from Telugu to Hindi model, the same pattern is observed as above. The proposed approach translated the domain term (sentriphyoogeshan) and overall sentence correctly whereas others failed to do it. From these examples we can observe our proposed approach is handling domain specific terms implicitly and translating them better compared to others. As we are mining sentences from monolingual data where the out of vocabulary words with respect to each domain (we can treat them as domain terms which are not present in general data) are present, by doing this it ensure to translate unseen words especially domain terms properly.

In Table 6, the BLEU score of AI is improved with the gen+Chem model compared to the gen model, the same pattern is observed for Chemistry as well. From this, we can assume there is a similarity between these domains in terms of domain terms or context, etc. Based on this assumption we can further experiment models with combination of similar domains.

6 Conclusion and Future work

We presented an approach called domain specific back translation to produce synthetic data from available monolingual data which can be applied to any language pair for any domain. we did our experiments on two domains Chemistry and Artificial Intelligence for Hindi and Telugu. The approach follows extracting Out Of Domain words from large amount of general data with respect to particular domain (here Chemistry and AI), then mining the sentences from domain monolingual data where these OOD words are present. By doing this the system will learn to translate unknown words and domain terms properly. Without adding direct monolingual data which contains lots of noise, we select only sentences where general OOD words with respect to a domain are present. In this paper we showed how addition of domain specific back translated data to the general and little amount of domain data improved the translation performance in terms of BLEU scores. From the results it has been observed that the proposed approach improving BLEU score significantly. we would like to apply this generic approach to all possible Indian languages and multiple domains with combination of similar domains.

Abstract

Using pre-trained transformer models such as BERT has proven to be effective in many NLP tasks. This paper presents our work to fine-tune BERT models for Arabic Word Sense Disambiguation (WSD). We treated the WSD task as a sentence-pair binary classification task. First, we constructed a dataset of labeled Arabic context-gloss pairs (~167k pairs) we extracted from the Arabic Ontology and the large lexicographic database available at Birzeit University. Each pair was labeled as True or False and target words in each context were identified and annotated. Second, we used this dataset for fine-tuning three pre-trained Arabic BERT models. Third, we experimented the use of different supervised signals used to emphasize target words in context. Our experiments achieved promising results (accuracy of 84%) although we used a large set of senses in the experiment.

1 Introduction

Word Sense Disambiguation (WSD) aims to determine which sense (i.e. meaning) a word may denote in a given context. This is a challenging task due to the semantic ambiguity of words. For example, the word “book” as a noun has ten different senses in Princeton WordNet such as “a written work or composition that has been published” and “a number of pages bound together”. WSD has been a challenging task for many years but has gained recent attention due to the advances in contextualized word embedding models such as BERT (Devlin et al., 2019), ELMo (Peters et al., 2018) and GPT-2 (Radford et al., 2018). Such language models require less labeled training data since they are initially pre-trained on large corpora using self-supervised learning. The pre-trained language models can then be fine-tuned on various downstream NLP tasks such as sentiment analysis, social media mining, Named-Entity Recognition, word sense disambiguation, topic classification and summarization, among others.

A gloss is a short dictionary definition describing one sense of a lemma or lexical entry (Jarrar, 2006, 2005). A context is an example sentence in which the lemma or one of its inflections (i.e. the target word) appears. In this paper, we aim to fine-tune Arabic models for Arabic WSD. Given a target word in a context and a set of glosses, we will fine-tune BERT models to decide which gloss is the correct sense of the target word. To do that, we converted the WSD task into a BERT sentence-pair binary classification task similar to (Huang et al., 2019; Yap et al., 2020; Blevins and Zettlemoyer, 2020). Thus, BERT is fine-tuned on a set of context-gloss pairs, where each pair is labeled as True or False to specify whether or not the gloss is the sense of the target word. In this way, the WSD task is converted into a sentence-pair classification task.

One of the main challenges for fine-tuning BERT for Arabic WSD is that Arabic is a low-resourced language and that there are no proper labeled context-gloss datasets available.

To overcome this challenge, we collected a relatively large set of definitions from the Arabic Ontology (Jarrar, 2021) and multiple Arabic dictionaries available at Birzeit University’s lexicographic database (Jarrar and Amayreh, 2019; Jarrar et al., 2019) then we extracted glosses and contexts from lexicicon definitions.

Another challenge was to identify, locate and tag target words in context. Tagging target words with special markers is important in the fine-tuning phase because they act as supervised signals to highlight these words in their contexts, as will be explained in section 5. Identifying target words is not straightforward as they are typically inflections of lemmas, i.e. with different spellings. Moreover, locating them is another challenge as the same word may appear multiple times in the
same context with different senses. For example, the word (تَنْبًى) appears two times in this context with two different meanings: went and gold. We used several heuristics and techniques (as described in subsection 3.3) to identify and locate target words in context in order to tag them with special markers.

As a result, the dataset we constructed consists of about 167K context-gloss pair instances, 60K labeled as True and 107K labeled as False. The dataset covers about 26k unique lemmas (undiacritized), 32K glosses and 60k contexts.

We used this dataset to fine-tune three pre-trained Arabic BERT models: AraBERT (Antoun et al., 2020), QARiB (Abdelali et al., 2021) and CAmeLBERT (Inoue et al., 2021)

Each of the three models was fine-tuned for context-gloss binary classification. Furthermore, we investigated the use of different supervised signals used to highlight target words in context-gloss pairs.

The contributions of this paper can be summarized as follows:

1. Constructing a dataset of labeled Arabic context-gloss pairs;
2. Identifying, locating and tagging target words;
3. Fine-tuning three BERT models for Arabic context-gloss pairs binary classification;
4. Investigating the use of different markers to highlight target words in context.

The remainder of this paper is organized as follows. Section 2 presents related work. Section 3 describes the constructed dataset and our methodology to extract and label context-gloss pairs, and splitting the dataset into training and testing sets. Section 4 outlines the task we resolved in this paper and Section 5 presents the fine-tuning methodology. The experiments and the obtained results are presented in Sections 6 and 7 respectively. Finally, Section 8 presents conclusions and future work.

2 Related Work

Recent experiments in fine-tuning pre-trained language models for WSD and related tasks have shown promising results, especially those that use context-gloss pairs in fine-tuning such as (Huang et al., 2019; Yap et al., 2020; Blevins and Zettlemoyer, 2020).

Huang et al. (2019) proposed to fine-tune BERT on context-gloss pairs (label ∈ {yes, no}) for WSD, such that the gloss corresponding to the context-gloss pair candidate, with the highest output score for yes, is selected. Yap et al. (2020) proposed to group context-gloss pairs with the same context but different candidate glosses as 1 training instance (groups of 4 and 6 instances). Then, they proposed to fine-tune BERT model on group instances with 1 neuron in the output layer. After that, they formulated WSD as a ranking/selection problem where the most probable sense is ranked first.

Others also suggested to emphasize target words in context-gloss training instances. Huang et al. (2019); Botha et al. (2020); Lei et al. (2017); Yap et al. (2020) proposed to use different special signals in the training instance, which makes the target word “special” in it. As such, Huang et al. (2019) proposed to use quotation marks around target words in context. In addition, they proposed to add the target word followed by a colon at the beginning of each gloss, which contributes to emphasizing the target word in the training instance. Yap et al. (2020) proposed to surround the target word in context with two special [TGT] tokens. In contrast, Botha et al. (2020); Lei et al. (2017) proposed to surround the target word in context with two different special tokens as marks of opening and closing. In this paper, we investigate the use of different types of signals to emphasize target words in context for Arabic WSD.

El-Razzaz et al. (2021) fine-tuned two BERT models on a small dataset of context-gloss pairs, consisting of about 5k lemmas, about 15k positive and 15k negative context-gloss pairs. They claimed an F1-score of 89%. However, this result is not reliable. After repeating the same experiment, we found that the majority of the context sentences used in the tests were already used for training. In this paper, we carefully selected the test set such that no contexts are used in both the training and the test sets. Additionally, we used a much larger sense repository (26k lemmas, 33k concepts and 167k context-gloss positive and negative pairs), which makes the task more challenging.

Other works related to Arabic WSD includes the use of static embeddings such as context and

3 Dataset Construction

This section describes how we constructed a dataset of labeled Arabic context-gloss pairs (See examples of pairs in Figure 1). We extracted the context-gloss pairs from the Arabic Ontology and multiple lexicons in the Birzeit University’s lexicographic database. The extracted pairs are labeled as True, and based on these True pairs, we generated the False pairs. Additionally, we identified the target word in each context and tagged it with different types of markers.

3.1 Context-Gloss Pairs Extraction

Arabic is a low-resource language (Darwish et al., 2021) and there are no proper sense repositories available for Arabic (Naser-Karajah et al., 2021; Jarrar et al., 2021) that can be used to generate a dataset of context-gloss pairs, e.g. similar to the Princeton WordNet for English (Miller et al., 1990). The largest available lexical-semantic resource for Arabic is the Birzeit University’s lexicographic database, which contains the Arabic Ontology (Jarrar, 2021, 2011) and about 400K glosses extracted from about 150 lexicons (Jarrar and Amayreh, 2019; Jarrar et al., 2019; Alhafi et al., 2019). The problem is that each of the 150 lexicons covers a partial set of glosses and lemmas. Thus, for a given lemma, collecting the glosses from all lexicons may result in a set of redundant senses. Another problem is that some lexicons provide multiple senses within the same definition with no clear structure or separation markers, which makes it difficult to extract senses. Furthermore, some lexicons do not provide contexts (i.e. example sentences) or they mix them with the definitions.

To overcome the above challenges and build a context-gloss pairs dataset, we performed the following steps:

**First, selection of candidate definitions:** We acquired the 400K lexicon definitions to select a set of good candidate definitions. A good definition represents either one sense or multiple senses that are easy to parse and split (i.e. contains some markers) and has context examples. That is, definitions that are not easy to parse or do not provide contexts were excluded.

**Second, extraction of glosses and contexts:** Each of the collected candidate definitions in the first phase was parsed and split into gloss(es) and context(s). Some definitions did not need to be split and some were split into separate glosses (one for each sense) in case a definition contains multiple glosses (i.e. senses). Contexts were also extracted from the candidate definitions, taking into account that a definition may include multiple contexts for one sense. A parser was developed for each lexicon as each lexicon has its structure and text markers. Nevertheless, some lexicons were clean and well-structured (e.g. the Arabic Ontology) that did not need any parsing.

**Third, selection of glosses and contexts:** Given that the glosses and contexts were extracted in the second phase, we applied the following criteria to select the glosses and contexts that we need to build a dataset of context-gloss pairs:

- Short glosses and contexts (i.e. one-word long) were excluded as they do not add useful information in the fine-tuning phase.
- For each lemma, if one of its glosses does not have a context example then all glosses for this lemma were not selected. That is, for a lemma and its glosses to be selected, each gloss must have at least one context example.
- In case the same lemma appears in multiple lexicons, the one with more glosses was selected. For example, let \( m \) be a lemma with two glosses in lexicon A and three glosses in lexicon B, then the lexicon B set of glosses for \( m \) is favored. If the same lemma has an equal number of glosses in multiple lexicons, we manually favor the more renowned lexicon. The idea of favoring lemmas with more glosses is because it indicates a richer set of distinct senses, and in this way, we avoid redundant senses for the same lemma in the dataset.

---

- Only glosses for single-word lemmas are selected. Although multi-word expression lemmas are important, in this phase, we only focus on single-word lemmas as BERT can process single-word tokens. We plan to consider multi-word lemmas in the future.

As a result, we selected about 32k glosses and 60k contexts for about 26K single lemmas (undiacritized), resulting in about 60k context-gloss pairs that we labeled as True pairs (see Table 1 for more statistics). It is important to note that our dataset cannot be considered an Arabic sense repository because a sense repository should contain all senses for a given lemma, but our dataset does not necessarily include all senses for every lemma.

### 3.2 Labeling Context-Gloss Pairs

The 60k context-gloss pairs extracted in the previous phase were labeled as True. The False context-gloss pairs were then generated based on the True pairs, as follows: For each lemma with more than one gloss, we cross-related its glosses with its contexts. For example, let (context1 - gloss1) and (context2 - gloss2) be the two True pairs for the same lemma, then (context1 - gloss1) and (context2 - gloss1) are generated and labeled as False pairs. As a result, about 107K context-gloss False pairs were generated in this way.

### 3.3 Annotating Target Words

This section presents our methodology for identifying the target word inside a given context and tagging it with a special supervised signal, which we need in the fine-tuning phase (see section 5). Figure 2 illustrates different tags of target words.

Given a lemma and a context, our goal is to identify which word is the target word in this context. As explained in section 1, a context is an example sentence in which a word (called target word) is mentioned with its sense defined in the gloss. Identifying a target word inside its context is not straightforward because: (i) it does not necessarily share the same spelling with its lemma, e.g., the word (محمود) and its lemma (محمد) and, more importantly, (ii) it might occur multiple times and each time with a different sense such as (كتب) which appears two times in this context (كتب عدة كتب), with two different meanings: wrote and books.

The following four methods were performed at the same time to maximize the certainty in identifying target words. The resulting target words were verified manually:

- **Sub-string**: We compared every word in the context with the given lemma (string-matching, after undiacritization). If the lemma is a sub-string of one or more words, then these words are candidate target words.

- **Character-level cosine similarity**: We developed a function\(^4\) that takes a lemma and a context and returns the word with the max cosine similarity with the lemma. The minimum cosine value should be more than 0.75 — an empirical threshold that we learned while reviewing the results. If a word is returned, then we considered it a candidate target word.

- **Levenshtein distance**: This function takes a lemma and a context and returns the word with max Levenshtein distance (after removing diacritics) by comparing each word in the context with the lemma. The returned word is considered a candidate target word.

- **Lemmatization**: We used our in-house lemmatizer and lexicographic database to lemmatize every word in the given context and return those words that have their lemmas the same as the given lemma. The returned words are considered candidate target words.

These four methods were applied in parallel to maximize the certainty of correct matching and identification of target words. The results (candidate words, their scores and position) of the four methods were then combined and sorted (from

\(^4\)The function converts two Arabic words (after removing diacritics) into two vectors (each cell represents the occurrence of a character), then computes their cosine similarity.
more to less certain) and given to linguists to review. Each identified target word\(^5\) was manually verified and, if needed, corrected by a linguist.

### 3.4 Training and Test Datasets

This section describes how we divided our dataset into training and test sets and the criteria we used to avoid repeated context in training and test sets. Recall that our dataset contains one or more glosses for each lemma and one or more contexts for each gloss, which we used to generate the context-gloss pairs dataset. The dataset cannot be arbitrarily divided as contexts used for training should not be used for testing. We selected the test set taking into account these two criteria: (i) every context selected in the test set should not be selected in the training set and (ii) every gloss should be selected in both the training and the test sets.

Given these criteria, we selected the test set as follows: (First) we selected the pairs with repeated glosses from the set of context-gloss pairs (i.e. glosses with more than one context). (Second) we grouped pairs according to their glosses then selected one pair from each group larger than one and included it in the test set. All of these pairs were labeled as True. (Third) we cross-related contexts with glosses of the same lemma to generate False pairs in the test set from the True pairs — as described in subsection 3.2. That is, again, the False pairs were generated after selecting the True pairs, and every pair selected for testing should not be part of the training set.

The resulted training and test datasets\(^6\) consist of 152,035 and 15,172 pairs, respectively. Table 2 provides statistics about the training and test sets.

### 4 Task Overview

Given a context, a target word in the context and a gloss, our task is to decide whether or not the gloss corresponds to a specific sense of the target word. We approached the problem as a binary sequence-pair classification task. We concatenated the context and the gloss and separated them by the special [SEP] token (See Figure 1). Afterward, we fine-tuned Arabic BERT models on our labeled dataset of context-gloss pairs \((label \in \{True, False\})\).

It is worth noting that although this binary context-gloss pair classification task is related to the WSD task, they are not exactly the same task. The WSD task aims at determining which sense (or gloss) a word in context denotes from a given set of senses. It is also worth noting that these two tasks are not the same as the Word-In-Context (WIC) task (Al-Hajj and Jarrar, 2021; Martelli et al., 2021), which aims at determining whether a target word has the same sense in two given contexts.

### 5 Methodology

To address the binary context-gloss classification task, we experimented with four variations of the context-gloss pairs. The idea is to investigate using different supervised signals around target words to give them special attention during the fine-tuning. Figure 2 illustrates these four variations. In variation 1, context-gloss pairs were left intact, without any signal. In the other three
Figure 2: Illustration of the four context-gloss pairs variations.

variations, we followed the techniques used by Huang et al. (2019), Yap et al. (2020) and Blevins and Zettlemoyer (2020) to signal target words. We surrounded target words with (i) single quotes in variation 2, (ii) the special token [UNUSED0] in variation 3, and (iii) [UNUSED0] before and after the target word in variation 4. Moreover, in the last three variations, we added the target word followed by a colon at the beginning of each gloss. In these four variations, the context and the gloss were concatenated into a sequence separated with the [SEP] token.

We fine-tuned three Arabic pre-trained models: AraBERT (Antoun et al., 2020), QARiB (Abdelali et al., 2021) and CAMeLBERT (Inoue et al., 2021) using our training dataset described in Section 3. Before fine-tuning AraBERT, we used the pre-processing method used in (Antoun et al., 2020) to pre-train version 2 of their model. Before fine-tuning CAMeLBERT and QARiB models, we used the pre-processing method used in (Inoue et al., 2021) to pre-train the CAMeLBERT which consists in the normalization of alif maksura (ạ), teh marbuta (ِ), alif (ا) and undiacritization.

Since BERT has a max length limit of tokens equal to 512, we limit the length of each training instance (i.e. context-gloss pair) with a maximum of 512 tokens. Given, for example, the tokenizer used in AraBERTv02, only 216 pairs are larger than 512 tokens out of the 167,207 pairs in our dataset. Instances shorter than 512 were padded to the max length limit.

The BertForSequenceClassification model architecture is used in fine-tuning the three Arabic BERT models. The last hidden state of the token [CLS] is used for the classification task. The linear layer in the output consists of two neurons for the True and False classes.

6 Experiment Setup

We selected the base configuration of AraBERTv02, QARiB, and CAMeLBERT models due to computational constraints and as larger models do not necessitate better performance (Abdelali et al., 2021; Inoue et al., 2021). We used the huggingface “Trainer” class in the fine-tuning. We performed a limited grid search to find a good hyperparameters combination then we fine-tuned each of the three models using the optimal configuration: initial learning rate of 2e-5, warmup_steps of 1412 with a batch size of 16 over 4 training epochs. All other hyperparameters were kept at their default values. We used a single Tesla P100-PCIE-16GB in fine-tuning models.

7 Results and Discussion

This section presents the results of two experiments. Table 3 presents the results of the first experiment in which we fine-tuned three BERT models on the variation 2 (i.e. single quotes signal) of context-gloss pairs.

As AraBERTv02 outperformed other models in the first experiment, it has been chosen for conducting a second experiment in which we fine-tuned on variation 1 (intact context-gloss pairs), variation 3 (two [UNUSED0] tokens around the target word in context-gloss pairs) and variation 4 ([UNUSED0] and [UNUSED1] tokens around the target word in context-gloss pairs). Reported results in Table 4 reveal that the use of different supervised signals around the target word did not significantly improve the overall results. The use of supervised signals reveals only 1% of improvement over variation 1 (no signals). This improvement is comparable to the improvement of 1-2% achieved by Huang et al. (2019) using special signals on English datasets.

8 Conclusion and Future Work

We presented a large dataset of context-gloss pairs (167,207 pairs) that we carefully extracted from the Arabic Ontology and diverse lexicon definitions. Each pair was labeled as True and False and each target word in each context was annotated and tagged. We used this dataset to fine-tune three Arabic BERT models on binary context-gloss

</tbody>
</table>

Table 4: Achieved results (%) with AraBERTv02 using the other three supervised signals around the target word.

We achieved a promising accuracy of 84%, especially as we used a large set of senses. Our experiments show that the use of different supervised signals around target words did not bring significant improvements (about 1%).

We will further build a large-scale content-gloss dataset. We also plan to include contexts written in Arabic dialects (Jarrar et al.) so that dialectal text can be sense-disambiguated. Additionally, we plan to consider Arabic text that is partially or fully diacritized, which requires lemmas across lexicons to be linked with each other (Jarrar et al., 2018). Lastly but more importantly, we plan to extend our work to address the WSD task and build a semantic analyzer for Arabic.

**Acknowledgments**

We would like to thank the reviewers for their valuable comments and efforts for improving our manuscript. We would also like to thank Taymaa Hammouda for her technical support while preparing the dataset and annotating the contexts. We extend our thanks to Dr Abeer Naser Eddine for proofreading this paper.

Abstract
The advancement of the web and information technology has contributed to the rapid growth of digital libraries and automatic machine translation tools which easily translate texts from one language into another. These have increased the content accessible in different languages, which results in easily performing translated plagiarism, which are referred to as “cross-language plagiarism”. Recognition of plagiarism among texts in different languages is more challenging than identifying plagiarism within a corpus written in the same language. This paper proposes a new technique for enhancing English-Arabic cross-language plagiarism detection at the sentence level. This technique is based on semantic and syntactic feature extraction using word order, word embedding and word alignment with multilingual encoders. Those features, and their combination with different machine learning (ML) algorithms, are then used in order to aid the task of classifying sentences as either plagiarized or non-plagiarized. The proposed approach has been deployed and assessed using datasets presented at SemEval-2017. Analysis of experimental data demonstrates that utilizing extracted features and their combinations with various ML classifiers achieves promising results.

1 Introduction
The advancement of the Internet and information technology have expanded rapidly the availability of digital libraries and automatic machine translation tools, which facilitate translating a text from one language to another language. This has caused the number of cases of translated plagiarism, referred to as “cross-language plagiarism”, to perform substantially. It is a type of plagiarism that occurs when textual content is translated into another language without giving acknowledgment of original sources. This type of plagiarism is more difficult to detect since each language has its own structure.

Several plagiarism detection techniques have been proposed to address monolingual plagiarism, that identify plagiarism instances written in the same language. However, there have been few studies that concentrate on researching and developing methods for identifying cross-language (and in particular English-Arabic) plagiarism. These techniques cannot effectively detect more extensively disguised cases of cross-language plagiarism. Eisa et al. (2015) observed that existing techniques have difficulty detecting linguistic modifications like replacing words and phrases by synonyms. When a text is translated from Arabic into English, synonyms are introduced after the translation, thus it is difficult to identify plagiarism.

This paper proposes a new approach for enhancing English-Arabic cross-language plagiarism detection at the sentence level. This technique is based on semantic and syntactic feature extraction using word alignment, word order, word embedding and multilingual encoder models. We investigate the effectiveness of using those features and their combination with different machine learning (ML) algorithms for classifying sentences as either plagiarized or non-plagiarized. The rest of this paper is structured as follows: Section 2 presents a review of related work on cross-language plagiarism detection techniques. In Section 3 we illustrate the proposed approach. The experimental results and discussion are provided in...
Section 4. Finally, Section 5 concludes and presents future work.

2 Related Work

A number of studies have been scrutinized cross-language plagiarism detection. Potthast et al. (2011) presented a classification of cross-language similarity detection methods which was subsequently developed by Danilova (2013). These approaches were classified on the basis of the mechanism used for detecting similarity as shown in Figure 1.

![Cross-language similarity analysis](image)

Figure 1: Classification of various techniques for cross-language similarity analysis (Potthast et al., 2011; Danilova, 2013).

For an instance, Cross-Language Character n-Grams (CL-CNG), which were presented by McNamee and Mayfield (2004), segmenting texts into n-grams for performing comparisons between pairs of texts and measuring the similarity without translation. Another study was on the basis of comparable corpora and was presented by Potthast et al. (2008), who introduced the Cross-Language Explicit Semantic Analysis (CL-ESA) model that were used Wikipedia for computing the similarity between pairs of documents in different languages. For parallel corpora, Barrón-Cedeño et al. (2008) offered Cross-Lingual Alignment-based Similarity model (CL-ASA), creating a bilingual unigram dictionary for comparing pairs of texts. Gupta et al. (2012) introduced the dictionary-based Cross-Language Conceptual Thesaurus Similarity model (CL-CTS) which detects similarity between texts from different languages. Franco-Salvador et al. (2013) introduced a technique based on knowledge graphs for comparing between documents in different languages. Barrón-Cedeño (2013) presented a machine translation model to convert texts into the common language followed by employing a monolingual analysis.

Some published research has focused on English-Arabic cross-language plagiarism detection. For example, Aljohani and Mohd (2014) proposed an English-Arabic cross-language detection approach based on Google Translate to translate the texts and applying a winnowing algorithm, which proposed by Schleimer et al. (2003). Another study presented by Hattab (2015) proposed a technique based on Latent Semantic Indexing (LSI) and parallel corpora to build a cross-language semantic vector space to compute similarity of the context. Alaa et al. (2016) used a logistic regression classifier based on longest common subsequence and cosine similarity measurements and n-gram features at keyphrase level. A study utilized semantic metrics and WordNet for gauging the degree of semantic similarity between words and used it to calculate the similarity for texts and paragraphs of English-French and English-Arabic plagiarism instances Hanane et al. (2016). Ezzikouri et al. (2018) employed a fuzzy semantic approach to identify cross-language plagiarism cases employing Wu and Palmer’s (1994) similarity metrics and WordNet to compute semantic similarity between words.

Based on this review, we have only identified a few studies which have attempted to detect cross-language plagiarism in the English-Arabic domain. Most of these studies have tried to identify plagiarism based on semantic features and key phrases. To the best of our knowledge, none of these studies has tried to detect plagiarism using English-Arabic pairs based on sentence level analysis, nor has any integrated semantic and syntactic features using word embedding and word alignment features with multilingual encoder models.

3 Proposed Method

The key idea of the proposed plagiarism detection technique for English-Arabic pairs of sentence is formulated as a classification task, which classifies each pair of sentences as either plagiarized or non-plagiarized. In order to tackle this problem, it is necessary to analyze texts using different features extracted at syntactic and semantic levels. Thus, we propose methods based on word embedding, word order and word alignment with multilingual
3.1 Feature Extraction

Analysis of semantic and syntactic features forms an essential step for plagiarism detection algorithms. Various sets of extracting features are proposed depending on word embedding, word order and word alignment for pair of sentence comparison. The following subsection describes the extracting features.

3.1.1 Word Order Similarity Features

Syntactic features based on word order are employed in similarity and plagiarism detection algorithms such as those by Li et al. (2006) and Abdi et al. (2015). Therefore, we propose a method that relies on word order features based on machine translation, since word order exhibits beneficial information about the relationships between words. In the case where two sentences have exactly the same words, but in a different order, any approach that measures similarity between texts based on a “bag of words” will show them to be exactly the same. Consequently, the influence of the word order should be taken into consideration when text similarity is computed. Thus, we are motivated by Li et al.’s (2006) approach. However, the proposed method is based on a pre-trained word2vec model released by Mikolov et al. (2013), representing words as vectors that characterize identification of semantic and syntactic features.

In order to gauge word order similarity between pairs of sentences, it is required to convert words into vectors based on a joint word set, which is formed utilizing distinct words from each pair of sentences. For example, given a pair of sentences T1 “A quick brown dog jumps over the lazy fox” and T2 “A quick brown fox jumps over the lazy dog”, a joint word set T contains all distinct. Words from T1 and T2, so T is {A quick brown dog jumps over the lazy fox}. Each word in T1 and T2 has an assigned unique index number, representing the word’s location in the sentence. A word order vector is created for each sentence (r1 and r2 respectively), based on word embedding and the joint word set T. Taking T1 as an example, for each word in T, we look for the same or the most similar word using

1. If the word exists in T1, the value for this word in r1 will take the same index number from T1.
2. If the word does not appear in T1, then we use the pre-trained word2vec model for finding the most similar word using
based on computing cosine similarity between the words. If the similarity score is greater than the predefined threshold (wt), the value of the word in r1 is set to the index number of the word in T1.

3. If the above two processes fail, the value of the index number in r1 is set to 0.

The procedure used for creating r1 will be applied for creating r2, which represents the second sentence. Therefore, word order vectors are constructed as:

\[ r1 = [1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9] \]
\[ r2 = [1 \ 2 \ 3 \ 9 \ 5 \ 6 \ 7 \ 8 \ 4] \]

Then, the word order similarity is calculated by using Equation 1.

\[ \text{OrderSim}(r1, r2) = 1 - \frac{\|r1 - r2\|}{\|r1 + r2\|} \] (1)

3.1.2 Sentence Embedding Features

Due to the detection being based at sentence level, extracting features from a pair of sentence uses the technique proposed by Alotaibi and Joy (2020). They proposed an approach for calculating the degree of semantic similarity between two sentences. The authors leverage models that represent sentences embedding, including universal sentence multilingual encoder (MUSE) and averaging word embedding, for constructing sentence vectors. They represent sentence embedding based on: (i) word embedding and term weight schemes (i.e., term frequency inverse document (TFIDF) and part of speech (POS)), referred to as CL-WE-Tw, and (ii) the MUSE model. Based on the methods, computing the degree of semantic similarity between two sentences is by following these steps:

- **Sentence vector based on CL-WE-Tw:** represents vectors for each sentence by taking the average vectors with their weighting according to Equation 2

\[ Sv = \frac{1}{n} \sum_{i=1}^{n} vec \ast (\text{TFIDF} \ast \text{POS}(wi)) \] (2)

where \( Sv \) is sentence embedding, vec is a function that gets word vector, wi is the \( i^{th} \) word of text.

- **Sentence Embedding based on MUSE:** uses a pre-trained model released by Yang et al. (2019) to represent sentence vectors then cosine similarity is employed to measure semantic similarity between pair of vectors as shown in Equation 3.

- **Semantic similarity measure:** after representing vectors for each sentence, cosine similarity is applied to find the degree for pairs of sentence according to Equation 3.

\[ S_{\text{sim}}(veE, veA') = \frac{veE \cdot veA'}{\|veE\| \cdot \|veA'\|} \] (3)

where \( S_{\text{sim}} \) is sentence similarity that calculated using cosine similarity on sentence embedding, \( veE \) is the sentence vector for the English sentence, and \( veA' \) is the sentence vector translated from the Arabic sentence.

- Finally, the authors proposed to integrate semantic similarity features, obtained from the CL-WE-Tw and MUSE methods given by Equation 4.

\[ S_{\text{sentence}} = \frac{(S_{\text{CL-WE-Tw}} + S_{\text{MUSE}})}{2} \] (4)

where \( S_{\text{CL-WE-Tw}} \) is the similarity score obtained from CL-WE-Tw method, and \( S_{\text{MUSE}} \) is obtained from the MUSE model.

3.1.3 Combined Similarity Measures

Since semantic and syntactic features play an important role in interpreting the meaning of a sentence, we propose to combine all sentence similarity measure features, which are described in Section 3.1.1 and CL-WE-Tw, and refer to it as “CL-WET-WO”, as shown in Equation 5.

\[ S(T1, T2) = \delta S_{\text{sim}} + (1 - \delta) \text{OrderSim} \] (5)

Li et al., (2006) suggested that \( 0.5 < \delta \leq 1 \), should be the threshold for weighting significance between components based on word order (OrderSim) and CL-WE_Tw (Ssim).

3.1.4 Word Alignment Features

The word alignment features are employed in different natural language processing tasks like sentence similarity (Sultan et al., 2015) and
paraphrase identification (Mohammad et al., 2017). Therefore, we propose to use semantic based features depending on word alignment. The proposed method is based upon the word alignment approach of Michlase et al. (2006) and Zhou et al. (2019), however, the difference is to use the pre-trained multilingual encoder model, such as that released by Yang et al. (2019) as a bilingual resource. It provides rich semantic information and enables the representation of words from different languages (e.g., English and Arabic) in a single vector space, where it directly determines similarity between words that are written in different languages. Such words are aligned according to their semantic similarity in the model, and cosine similarity is applied to find the similarity between pairs of words. The proposed method consists of two components, that can be used to describe pairs of sentences. The first component finds the similarity score between pairs of sentences as shown in Equation 6, which we call cross-language weighted alignment (CL-WA). This component consists of two processes.

$$S = \frac{1}{2} \left( \frac{\sum_{w \in T_1} \left( \text{maxsim}(w, T_2) \ast \text{idf}(w) \right)}{\sum_{w \in T_1} \text{idf}(w)} + \frac{\sum_{w \in T_2} \left( \text{maxsim}(w, T_1) \ast \text{idf}(w) \right)}{\sum_{w \in T_2} \text{idf}(w)} \right)$$

To compute the semantic similarity between two sentences $T_1$ and $T_2$, we use the pre-trained multilingual encoder model instead of a monolingual dictionary, then cosine similarity is employed for measuring similarity between pairs of words. The following steps are used.

1. According to Equation 7, for each term in sentence $T_1$ we determine its aligned word in the sentence $T_2$ which gets the highest semantic similarity and is greater than the threshold ($t_1$). This threshold is suggested to avoid excessive noise that leads to deterioration of overall performance. For example, when we align word “يضع” which means ‘put’ in English language, with other words like “dance”, “put” and “cook”, we find their vectors such as $[(\text{vector (dance)}), (\text{vector (put)}), (\text{vector (cooking)})], (\text{vector (cook)}), (\text{vector (يضع)})]$, then we determine the maximum degree of semantic similarity between their vectors by applying cosine similarity.

$$\text{maxsim}(w, T_2) = \text{maxsim}(w, T_2)$$

2. Determine the importance of words in $T_1$ using inverse document frequency (idf).

The same process is employed to determine the most similar word in $T_1$ beginning with words in $T_2$. Finally, the similarity between the input sentence $T_1$ and $T_2$ is computed using Equation 6.

The second component is to calculate the semantic similarity for given two sentences $T_1$ and $T_2$ according to Equation 8, which we call “cross-language alignment (CL-A)”. The process is as follows.

1- For each term in an Arabic sentence, we try to determine the word in the English sentence that has the highest semantic similarity (i.e., using the pre-trained multilingual encoder model and employing cosine similarity) that is greater than the threshold ($t_2$). This threshold is suggested to avoid excessive noise which causes deterioration of overall performance.

2- Finally, we take the average score over all the maximal similarity scores as given by Equation 8.

$$ssim(S, T) = \frac{1}{m} \sum_{i=1}^{m} \text{max Cos}(si, tj)$$

Finally, the overall sentence similarity score is computed based on CL-WA and CL-A, which we name “CL-WA+CL-A”, as shown in Equation 9.

$$\text{Sentence}_{sim} = th \ast S + (1 - th)ssim$$

where the value of $th$ value ranges within $[0.5, 1]$, and is the threshold for weighting importance between components based on CL-WA ($S$) and CL-A ($ssim$).

### 3.2 Classification Model

Machine learning algorithms have been applied in several fields, such as image processing and natural language processing. We use the extracted features, based on syntactic and semantic computation, along with different ML classification frameworks for detecting whether an English-Arabic pair of sentences is plagiarized or not. We investigate
different ML classifiers such as Logistic Regression (LR), Support Vector Classifier (SVC), Linear Support Vector Classifier (LSVC), Decision Tree (DT), Random Forest (RF), K Nearest Neighbors (KNN), and Extreme Gradient Boosting (XGBoost), using those extracted features.

4 Experiments and Results

To assess the performance of the proposed techniques, we have conducted experiments to examine the impact of both individual and combined features used to train each classifier. For evaluating the performance of the classifiers, we have used 10-fold cross-validation and the F1-measure (F1 score), which is the harmonic average of precision and recall, as shown in Equation 10. The experiments have been carried out using Python with the scikit-learn library to build each classifier, and we have used the Grid Search method to find the best values of hyperparameters for configuration of the ML models.

\[
F - measurement = \frac{2 \times precision \times recall}{precision + recall}
\]  

(10)

4.1 Dataset

We used SemEval-2017 (Cross-lingual Arabic-English) datasets, released by Cer et al. (2017). The total size of the dataset is 1234 pairs of sentences, which were used for both training and testing data. Humans have labeled each pair of sentences on an integer scale from 0-5 (5 indicates exactly similar, whereas 0 shows that the two sentences in the pair are completely different), which was linearly scaled into the interval [0,1] then each pair of sentences was labeled 1 (means plagiarized) or 0 (means non-plagiarized) if the human similarity score is greater than or equal to a threshold of 0.5. Table 1 illustrates more information about the dataset.

Table 1: Evaluation dataset

4.2 Pre-processing Stage

The pre-processing phase is an essential step for preparing the text for further evaluation. As the first two extracted features described in 3.1.1 and CL-WE_Tw are based on machine translation, we used the Google Translation tool to translate Arabic sentences into English sentences. Then, we used the Natural Language Toolkit (NLTK) tool for the following processing: (1) tokenization, (2) part of speech tagging, (3) removing punctuation marks and (4) normalization. On the other hand, the extracted features described in 3.1.4 are based on a pre-trained multilingual encoder model, which represents different languages on the same vector space, therefore, we used NLTK for performing: (1) tokenization, (2) removing punctuation marks and (3) removing stop words for both English (e.g. ‘that’, ‘is’ and ‘were’) and Arabic such as ‘في’، ‘ الى’ and ‘التي’، meaning “in”, “to” and “that” in English respectively.

4.3 Parameters Setting

The proposed methods of extracting features contain a number of parameters that are required to be tuned parameters for constructing word order vectors, for weighting the importance between syntactic and semantic features, and for word alignment features. Many experiments are performed to determine a suitable value for each parameter. For setting these parameters, we have used pairs of sentences from the Microsoft Research Video Description Corpus dataset, and computed Pearson correlation coefficient between human rates and results obtained from proposed approaches, thus the best Pearson correlation indicates suitable values for these parameters. Therefore, the results acquired from the experiments show the suitable values of the parameters, and we have found the best correlation coefficient values for determining word order similarity is achieved at (wt= 0.54). For weighting importance of syntactic and semantic similarity features, we have obtained the best results at (δ=0.80). In terms of the parameters related to word alignment, the best performance is attained at (t₁= 0.53, t₂= 0.40 and th=0.70). As a result, we
have used these parameters and values on the rest of the dataset.

4.4 Results

This section shows the contribution of using extracted features, described in Section 3.1, along with a set of classifiers for detecting cross-language plagiarism. Table 2 shows the performance results of utilizing the proposed features along with LR, SVC, L SVC, DT, RF, KNN and XGBoost classifiers, where the first column illustrates the extracted features while the rest of the columns presents the results according to the F1 Score metric.

4.5 Discussion

As presented in Table 2, the performance of the classifiers using sets of extracted features shows encouraging results for classifying pairs of English-Arabic sentences. We can see that the integration of semantic and syntactic features with the classifiers as one feature, based on word embedding and word order features, demonstrates enhancement of the performance through LR, L SVC, KNN and XGBoost. Furthermore, it can be observed that using CL-WA+CL-A features along with the different classifiers obtained better results than CL-WA and CL-A individually. It can be also seen that combinations of features based on CL-WET-WO and CL-WA+CL-A with the classifiers show improvements in the results. Interestingly, using all combined features based on CL-WET-WO, CL-WA+CL-A and CL-WE-Tw+MUSE is efficient in enhancing the performance of most classifiers including LR, SVC, L SVC, DT and RF. We believe this improvement can be ascribed to the word embedding and multilingual encoder models capturing semantic and syntactic features.

5 Conclusion

In this paper we introduced a technique based on analyzing sentences using syntactic and semantic features with ML classifiers to detect English-Arabic cross-lingual plagiarism. The features we used involve word order, word embedding and word alignment with multilingual encoders. We also explored the effects of using extracted features and their combinations along with the different classifiers. The proposed method has been assessed by using a compilation of four datasets. According to the evaluation, the integration of combined extracted features with the classifiers demonstrates improved performance. Overall, the SVC classifier based on combination of all features accomplishes the best results with the F1 score of 0.879. In future work, the approach will be expanded to include use of neural network techniques.

Towards a Better Understanding of Noise in Natural Language Processing

Abstract

In this paper, we propose a definition and taxonomy of various types of non-standard textual content – generally referred to as “noise” – in Natural Language Processing (NLP). While data pre-processing is undoubtedly important in NLP, especially when dealing with user-generated content, a broader understanding of different sources of noise and how to deal with them is an aspect that has been largely neglected. We provide a comprehensive list of potential sources of noise, categorise and describe them, and show the impact of a subset of standard pre-processing strategies on different tasks. Our main goal is to raise awareness of non-standard content – which should not always be considered as “noise” – and of the need for careful, task-dependent pre-processing. This is an alternative to blanket, all-encompassing solutions generally applied by researchers through “standard” pre-processing pipelines. The intention is for this categorisation to serve as a point of reference to support NLP researchers in devising strategies to clean, normalise or embrace non-standard content.

1 Introduction

In Natural Language Processing (NLP), “noise” as a concept is not well understood and often described as hard to define (Taghipour et al., 2011). In this paper, we attempt to outline what different types of noise mean in order to support NLP researchers in devising strategies to clean, normalise or embrace unexpected content at either training or inference time.

The term “noise” has been generally used to cover both harmful and meaningful types of non-standard content. We however believe that a distinction should be made between content that should be removed/normalised because it harms NLP systems – henceforth harmful noise – and content that should be kept to improve the performance of such systems – henceforth useful noise1. To clarify further, the usual approach to handling “noise” is to attempt to clean or normalise the data as much as possible, but this content can be as important as any other elements in the data because it carries meaning or intentions. In text classification applications, for example, some types of noise should be kept and taken into account, e.g. certain punctuation patterns in sentiment analysis. Furthermore, in generation applications, noise often needs to be transferred to the output, such as emojis in machine translation to preserve sentiment. Moreover, in tasks such as correction of second language learners’ essays, errors such as lack of cohesion and incorrect punctuation need to be retained.

Handling noise in NLP has been attracting significant attention especially with the widespread availability of data from social media platforms such as Twitter, Reddit, among others, that created not only new opportunities but also new and different needs (Karpukhin et al., 2019). Text found on these platforms, as well as other user-generated materials, is full of non-standard content (Eisenstein, 2013) which causes problems to NLP systems – typically trained on clean data – and these fail to handle them correctly (Baldwin et al., 2015; Belinkov and Bisk, 2018; Heigold et al., 2018). Dealing with non-standard data has been targeted as a research direction in some areas, for example, machine translation (MT), with methods that aim to be robust to unexpected noise (Belinkov and Bisk, 2018; Karpukhin et al., 2019; Vaibhav et al., 2019). However, work has been mainly limited to a few sources of artificially injected noise types.

1We will keep using the term “noise” to adhere to a term known and used in the existing literature in NLP, but we make a distinction between harmful noise and useful noise.
In this paper, we start by providing an overview of previous work addressing this issue (Section 2); to then propose a definition of noise including cases that needs to be cleaned/normalised (harmful noise) and other cases that needs to be kept (useful noise), and present a comprehensive taxonomy of types of noise (Section 3); and to finally demonstrate the impact of addressing noise in a task-based fashion through experimenting with three tasks, where we compare filtering out harmful noise and keeping useful noise versus cleaning/normalising or keeping all types of noise (Section 4).

Our focus is on linguistic noise rather than other types of noise (such as numeric mislabelling). Therefore, our definitions and categorisation broadly cover (i) text classification/regression tasks, where the noise is in the input text, e.g. sentiment analysis; and (ii) text-to-text tasks, where the noise is in the input text and – at training time – can also be in the output text, e.g. machine translation.

2 Related Work

Noise in NLP has typically been defined in context of a specific dataset, intermediate or end-task, rather than in general. For example, noise is limited to sentence pairs “not being parallel” in parallel corpus filtering (Taghipour et al., 2011). Han and Baldwin (2011) describe their task as lexical normalisation of “ill-formed words”, where the definition is narrowed down to “instances of typos, ad hoc abbreviations, unconventional spellings, phonetic substitutions and other causes of lexical deviation found on Twitter and SMS messages”. Subramaniam et al. (2009) define text normalisation where noise becomes “any kind of difference in the surface form of an electronic text from the intended, correct or original text”. For an end task where the focus is on improving the performance of a certain task, however, the definition of noise becomes very specific, serving one purpose. For example, noise is referred to as the task of removing unconventional casing by truecasing the data when the aim is to get better vocabulary generalisation. Very often such a blanket, one-size-fits-all pre-processing pipeline is applied without enough consideration to other possible sources of noise, or which sources should actually be kept in the data.

Our work is driven by the lack of studies aimed at defining and providing a comprehensive categorisation of noise types in a way that reflects a better practice and shows sensitivity towards such content. The few exceptions limit their categories to noise found in specific text types. Subramaniam et al. (2009) provide a general overview of noise types in SMS, emails and online chats, while Eisenstein (2013) focuses on identifying types of what is called bad language and their possible causes.

Most of the previous studies on handling noise have focused on MT. While some studies have revealed that training with noise increases the robustness of systems towards noisy data, others have indicated that the quality of their systems degraded. This can be attributed to the differences in noise types and their potential impact on the task. For instance, Khayrallah and Koehn (2018) have showed that training MT models on noisy parallel data (such as misaligned sentences or wrong language) leads to weaker systems. However, when models are trained on more specific types of noise such as spelling, profanity, grammar and emoticons, they have been shown to perform better on similar types of noise (Belinkov and Bisk, 2018; Heigold et al., 2018; Ott et al., 2018; Berard et al., 2019; Vaibhav et al., 2019). We note that most of the latter work aims to adapt MT systems built on clean data to noisy test settings by artificially injecting errors to the training set. This is a different problem to the one we discuss in this paper where both training and test sets are taken from the same larger population with naturally occurring noise.

These studies show that different types of noise have different effects in MT and other NLP tasks. However, the types of noise addressed and their effect vary considerably and a consistent definition has not been provided.

Noise is better defined and understood in other related fields. In Automatic Speech Recognition, a distinction is made between what is considered as noise (e.g. environmental noise, reverberation) and other speech variations (e.g. accent, speaking style and rate, emotional states, speech impairments). Noise is defined as “any unwanted disturbances superposed upon the intended speech signal” (Li et al., 2015), e.g. by additive noise (e.g. background noise, traffic noise) and convolutional noise (e.g. transmission channel distortions, room reverberation, microphone filtering) (Xiong, 2009). In Optical Character Recognition, noise refers to “the error in the pixel value or an unwanted bit pattern, which do not have any significance in the output”, where the unwanted bit patterns are introduced by uneven writing surface or poor quality of the data.
acquisition device and include textured or coloured background (Bansal and Kumar, 2013). Different handwriting however is not seen as noise which needs removing but as a problem which needs to be addressed.

Similar to what has been done in these areas, this paper is an attempt to clearly define and categorise noise in NLP in a way that is not constrained to any particular application, task or dataset. While noise is mainly found in non-standard text, the taxonomy is agnostic to the type of text.

3 A Taxonomy of Noise

We intend to move away from the general labelling of noise as “errors”, “difficult data”, “ill-formed words”, “contamination”, “disfluent language” and “corruption” to a more specific one that reflects the current practice which have shifted from denoising to training with noisy text. We therefore look at noise through the same lens as in other related fields where a distinction should be made between unwanted constructs that occur in the text (generally unintentionally), and other (generally intentional) constructs that do not adhere to the conventions and rules of a given language to serve a purpose. Based on this distinction, we define harmful noise as any unwanted disturbances that are either harmful or useless or both: Harmful in that it affects the intended meaning of the text and/or the performance of the NLP system; and useless in that their existence does not serve a purpose. Useful noise, on the contrary, covers wanted content that serves a purpose and carries meaning that is important for the task and/or for the performance of the NLP system. Our definition does not includes cases where a special language is used in a cryptical fashion, i.e. hiding some codes/messages in the text so that only a particular addressee understands the true message. It is also worth noting that it depends on the NLP application under consideration, where harmful noise for one system could be useful noise for another one.

Our taxonomy of noise, displayed in Figure 1, focuses on applications that take sentences as input, as in most NLP tasks. From this work, we exclude types of noise that are related to errors in parallel corpora with text in both input and output such as misalignments, incorrect output, untranslated sentences, among others. The taxonomy is divided into several types and sub-types of noise that are limited to those naturally occurring, produced by humans. Machine-generated errors, e.g. stemming from back-translation or intentionally injected, are seen as a way to mimic the naturally occurring noise, and as such not represented separately. The taxonomy is designed to serve as an initial point of reference. It should be seen as language-independent, but it may require modifications to cover very specific language phenomena the authors are not familiar with. Our taxonomy is based on previous works that address different types of noise as well as taxonomies of errors and also on our wide experience improving robustness in NLP. The selection criteria are driven by the intention to include general categories that are applicable to different languages and tasks, and for non-standard content. In what follows, we describe the types and sub-types of noise coming under the proposed taxonomy and provide examples.

Orthography: This type of noise is concerned with the way words are written. Several sub-types come under this type, which we describe below. Some of them are considered as errors, e.g. spelling errors, while others are looked at as variations or deviations from the standard way of writing to serve a purpose, e.g. word obfuscation, word lengthening.

Spelling Errors: This is when a word is spelt in a way that deviates from reference dictionaries, standardised or accepted norms, or recognised usage. The misspelling of a word takes different forms. For example, the word “receive” can be misspelt by deleting a character, e.g. “receve”; inserting an extra character, e.g. “recieve”; swapping adjacent characters, e.g. “recieve”; or replacing a character with another, e.g. “recieve” (Sakaguchi et al., 2017; Belinkov and Bisk, 2018). Additionally, a spelling error can occur when writing a word without a hyphen where needed or with a space where it should be written as one word such as writing “4 MB” instead of “4MB” (Bušta et al., 2009).

Orthographic Variants: This covers the spelling of words in different ways due to: 1) regional variations: e.g. British English spelling vs. American English spelling, e.g. “centre”, “center”; 2) words with different correct spellings: e.g. “spelled”, “spelt”, “سورية” or “سورية” for “Syria” in Arabic, or when words are transliterated, e.g. proper name “محمد”, having one spelling in Arabic, could be written as “Muhamed”, “Mohamed” or “Mohammed” in English; or 3) diacritical marks:
in some languages, such as Arabic, words have accents (or what is called diacritics), which are not always used. These diacritics can change the meaning of the word. For example, the word “جد” could mean “grandfather” with the diacritical mark placed above the first letter “جد jed” and “dil- lIGENCE” if this mark is placed under the first letter “جد jid”. It is therefore important that the models are trained to recognise the difference.

**Casing:** This sub-type refers to instances where casing is used for a purpose. Some words are capitalised for emphasis, e.g. “NOTED!” It also covers cases where casing is incorrect or missing where needed, generated by mistake and not deliberately to serve a purpose such as random capitalisation of some characters in a word, e.g. “SUre”; or absence of casing where needed, for example, on proper names, e.g. “john”.

**Word Obfuscation:** This sub-type refers to cases where some characters within a word are obfuscated, or in other words, disguised, using numbers or symbols. It can be used for purposes such as disguising violence, e.g. “ki11” instead of “kill”; or masking profanity, e.g. writing “fuck” as “f*ck” (Michel and Neubig, 2018).

**Word Lengthening:** It refers to elongating a word by replicating a letter(s) in it, often to express emphasis, e.g. “Yes, Nooow!”; or sentiment, e.g. “قمرور” which means “moon” in Arabic and used to compliment a girl’s beauty.

**Symbols:** This covers any special symbol or sign used to express an idea, mood or feelings, e.g. emoticons “:-)”, emojis “ energía”; or as a replacement for a word, e.g. using “@” to mean “at”.

**Informal Word Forms:** This type refers to cases where multiple words are written jointly as one word, following a certain dialectal convention (Subramaniam et al., 2009), for example, dialectal words or slang, e.g. “wanna” for “want to”, “whatcha” for “What are/do you ...?”. This form of contraction does not normally follow the conventions of how words are contracted and is different from other more common forms of contraction such as “isn’t” for “is not” and “aren’t” for “are not”. In the extreme case, most of the text could be written in dialect such as in Arabic (Darwish, 2014).

**Shortening:** This type refers to cases where a word or phrase is written in a short form using different techniques, including three sub-types: 

- **Abbreviations** includes any form of shortening of a word or phrase used to refer to the whole word or phrase, for example, “Professor” is abbreviated as “Prof”. It also covers acronyms such as Internet slang, e.g. “LOL” for “Laugh Out Loud”; and initials, e.g. “idk” for “I don’t know” (Subramaniam et al., 2009).

- **Deletion** refers to cases where words and phrases are shortened without following any well-established patterns (i.e. more arbitrarily), for example, by character deletion, e.g. “msg” for “message”; by cutting part of a word, i.e. truncation, e.g. “tom” for “tomorrow”; or deleting an entire
word, e.g. “drvng hm” for “I am driving home” (Subramaniam et al., 2009).

**Substitution** happens when words or characters are replaced with numbers or letters which have the same phonetic sound to make it shorter. Substitutions may encompass several sounds. Examples include writing “2day” for “today”, “18r” for “later”, and “byk” for “bike” (Subramaniam et al., 2009; Gouws et al., 2011; Han and Baldwin, 2011). The use of numerals in place of letters can also happen for other proposes, e.g. writing Arabic text in Latin letters and using Arabic numerals to represent letters when there is no equivalent in the Latin script (Darwish, 2014). For example, the word “تحرير” which means “liberty” could be written as “ta7r¯ır” with the letter “h” being replaced with number “7” (ibid.). Another type of substitution errors occurring in texts includes when typing wrong keys on a keyboard instead of the intended ones (Kane et al., 2008) (this could also be seen as a spelling error, see Orthography type).

In some instances, shortening can using a mix of techniques, for example, by both deletion and substitution, e.g. “f2f” for “face-to-face”.

**Grammatical Errors:** This type of noise implies a deviation from the grammatical rules of a language apart from spelling errors (Lommel and Melby, 2015; Garnier and Saint-Dizier, 2016), including the following sub-types:

**Function Words:** Function words include prepositions, articles, determiners that are used incorrectly (Lommel and Melby, 2015), e.g. wrong preposition, “I bought this book to her” instead of “I bought this book for her”.

**Word Form:** This sub-type refers to a problem in the form of a word and includes agreement, tense-mood-aspect, and part-of-speech (Lommel and Melby, 2015), e.g. “I have a good day yesterday” (present tense) instead of “I had a good day yesterday” (past tense).

**Word Order:** This sub-type refers to instances where the order of words is incorrect (Lommel and Melby, 2015). For example, unlike in English, in Arabic, an adjective comes after a noun to describe it, so it is incorrect to say “a big house” where it must be “a house big”.

**Incorrect Punctuation:** Punctuation errors may include missing or incorrect placement of punctuation marks (e.g. !, ?, etc.) (Bušta et al., 2009). Punctuation plays a major role in our understanding of a text and text readability. For example, the sentence “Eat, dog!” could be read and interpreted differently with or without a comma.

**Cohesion Errors:** This type generally refers to structural errors that affect the flow of the text (within or across sentences) caused by using wrong linking words or pronouns, e.g. “Your car is newer, hence mine is faster”.

**Disfluencies in Human (transcribed) Data:** This type covers disfluencies that occur in spontaneous spoken language (Shriberg, 1994), including:

**Pause-filling Words:** This type refers to words or phrases used to express pausing in writing that mimics natural speech, e.g. “uh”, “er”, “um”. They generally do not have any meaning on themselves but may be indicative of important aspects, e.g. hesitation or surprise reaction (positive or negative), as well as style.

**Repetition of Words:** It refers to the occurrence of the same words several times or syntactically similar units unintentionally or on purpose, e.g. “I have I have discussed this matter matter with her again. Still, she is not convinced”.

**Repetition of Punctuation:** Unlike incorrect punctuation sub-type, this type refers to instances where punctuation marks such as exclamation mark or question mark are repeated to serve a purpose, i.e. for emphasis, e.g. “Really! You want me to go now???”; or to express an emotional state, e.g. “What???? This is really annoying!!!”.

**Code-switching:** This type refers to the alternation between different languages in a single sample. For example, “努力” is a phrase mixed with Chinese and English texts, which means “working hard”, with the English suffix “-ing” added to the Chinese word. An entire word or phrase could also be in a different language.

**Internet Jargon:** This type refers to new words and acronyms that gained special meaning and usage in certain social media platforms. Words such as “downvote”, “upvote”, and acronyms such as “TIL” for “Today I Learned”, “OP” for “Original Poster” are examples of jargon found on Reddit (Berard et al., 2019).
**4 Experimental Setup**

This section describes the settings of the experiments we carried out so as to show the impact of different pre-processing strategies on different NLP tasks. We experiment on three tasks based on data (in English) collected from Twitter: Offensive Language Identification, Informative COVID-19 Tweets Identification, and Tweets Sentiment Analysis tasks. We start by describing each task and the data used (Section 4.1), followed by the pre-processing steps of different sources of noise (Section 4.2), and the model architectures (Section 4.3).

Due to length restrictions, we limit ourselves to experimenting with a few types of noise, with the aim to show their role as of being “harmful noise” to filter out or “useful noise” to keep, and to what extent this is dependent on the task.

**4.1 Tasks and Datasets**

Since it is not possible to find corpora that cover all types of noise as defined in the taxonomy, we select three datasets sourced from social media, where the texts are informal and contain several common types of noise. We use the following tasks and their respective freely available datasets (statistics in Table 1):

**Offensive Language Identification (OLID)** (Zampieri et al., 2019a,b): This task focuses on the problem of identifying and categorising offensive language on Social Media. We take the main type of annotation and treat the task as a binary classification task. Given the lack of standard training/development splits in the OLID dataset, we randomly split the training data into training and development sets with a ratio of 0.8/0.2. The official test set in this dataset is used for evaluation.

**Informative COVID-19 Tweets Identification (COVID)** (Nguyen et al., 2020): This is a binary classification task identifying whether a COVID-19 related Tweet is informative or not. We use the official train/dev/test splits in the dataset.

**Twitter US Airline Sentiment Analysis (SA):**

This consists of annotated user reviews on Twitter classified into positive, negative and neutral. We filter the data by only including the annotations where the sentiment confidence is 1, and then randomly split the data into train/dev/test sets with a ratio of 0.8/0.1/0.1.

**4.2 Pre-processing**

The pre-processing step is where we generally make decisions on how to deal with the data in terms of whether to clean, normalise, or keep the data as it is. We experiment with different pre-processing strategies for each task by removing, normalising or keeping seven types and sub-types of noise listed in our taxonomy: casing, @mention tag, hashtag, emoji, code-switching, URL and punctuation. For casing, the pre-processing involves normalising all characters to lowercase. For hashtags and emojis, pre-processing can either remove or normalise them by transforming them into corresponding word phrases that share the same semantic meaning (e.g. “#PutUpOrShutUp” transformed into “Put Up Or Shut Up”, the emoji “😉” transformed into “smiling face”). For the other types of noise, pre-processing means removing them. In this work, we apply the same pre-processing steps to the training, development and test sets.

**4.3 Model and Hyperparameters**

We used a pre-trained BERT (Devlin et al., 2019) model with the “bert-base-cased” architecture\(^3\) as our classifier. A dropout with a rate of 0.1 is applied to the output layer on top of the pre-trained model. Models were trained for 5 epochs on the training set, and the checkpoint with highest macro F1 score on the development set was selected for evaluation on the test set. We fine-tuned BERT using AdamW (Loshchilov and Hutter, 2019) optimiser with a learning rate of $1e^{-5}$. All models were trained on a single V100 GPU, with a batch size of 128 sentences. Our code was based on the [https://www.kaggle.com/crowdflower/twitter-airline-sentiment](https://www.kaggle.com/crowdflower/twitter-airline-sentiment)

\(^3\)We did not use the uncased BERT because it treats the uncased text the same way as its cased version, which would not allow for the comparisons by normalising/keeping the casing information.
Table 1: Number of sentences in the three datasets. For the sentiment analysis data, we report the statistics after filtering. OFF: label “offensive”. NOT: label “non-offensive”. INFOR: label “informative”. UNINF: label “uninformative”. POS: label “positive”. NEG: label “negative”. NEU: label “neutral”.

5 Results

We first present our baseline performance without any pre-processing in Table 2. We then show the percentage change in macro-F1 scores for each of the three tasks by addressing one type of noise from the baseline at a time in Figure 2. Each time one type of noise is removed in the pre-processing except the casing, which is lowercased. We consider noise to be “useful” noise when the removal results in decrease in performance (negative bars). It is worth noting that if the performance drops, that means removing the noise might deviate the intended meaning of the original sentence.

Comparing the three tasks, removing/normalising the same type of noise clearly has opposite effects (e.g., casing), or different magnitudes of effect (e.g., punctuation):

Normalising casing leads to a decrease on OLID task whereas the performance on the other two tasks increases. This is intuitive as offensive texts are likely to be written in uppercase while it might be less useful for identifying informative tweets or sentiment (i.e., for sentiment, when both strong positive and strong negative texts involve upercasing, the casing information does not indicate sentiment correctly). A similar trend can be witnessed when removing URLs, but the decrease on OLID task is larger. This might be because, in the OLID dataset, web addresses have already been normalised with a unified “URL” token, thus it might contain useful rather than noisy information. We can therefore say that casing and URLs are useful noise and should be kept on OLID task for better performance.

Hashtags are more useful on the sentiment analysis task because, when removed, the performance drops on the SA task while improves on the other two tasks. We notice that in the data for sentiment analysis, hashtags are mostly single words such as “#mad” and “#senseless” so that the sentiment could be detected by the model. However, in the OLID dataset, hashtags hinting toxicity mostly include multiple words, e.g., “#Liberalismisamentaldisorder”, which increases the difficulty of utilising these hashtags. In the COVID dataset, almost all tweets consist of hashtags related to COVID-19, thus the hashtags do not help identifying whether the tweet is informative or not.

Removing @mentions causes a more obvious decrease in the SA task than the other two tasks. This is because the @mentions in OLID and COVID datasets have been normalised with a unified “@USER” token, but in the SA data @mentions stay in the form of usernames. We found that the @mentions in sentiment analysis data helps indicate the sentiment. For example, 32.0% of sentences with “@VirginAmerica” are labeled as...
positive while there are only 10.9% positive tweets with “@united”. Similarly, removing emojis, code-switching and punctuation leads to a decrease on all three tasks. However, emojis are less influential for identifying informative tweets. The decrease therefore is not significant for this specific task. Furthermore, as the non-English words are mostly named entities, the removal of code-switching could break the sentence structure. Regarding punctuation, it is important for the three tasks where its removal causes larger performance drop especially on the SA task as it leads to the removal of emoticons “:-)”, which can be useful for classifying sentiment.

Based on our findings that show how different strategies lead to different results, we took a step further to show the validity of our reasoning for how noise should be understood and handled on different NLP tasks. To that end, we combined the different pre-processing strategies and trained two other systems: remove all, which does the lower-casing and removes all other types of “noise” we dealt with in our experiment (i.e. URLs, hashtags, @mentions, emojis, code-switching and punctuation), and remove+keep, which only removes the harmful noise in the specific task as showed in Figure 2 for each type of “noise” (e.g. for OLID task only hashtag is removed while for SA task, URL is removed and the texts are lowercased). In addition, to make use of the potentially useful information in hashtags and emojis, we followed the state-of-the-art approaches (Liu et al., 2019; Kumar and Singh, 2020) and segmented hashtags into separate words and transformed emojis into corresponding English phrases as we stated in Section 4.2 (pre-processing of other types of noise is the same as remove+keep). The system trained on this data is noted as remove+keep+transform. The results are presented in Figure 3.

The system with data removing all sources of noise in the pre-processing shows a poorer performance than the baseline, which keeps all sources of noise. However, both “remove+keep” and “remove+keep+transform” systems outperform the baseline, with improvement on sentiment analysis task being the most significant. However, after transforming hashtags and emojis into English phrases, the performance only improves on the OLID task compared to the “remove+keep” system, which confirms our claim that the same noise normalisation strategy to noise might have different influence on different tasks.

These results are in line with our proposed definition of noise in NLP where some types of noise can be useful and others harmful, and how this is greatly dependent on the task. They also confirm our suggestion that one should not simply follow “standard” pre-processing pipelines, but carefully devise appropriate strategies to deal with different types of noise depending on the task.

6 Conclusions

In this paper, we proposed a definition and taxonomy of noise in NLP so as to serve as a point of reference for NLP researchers to consult when they devise strategies to clean, normalise, or embrace non-standard content at either training or inference time to improve the robustness of their systems to this unseen or unexpected naturally occurring harmful and useful noise. We highlighted that noise in NLP should be carefully handled in light of what we call “harmful noise” that needs to be removed when it affects the performance of the system and/or it does not carry the intended meaning of the text, and “useful noise” that needs to be kept because it is an integral part of the data and useful for a task, or even should be added to the training data when it only happens naturally at test time.

Our experiments support our argument by demonstrating that tailored approaches are better than blanket, all-encompassing solutions generally applied by researchers through “standard” pre-processing pipelines. For instance, we found out
that casing and URLs are useful noise and should be kept on OLID task, but having a negative impact on the other two tasks (SA and COVID tasks) and should therefore be removed. We have also shown how special handling of harmful and useful noise could result in better performance where remove-all and keep-all approaches resulted in poorer performance. Our approach to noise was based on their impact on the tasks - we removed types of noise which had negative influence on the tasks. Our goals were to bring awareness to the different types of unexpected content and provide a definition and a taxonomy, and to highlight the fact that they need to be handled carefully rather than being avoided or treated using the same strategies.

Abstract

Written communication is of utmost importance to the progress of scientific research. The speed of such development, however, may be affected by the scarcity of reviewers to referee the quality of research articles. In this context, automatic approaches that are able to query linguistic segments in written contributions by detecting the presence or absence of common rhetorical patterns have become a necessity in the refereeing process. This paper aims to compare supervised machine learning techniques tested to accomplish genre analysis in Introduction sections of software engineering articles. A semi-supervised approach to augment the number of annotated sentences in SciSents¹ was performed. Two supervised approaches using SVM and logistic regression to assess the F-score for genre analysis in the corpus were undertaken. A technique based on logistic regression and BERT has been found to perform genre analysis highly satisfactorily with an average of 88.25 on F-score when retrieving patterns at an overall level.

1 Introduction

Written communication plays a fundamental role in scholarly development. Evidence for this is the high number of estimated publications and journals (Larsen and von Ins, 2010; Björk et al., 2008; Mabe, 2003). In this scenario, the reviewing process is a crucial pathway for improving publication quality, as it acts as a filter through which suitable research papers are selected for publication (Ware and Mabe, 2015). In principle, although academic gatekeeping does not entail rigid language rubrics, scientific publications on the whole present standardised conventions such as preference for passive constructions, high nominal style, paper division in sections, and use of lexical and phrasal structures to indicate the function and purpose of each text portion (Seaghdha and Teufel, 2014). Disseminated linguistic work aiming to systematically describe writing organization with a focus on the Introduction section is the CARS (Create a Research Space) model (Swales, 1990). CARS approaches genre analysis by introducing two concepts, namely Moves and Steps. Whereas a Move represents the objectives and functions of a text segment at an overall level, a Step further elaborates on explaining how the rhetorical means are specifically used to perform the function of a Move (Ruiying and Allison, 2003) (see examples in Table 1). Despite models serving as a basis for the reviewing process (e.g. CARS), the availability of reviewers to evaluate scientific publications does not keep pace with the ever-growing number of papers which require gatekeeping (Fox, 2017), therefore making computational techniques necessary.

Computational approaches may be implemented to query linguistic segments automatically in research articles by indicating the presence or absence of commonly used rhetorical patterns. Automatic approaches such as Support Vector Machines (SVM) (Bennett and Demiriz, 1999; Tang et al., 2007) can be employed to perform genre analysis due to its productive results regarding textual issues (Horn et al., 2014; Fernández-Delgado et al., 2014). Nonetheless, they require annotated data, which are scant in the literature and not easily obtained, with the existing ones having limited amount of input (Fisas et al., 2015, 2016; Seaghdha and Teufel, 2014; Anthony and Lashkia, 2003; Pendar and Cotos, 2008; Cotos and Pendar, 2016; Fiacco et al., 2019). Manual annotation is an arduous, expensive and time-consuming task as it requires expert human annotators. To tackle this issue, SVM may be used as a semi-supervised approach, in which considerable amounts of labeled and unlabeled data are
utilized together to form more solid classifiers (Zhu, 2005). In this context, this work aims to evaluate supervised and semi-supervised machine learning techniques for automatic retrieval of rhetorical patterns within Swales’ CARS genre analysis schema in research articles. This investigation was carried out into SciSents corpus and, for this reason, is restricted to the Introduction section of software engineering articles. This paper has two main objectives: the first is to augment the number of annotations in SciSents corpus, and the second is to compare and assess F-Scores generated by supervised approaches for genre analysis. For such, we performed a comparison between SVMs and logistic regression techniques for the classification task. For sentence encoding, we evaluated novel approaches such as Universal Sentence Encoder (Cer et al., 2018a) and BERT (Devlin et al., 2019).

This paper proceeds as follows: firstly, we review state-of-the-art works on genre analysis automation. Next, we present and describe the corpus and the semi-supervised annotation procedures. Also, we comparatively discuss the main features of the techniques employed in the experiments. We then address the included implementation details and, finally, report the results.

2 Related Work

One relevant reference for genre analysis automation is the work of Anthony and Lashkia (2003), who proposed a computer software tool for outlining a research article’s structure. Based on Swales’ schema, the tool (named Mover) aimed at presenting to learners a panorama of the move structure utilized in RA. The tool scanned 100 information technology articles abstracts comprising 692 sentences. The abstracts were manually annotated on the grounds of a Modified Create a Research Space (CARS) model proposed by Anthony (1999). The model includes Swales’ (1990) 3 Moves, as well as 12 Steps. Since this is a general and small-sized model designed for the Introduction section, not all Steps appeared in the dataset. A modified bag of words was utilized to represent the text so it could be machine manipulated. In a traditional bag of words, dataset sentences would be tokenized in single words. However, the authors added clusters of sequential words in order to allow the system to operate at the discourse level, therefore naming the model as Bag of Clusters. As well as allowing the system to identify steps only possible to classify if preceding or subsequent Steps are known, an additional “location” feature was added to the bag of clusters model. The model’s output fed a Naive Bayes classifier which performed consistently with an average Step accuracy rate of 68% (ranging from 17% - Indicate gap - to 92% - Announce research). The authors justified the poor results by the scarce training items from these Steps. Through error analysis, they observed that when the software presented flaws, the incorrectly categorized Step tended to fall within the same Move. In order to improve accuracy the two most probable classifications were used in a second experiment. In this turn, the user had to select the most appropriate option. With this procedure, accuracy achieved 86%. However, despite the productive result, the reduced number of articles and sentences was a hindrance for further validation.

Pendar and Cotos (2008) attempted to devise a pedagogical tool for automating discourse evaluation. The purpose was to appraise academic writing drafts in agreement with an adapted model based on CARS, to compare it with other papers from the same discipline and to provide feedback to the student. To develop such a tool, a text-categorization approach using Support Vector Machine (SVM) for sentence classification in research article introductions drawn on Swales’ rhetorical moves was employed. An experiment was conducted with a corpus named Intelligent Academic Discourse Evaluator (IADE) consisting of 11,149 sentences from 401 Introduction sections in 20 academic disciplines. Each sentence was manually annotated within the Moves from CARS schema. To execute the classification, sentences were stemmed and represented in an n-dimensional vector (up to word trigrams). Experiment results were encouraging (with an accuracy above 70%), but the dataset was relatively small and did not take Steps into account.

Cotos and Pendar (2016) made progress in their own 2008 work by increasing IADE’s size to 1,020 research articles across 51 disciplines. Sentences were also annotated according to the CARS model, but this time including both Moves and Steps. An SVM classifier with the previous settings achieved a Move accuracy of 72.6% and a Step accuracy of 72.9%.

Fiacco et al. (2019) presented a neural network architecture composed of a Bi-LSTM with CRF
as an automated approach to examine rhetorical structure in student writing. The embedding layer was initialised with a pre-trained representation of GloVe (Pennington et al., 2014) and was fine-tuned to the dataset to produce more accurate word representation. Two datasets were used to test the model: IADE (Pendar and Cotos, 2008; Cotos and Pendar, 2016) and Research Writing Tutor (RWT) comprising 900 full research articles (not only Introduction sections) across 30 academic disciplines. RWT was manually annotated and sentences with one communicative goal and more than one functional strategy could be labeled with several steps; a sentence could be assigned with a secondary Move/Step tag if it had more than one communicative goal. Experiments results achieved a precision and recall of 77%, and an F1-score of 76% for the classification task in RWT dataset.

Due to the data paucity problem present in the aforementioned works, this study proposes a semi-supervised approach as a contribution towards genre analysis automation as far as the CARS framework is concerned. A detailed explanation of the procedures can be found in the following sections.

3 Semi-Supervised Approach

3.1 Data

We used SciSents, a dataset of software engineering research article sentences. This data resource is based on 9,193 software engineering articles published between the years 2000 and 2018 in highly-cited journals and conference proceedings. The corpus consists of 322,630 sentences from Introduction sections. From this amount we randomly extracted 595 sentences as our dataset, which was then manually annotated across 13 Steps within 3 Moves as shown in Table 1.

3.2 Models

We automatically performed the genre analysis classification task comparing SVMs and logistic regression as classifiers as well as BERT (Devlin et al., 2019) and Universal Sentence Encoder (Cer et al., 2018a) as sentence embeddings.

3.2.1 Classifiers

SVM: Support Vector Machines are non-parametric and deterministic algorithms based on statistical learning. They have been used specially in NLP (Joachims, 1998; Yang, 1999; Goudjil et al., 2018). SVM builds a hyperplane in a multi-dimensional space with the aim of training a set of labeled instances which create a boundary between distinct classes (Hearst et al., 1998; Joachims, 1998).

Logistic Regression: Logistic regression is a statistical technique for binary classification that can also be applied to multi-class classification by treating genre analysis issues as a binary classification problem (Ifrim et al., 2008). It computes probabilities of classes using a logistic function and then constructs a linear hyperplane separating those classes.

3.2.2 Features

Universal Sentence Encoder: Universal sentence encoding (Cer et al., 2018a) generates embedding vectors by encoding greater-than-word length text using two models: transformer architecture (Vaswani et al., 2017) and Deep Averaging Network (DAN) (Iyyer et al., 2015). Transformer architecture encoder consumes substantial resources and imposes complexity to the model aiming at high accuracy. It is context-aware and takes into account the ordering and the identity of all words in context. It also uses attention to compute the representations of words in a sentence. The second encoding model (i.e. DAN) assumes lightly reduced accuracy aiming at efficient inference. It receives embeddings for words and bi-grams as input, computes its average and inserts it into a feedforward Deep Neural Network (DNN) to create sentence embeddings. The output of both models is a 512-dimensional sentence embedding.

BERT: Bidirectional Encoder Representations from Transformers or BERT (Devlin et al., 2019) is a masked-language model for representing text and comprises a multi-layered bidirectional transformer encoder used for pre-training on a large unlabeled text corpus. It aims at modelling masked-language as well as predicting the next sentence. A random sample of the tokens is masked (replaced with the special token), the next sentence is predicted and BERT proceeds with training and optimization until it obtains satisfactory results (Liu et al., 2019).

3.3 Method

3.3.1 Semi Supervision

To increase the number of annotated sentences in SciSents, we employed a semi supervised strategy, training an SVM in the labeled part of corpus to
classify the unlabeled part. For such, the corpus phrases were represented in a 1024-position vector using BERT (Devlin et al., 2019), following the implementation of Xiao (2018) as described in section 3.2.2.

Following the annotation stage, the probability of the corpus sentences falling into each of the 13 Steps in SciSents was computed. The 20 most likely sentences for each Step (260 in total) were manually checked by a human linguistic expert with considerable knowledge on Swales’ CARS model. Through this analysis we identified 228 correctly classified sentences against 5 wrongly classified ones. 27 sentences could not be categorized because of a few tokenization glitches. At the end of this stage, 233 sentences were added to the annotated set (including the former 5 incorrectly classified ones which were later corrected), amounting to a total of 828 manually annotated sentences. A new SVM training was then administered with this annotated set.

A second round of semi-supervised annotation followed, in which the linguistic expert analysed random sentences with different probabilities for Steps calculated by the second SVM training. A total of 481 random sentences were manually checked, of which 308 were marked as correctly classified and 173 marked as incorrectly classified. The misclassified sentences were manually reclassified so they could be added to the correct ones within the annotated set. Sentences with tokenization problems were discarded. At the end of this stage, 1,309 sentences were part of the manually annotated set (see Table 1). This corpus was used in the experiments, which are presented in the following section.

### 3.3.2 Evaluation

We used three measures to assess model performance: Precision, Recall, and F-score. Precision measures the proportion of correctly classified sentences out of the total number of annotated sentences, while Recall estimates the proportion of correctly annotated sentences out of the incorrectly predicted sentences plus the correctly classified sentences. F-Score in turn is the harmonic mean of both Precision and Recall (Goutte and Gaussier, 2005). Each technique was trained using 5 fold cross-validation and averages across F-Score results on test folds were reported.

Two embeddings were generated for the experiments. The first consisted of generating corpus sentence representation individually and the second

Table 1: Number of manually annotated sentences by Move and by Step in SciSents (SS), in semi supervised Round 1 (R1) and Round 2 (R2).
a representation in co-occurrence with the previous sentence. The purpose of this second approach was to investigate whether the previous sentence had an influence on the subsequent one in terms of genre analysis. In cases where the sentence was not preceded by any other, representation was calculated with that sentence solely. We highlight that the previous sentences were not necessarily the immediately preceding ones since invalid sentences were removed from SciSents during the preprocessing stage. The embedded sentences and phrase labels were the input for SVM training.

3.4 Baselines

The SVM-BERT pair, availed as the basis for the semi-supervised annotation (considering the embeddings generated from individual corpus sentences), was used for comparison with the rest of the experiment. For each technique, we explored two combinations of sentence embedding features: Universal Sentence Encoder and BERT. As to the former, a TensorFlow implementation\(^3\) (Cer et al., 2018b) was used and generated a 512-dimensional sentence embedding vector. Regarding the latter, BERT as a Service (Xiao, 2018) was employed and generated a 1024-position vector.

4 Results

We report the F-score averaged over the folds of our techniques in Tables 2, 3, 4 and 5. Each table column shows the result of an experiment type comprising a technique (SVM or logistic regression), a sentence embedding technique (BERT or universal sentence encoder), and an annotated set (SciSents, semi-supervised Round 1 and semi-supervised Round 2).

Table 2 summarizes the results of experiments on the Steps categories when using one sentence alone to generate the embeddings\(^4\). Except for 2 Steps (M1-S03- Establishing the importance of the topic as a problem to be addressed and M3-S11- Describing the limitations of the current study), logistic regression technique with BERT presented higher scores overall. In 6 times out of these the highest results in the semi-supervised annotation Round 2 were achieved for the following Steps: M1-S01-Establishing the importance of the topic for the discipline; M1-S02-Establishing the importance of the topic for the world or society; M1-S04-Referring to previous work to establish what is already known; M2-S05-Identifying and highlighting inadequacies, weaknesses, controversies and negative outcomes within the field of study; M3-S09-Describing the research design and the methods used; M3-S10-Explaining the significance or give reasons for personal interest in the current study. In the remaining 5 Steps (i.e. M2-S06-Identifying a knowledge gap, a lack of or paucity of previous research in the field of study; M3-S07-Stating the focus, aim, purpose or argument of the current research; M3-S08-Setting out the research questions or hypotheses; M3-S12-Outlining the structure of a chapter, paper, thesis or dissertation; M3-S13-Explaining Keywords (also refer to Defining Terms)), better scores were obtained in the semi-supervised annotation Round 1.

The best performance among all results was achieved for Step M3-S12 (Outlining the structure of a chapter, paper, thesis or dissertation) in semi-supervised annotation Round 2 using logistic regression and BERT, which showed a 0.8856 F-Score. The results in Table 2 for M3-S12 were higher than 0.84. This result can be explained by the fact that sentences within this Step are prototypical (e.g. “The paper is structured as follows”, “Finally, Section 6 concludes the paper and discusses its implications.”, and “The remainder of this paper begins with a comparison to related work (Section 2), followed by an overview of the approach used to create a corpus, perform change classification, and evaluate its performance (Section 3).”).

The worst performance among all results in Table 2 was a 0.1152 F-Score produced in M3-S10 (Explaining the significance or give reasons for personal interest in the current study) when using logistic regression and universal sentence encoder in SciSents annotated sentences. One possible explanation for this low performance is that the number of annotations is one of the smallest among all Steps (33 sentences). In addition, this result can be justified by the fact that sentence type used in this Step is quite varied such as “Our experiments, backed by a human study, suggest DeltaDoc could replace over 89% of human-generated What log messages.”, “This combines visualizations, providing a high level overview, and wiki pages, providing detailed information juxtaposed in a focus-plus-context oriented format.”, and “The backward analysis computes an over approxima-
tion of all possible inputs that can generate those attack strings." Throughout annotations rounds, M3-S10 improved its results and reached a performance of 0.4092. The best performance in Table 2 for M3-S10 scored 0.5081 when using the SVM-BERT pair.

Table 3 shows the performance of the experiments on Steps when using both actual and previous sentences to generate vector representation. The pair logistic regression with BERT surpassed other pairs in 7 (M1-S02, M1-S03, M2-S05, M2-S06, M3-S08, M3-S09, and M3-S10) out of the 13 Steps. As to the results regarding sole sentence embedding, the best performance among all was achieved in M3-S12 but this time in SciSents annotations using SVM and BERT with a 0.8932 F-Score. One of the reasons that may have contributed to this result even before semi-supervised rounds is the annotated sentence number (80) being the highest among all Steps. The worst performance in this type of experiment was a 0.1152 F-Score output for M3-S10.

We notice that results shown in Table 2 are more productive than the ones from Table 3 in 44 (or 56.41%) out of 78 when considering experiments that used BERT in isolation. When analysing only the best scores for each Step, Table 2 presents best results in 8 (61.53%), whereas Table 3 shows the most productive scores in 4 (30.77%) out of 13 cases. There was a draw in one case. Performance with universal sentence encoding was the same on both tables.

Table 4 summarizes the results of experiments on Moves when using one sentence solely to generate the embeddings. The best F-score for each Move was achieved with logistic regression and BERT in semi-supervised annotation Round 1 with an average of 0.8569 against an average of 0.8422 for Round 2. The lowest score in Round 2 was 0.7867 for M1 (Establishing the territory) whereas M2 (Establishing a niche) scored 0.8564. M3 (Occupying the niche) outperformed all other results with a score of 0.9275. When we compare these results with their respective scores in semi-supervised annotation (Round 2), there is a difference of 0.0126, 0.0129, and of 0.0187 between Moves M1, M2 and M3 respectively.

Table 5 presents results on Moves when the vector representation is created using the actual sentence in conjunction with the previous sentence. Similar to the technique with sole sentence embeddings for Moves, the best F-Score was reached with logistic regression and BERT. But this time M1 and M2 were reached in semi-supervised annotation in Round 2 and M3 in semi-supervised annotation in Round 1. When we compare scores from Table 4 with those from Table 5 we can notice that the figures on the former surpass all respective results on the latter when considering BERT alone. Again, when Universal Sentence Encoder was used there was no difference between the embedding from one sentence alone and from a sentence co-occurring with its previous one.

5 Discussion

The present study was designed to augment the number of annotations in SciSents corpus and to compare results in supervised machine learning techniques for genre analysis in software engineering research articles. The number of annotated sentences was increased from the 595 ones in SciSents to 1309 through two semi-supervised rounds using SVM.

SVM versus Logistic Regression: Logistic regression produced higher outcomes than SVM in 64% of the experiments. When associated with BERT, logistic regression beats SVM in 85% of cases, but when in conjunction with USE, SVM outperformed logistic regression in 57% of experiments.

Universal Sentence Encoder versus BERT: Vector representation provided by BERT delivered higher scores than Universal Sentence Encoder did in 75.5% of the tested sets. When BERT was employed with logistic regression, the results overcame other experiments in 81% of cases. Thus, from the pairs of techniques tested, the indicated one for genre analysis is logistic regression with BERT.

Vector representation - sentence alone versus co-occurring sentences: One finding in the experiments in supervised machine learning techniques is that, in most cases, the use of sentence embedding generated from the sentence alone provided more productive results than those with the use of the actual sentence together with its preceding one.

Table 5: Experiment results by Move on SciSents (SS), semi supervised Round 1 (R1) and Round 2 (R2) annotated sentence sets using the sentence co-occurring with its previous one to create the vector representation (LR = Logistic Regression; USE = Universal Sentence Encoder).
Semi-Supervised Approach: When analysing the evolution of results throughout the annotation process within each experiment type we can notice that they did not always improve accordingly. In Table 2, when we compare SciSents with annotations from Round 1, there was no increase in the F-score (despite one situation only representing 1.92% out of the total). When comparing annotations from Round 1 with Round 2, the latter outperformed the former in 46.15% of the cases. A possible explanation is that in Round 1 highest-ranked sentences by SVM were annotated while in Round 2 sentences with random probabilities were annotated. Thus, in Round 1, similar sentences to those the techniques already knew were included, whereas in Round 2 sentences which were different from those the techniques knew (but still fell into that Step) were included.

When approaching annotation evolution throughout Table 3 we observe that experiments within Round 1 annotations outperformed experiments in SciSents in 90.38% of the results. When comparing experiments in annotations between Round 1 and Round 2 there is a 50% (26 times) draw in which Round 2 showed better results than Round 1. The same analysis in Tables 4 and 5 shows that experiments in Round 1 annotations outperformed experiments in SciSents. When comparing annotations between Round 1 and Round 2 we observe no improvement in the latter (as shown in Table 4), but some improvement in 33.33% of the overall cases, as we see in Table 5. These results indicate that the second round of annotation may have included sentence types unknown to the technique.

Although most of the best results for Steps were achieved with a second round annotation set, setbacks were also present, thus indicating the need for more annotations for probabilities potentially corresponding to the categories set for Steps. These annotations may also contribute to genre analysis regarding Moves, despite results presenting insignificant improvements with a second round of annotations.

6 Conclusion

The present study compared supervised machine learning techniques which automatically retrieved linguistic segments from research articles. Firstly, we used a semi-supervised approach to increase the number of annotated sentences in SciSents corpus. Next, we used two supervised and two sentence embedding techniques to carry out genre analysis on the dataset. The results suggest that an approach based on logistic regression and BERT presents higher scores for genre analysis. In addition, although a semi-supervised annotation process has proven to contribute to the overall procedure, it lacks elements with random probabilities for substantial improvement.

As future work, the semi-supervised annotation process and the techniques hereby described can be used for annotating other sections of software engineering research articles. Also, the same analyses could be applied to articles from other domains so that cross-disciplinary rhetorical differences could be identified.

Abstract
Introducing factors, that is to say, word features such as linguistic information referring to the source tokens, is known to improve the results of neural machine translation systems in certain settings, typically in recurrent architectures. This study proposes enhancing the current state-of-the-art neural machine translation architecture, the Transformer, so that it allows to introduce external knowledge. In particular, our proposed modification, the Factored Transformer, uses linguistic factors that insert additional knowledge into the machine translation system. Apart from using different kinds of features, we study the effect of different architectural configurations. Specifically, we analyze the performance of combining words and features at the embedding level or at the encoder level, and we experiment with two different combination strategies. With the best-found configuration, we show improvements of 0.8 BLEU over the baseline Transformer in the IWSLT German-to-English task. Moreover, we experiment with the more challenging FLoRes English-to-Nepali benchmark, which includes both extremely low-resourced and very distant languages, and obtain an improvement of 1.2 BLEU.

1 Introduction
Many classical Natural Language Processing (NLP) pipelines used linguistic features (Koehn and Hoang, 2007; Du et al., 2016). In recent years, the rise of neural architectures has diminished the importance of the aforementioned features. Nevertheless, some works have still shown the effectiveness of introducing linguistic information into neural machine translation systems, typically in recurrent sequence-to-sequence (Seq2seq) architectures (Sennrich and Haddow, 2016; García-Martínez et al., 2016; España-Bonet and van Genabith, 2018). By factored Neural Machine Translation (NMT), we refer to the use of word features alongside the words themselves to improve translation quality. Both the encoder and the decoder of a Seq2seq architecture can be modified to obtain better translations (García-Martínez et al., 2016). The most prominent approach consists of modifying the encoder such that instead of only one embedding layer, the encoder has as many embedding layers as factors, one for words themselves and one for each feature, and then the embedding vectors are concatenated and input to the rest of the model, which remains unchanged (Sennrich and Haddow, 2016). The embedding sizes are set according to the respective vocabularies of the features. Note that they used Byte Pair Encoding (BPE) (Sennrich et al., 2016), an unsupervised preprocessing step for automatically splitting words into subwords with the goal of improving the translation of rare or unseen words. Thus, the features had to be repeated for each subword.

In España-Bonet and van Genabith (2018), the exact same architecture was used, except that this new proposal used concepts extracted from linked data database, BabelNet (Navigli and Ponzetto, 2012). These semantic features, synsets, were shown to improve zero-shot translations. All the cited works obtained moderate improvements with respect to the BLEU scores of the corresponding baselines.

Some works have previously proposed additional ways to combine sources and introduce hierarchical linguistic information (Currey and Heafield, 2019, 2018; Libovický et al., 2018; Tebbifakhr et al., 2018).

The main goal of this work, and differently from previous works using NMT architectures based on recurrent neural networks, is to modify the Transformer to make it compatible with factored NMT with an architecture that we call Factored Transformer and inject linguistic knowledge and concepts extracted from linked data, BabelNet (Nav-
igli and Ponzetto, 2012). We focus on low-resource datasets.

2 Factored Transformer

Unlike the vanilla Transformer (Vaswani et al., 2017), the Factored Transformer can work with factors; that is, instead of just being input the original source sequence, it can work with an arbitrary number of feature sequences. Those features can be injected at embedding-level, as in the previous works we described above (but in a Transformer instead of a recurrent-based seq2seq architecture), or at the encoder level.

1-encoder model (depicted in Figure 1, top): Each factor, including the words themselves, has its own embedding layer. The embedding vectors of the different factors are combined, positional encoding is summed and input to the following layer. The rest of the model remains unchanged. The positional encoding is summed to the combined vector and not to each individual embedding because we are not modifying the length of the sequence; therefore, the relative positions remain unchanged.

N-encoders model (depicted in Figure 1, bottom): We intuited that features with large vocabulary sizes could benefit from having a specific encoder. In this variant, each factor has its own full encoder (instead of just its own embedding layer). The outputs from the encoder are combined and input to the following layer. The rest of the model remains unchanged.

Once we have the outputs of the multiple embedding layers (the 1-encoder) or the N-encoders, they must be aggregated before being input to the next layer. We have considered two combination strategies:

Concatenation: The outputs of the different embedding layers or encoders are concatenated.

Summation: The outputs of the different embedding layers or encoders are summed.

In both cases, the dimensions must agree. The decoder embedding size must be equal to the encoder embedding size. If the outputs from the different encoders or embedding layers are concatenated, they do not need to have the same embedding size, but the resulting embedding size is increased. Instead, if they are summed, they must share the same dimensionality, but the resulting vector size is not increased.

#### 3 Linguistic Features

An arbitrary number of features can be injected into the Factored Transformer, provided they are aligned with words. As follows we describe how linguistic features were extracted and how they were aligned at the subword level.

**Linguistic tagging with StanfordNLP:** The corpus was tagged with linguistic information, namely lemmas, part-of-speech (PoS), word dependencies and morphological features, using StanfordNLP (Qi et al., 2018), and aligned with respect to the original tokenization.

**Synsets extraction:** BabelNet’s API retrieves all possible synsets (semantic identifiers) that a given token may have. Babelfy (Moro et al., 2014) is a word sense disambiguation service based on BabelNet that retrieves the disambiguated synset for each token depending on the sentence-level context. We split the corpus into chunks such that the daily usage limits of the API were not exceeded and no sentence was split in half (because otherwise Babelfy would have missed the context).

Babelfy returns a list of all the detected synsets with their character offsets, and they must be assigned and aligned to the original tokenization of the corpus. The following step was performed to resolve multiword synset conflicts since in the case of synsets composed of more than one token, Babelfy may retrieve one individual synset for each token and a collective one. We decided to prioritize the synset with the largest number of tokens since it seemed to give the most disambiguated information (e.g. the synset semantic network gives more specific information than the individual synsets semantic and network). For the tokens in the corpus that do not have an assigned synset (e.g. articles or punctuation marks), we assign a backup syntactic feature, namely, part-of-speech.

**Feature Alignment at the Subword-level:** To obtain state-of-the-art results in NMT, subwords (typically, BPE) is usually required. This presents a challenge with regard to word features since they must be aligned with the words themselves. The following alternatives were implemented and experimented with: just repeating the word features for each subword; using the BPE symbol in word features, in the same manner this tag is used in BPE for splitting subwords; and subword tags. This last approach was used in (Semnich and Haddow, 2016) and it consisted of repeating the word features for each subword and introducing a new factor, subword tags, to encode the position of the subword in the original word. The 4 possible tags are: B (beginning of subword), I (intermediate subword), E (end of the subword) and O (the word was not split). This approach is not compatible with the multiencoder architecture.

#### 4 Experimental Framework and Results

**Data:** Experiments were conducted with a pair composed of similar languages, the German-to-English translation direction of the IWSLT14 (Cettolo et al., 2014), which is a low-resource dataset (the training set contains about 160,000 sentences). For cleaning and tokenizing, we use the data preparation script proposed by the authors of Fairseq (Ott et al., 2019). We took the test sets from the corpus released for IWSLT14 and IWSLT16. The former was used to test the best configuration, and the latter was used to see the improvement of this configuration in another set. A joint BPE (ie. German and English share subwords) of 32,000 operations is learned from the training data, with a threshold of 50 occurrences for the vocabulary.

Other experiments were conducted with the English-to-Nepali translation direction of the FLoRes Low Resource MT Benchmark (Guzmán et al., 2019). Although this pair has more sentences than the previous one (564,000 parallel sentences), it is considered to be extremely low-resource and far more challenging because of the lack of similarity between the involved languages. In this case, we
learn a joint BPE of 5000 operations (both with an algorithm based on BPE, sentencepiece (Kudo and Richardson, 2018), as proposed by the FLoRes authors, and with the original BPE algorithm).

**Parameters and Configurations:** In the case of German-to-English, we used the Transformer architecture with the hyperparameters proposed by the Fairseq authors: specifically, 6 layers in the encoder and the decoder, 4 attention heads, embedding sizes of 512 and 1024 for the feedforward expansion size, a dropout of 0.3 and a total batch size of 4000 tokens, with a label smoothing of 0.1. For English-to-Nepali, we used the baseline proposed by the FLoRes authors: specifically, 5 layers in the encoder and the decoder, 2 attention heads, embedding sizes of 512 and 2048 for the feedforward expansion size and a total batch size of 4000 tokens, with a label smoothing of 0.2. In both cases, we used the Transformer architecture with the corresponding parameters we described above as the respective baseline systems, and we introduced the modifications of the Factored Transformer without modifying the rest of the architecture and parameters. As mentioned previously, linguistic features were obtained through StanfordNLP (Qi et al., 2018), except the Babelnet synsets. In the case of the latter, we found that approximately 70% of the tokens in the corpus we used did not have an assigned synset and were therefore assigned PoS.

**Preliminary experiments:** We experimented with BPE alignment strategies (including the approaches from section 4.2), and linguistic features extracted from Stanford tagger (lemmas, part-of-speech, word dependencies, morphological features). The preliminary experiments showed that BPE alignment strategies were not very relevant, so we adopted the alignment with BPE by repeating the word feature. In addition, we found that the most promising linguistic feature was lemmas (Sennrich and Haddow, 2016).

**Reported results:** We report experiments with features (lemmas and synsets), architectures (1-encoder and N-encoders systems), and combination strategies (concatenation and summation). Table 1 shows the performance of the baseline and the baseline architecture but with lemmas instead of the original words. We report how different features (lemmas or BabelNet) compare for a given architecture. Then, for the best feature, lemmas, Table 1 compares different architectures, and it is shown that the best architecture is the 1-encoder with summation. Finally, the best performing system (lemmas with a 1-encoder and summation) is evaluated in another test set, IWSLT16. The selected model is relatively efficient, because it only needs an additional embedding layer.

Once we had found that the 1-encoder Factored Transformer with summation and lemmas was a solid configuration for low-resource settings, we applied this combination the more challenging Facebook Low Resource (FLoRes) MT Benchmark. Specifically, we wanted to compare how this architecture performs against the baseline reported in the original work of this benchmark. The authors report the results before applying backtranslation and with sentencepiece, which is 4.30 BLEU. We reproduced that baseline and we got slightly better results (up to 4.38 BLEU). However, our system is designed to work with BPE, not sentencepiece, which is more challenging to align to features (since subwords coming from different words can be combined into a single token). Table 1 shows that our configuration clearly outperformed the baseline with BPE (almost 40% up), and was very close to the results with sentencepiece.

**Discussion:** The 1-encoder system outperforms the N-encoder one. We hypothesize that the N-encoder architecture does not give good results because a completely disentangled representation for each feature is being learned, and this is not an effective strategy for factored NMT. Therefore, it is better to combine features and words at the embedding level, not at the hidden-state level.

In the case of N-encoder with concatenation, if the linguistic features are not useful if they come from a different encoder, the decoder at least can learn to ignore them. In the case of the N-encoder architecture with sum, since the outputs from different encoders, which are potentially in very different spaces, are summed, it is tough for the decoder to interpret the vectors. In this case the decoder should learn to undo a sum, which is more difficult than just learning to ignore half of the vector (i.e., assigning low weights). In the case of the 1-encoder architecture, summation gives a much more compact representation. Summing lemmas allows the decoder layers to have a dimension of 512 (instead of doubling that, which may overfit).

Regarding the reasons why lemmas outperform synsets, we believe that the problem comes from the fact that a significant proportion of the tokens
do not get a synset. Instead, we can tag all words with lemmas. Besides, the use of synsets (BabelNet) intends to help at disambiguating, but the Transformer is already good at this task (Tang et al., 2018).

5 Conclusions

We have shown that the Transformer can take advantage of linguistic features but not synsets. We conclude the best configuration for the Factored Transformer is the 1-encoder model (with multiple embedding layers) with summation instead of concatenation. For the German-to-English IWSLT task, the best configuration for the Factored Transformer shows an improvement of 0.8 BLEU, and for the extremely low-resourced English-to-Nepali task, the improvement is 1.2 BLEU.

In future work, we suggest adapting the alignment algorithm to sentencepiece by combining features coming from different words into a single feature, provided their respective subwords have been merged into a single token. We suggest investigating whether linguistic features are still useful with backtranslation too.

valentina.kania@ui.ac.id, rahmad.mahendra@cs.ui.ac.id

Abstract

Coreference resolution is an NLP task to find out whether the set of referring expressions belong to the same concept in discourse. A multi-pass sieve is a deterministic coreference model that implements several layers of sieves, where each sieve takes a pair of correlated mentions from a collection of non-coherent mentions. The multi-pass sieve is based on the principle of high precision, followed by increased recall in each sieve. In this work, we examine the portability of multi-pass sieve coreference resolution model to Indonesian language. We conduct the experiment on 201 Wikipedia documents and multi-pass sieve system yields 72.74% of MUC F-measure and 52.18% of BCUBED F-measure.

1 Background

Many Natural Language Processing (NLP) tasks need to incorporate linguistic comprehension beyond semantics understanding. Coreference resolution is an important discourse-level NLP pipeline that can be used to support a number of NLP applications, such as question answering, summarization, and dialogue system. Coreference resolution task aims to evaluate whether a set of expressions in the text refer to each other, in other words whether they describe the same entity in real-world situation (Hirschman and Chinchor, 1998; Sukthanker et al., 2020)

There are not many coreference resolution studies in Indonesian. Budi et al. (2006) worked on the Indonesian coreference resolution task by applying the Association Rules. Suherik and Purwarianti (2017) developed a coreference resolution system using supervised classifier. They utilized lexical and syntactic features to connects pronouns to named entities, between named entities, and between pronouns.

2 Noun Phrases in Indonesian

The set of referential phenomena in Indonesian includes several types, i.e., pronouns, demonstratives, noun phrases, and named-entities. In this section, we briefly describe the first three types of nominal, while there is no difference of names between Indonesian and English.

Pronouns  Pronouns are a class of words that are used to refer to another noun (Alwi et al., 2010). A personal pronoun is a pronoun which refers to one or more persons. Personal pronouns in Indonesian are differentiated into singular and plural pronouns. Unlike English, pronouns in Indonesian are not

*Proceedings of Recent Advances in Natural Language Processing, pages 84–90
Sep 1–3, 2021.
https://doi.org/10.26615/978-954-452-072-4_011*
differentiated by gender, nor by its function in a sentence, i.e., same set of pronouns are used as a subject, an object, or to indicate possession. For example, the word "saya" is a personal pronoun in Indonesian which can be used as a subject pronoun, e.g., "Saya makan" (in English "I am eating."). An object pronoun, e.g., "Pak Bob memanggil saya." (in English "Mr. Bob is calling me."), and a possessive pronoun, e.g., "Ini buku saya." (in English "This is my book.").

Indonesian pronouns can be in form of the clitics (Larasati, 2012). A clitic is a morpheme that is attached to another word or phrase. Clitic pronouns in Indonesian include "-ku" as first-person pronouns, ",-mu" as second-person pronouns, and "-nya" as a third-person pronoun.

**Demonstratives** Demonstrative, also classified as a demonstrative pronoun by Alwi et al. (2010), are words that refer to a noun or noun phrase. In Indonesian, there are two common words that are classified as demonstratives, namely "ini" (in English: "this" or "these") and "itu" (in English: "that" or "those").

**Nouns** Nouns can be seen semantically as words that represent humans, animals, objects, meanings, and concepts that exist in the world as described in Alwi et al. (2010). Syntactically, a noun can be negated with "bukan" (in English: "not to be"), but cannot be negated with "tidak" (in English: "do not"). Nouns can be followed by one or more adjectives, either directly or connected by the word "yang" (in English: "which"). Several Indonesian nouns are multword expression (Suhardijanto et al., 2020), e.g., "kamar tidur" (in English: "bedroom") and "rumah sakit" (in English: "hospital").

**Noun Phrases** A noun phrase may consist of one or more noun(s), pronoun(s), numeral(s), verb(s), adjective(s), and demonstrative(s). A noun phrase in Indonesian is constructed by expanding the noun to the left, with a determiner, or to the right, with modifiers. The initial noun before the expansion is named as the core noun (the head word). While English put modifiers before the head word, modifiers come after the head word in Indonesian, e.g., "buku matematika" vs. "mathematics book".

Here are some rules for expanding a head word into a noun phrase in Indonesian (Alwi et al., 2010).

1. A head word can be expanded to the left with numerals or numeral phrases.

<table>
<thead>
<tr>
<th>satu</th>
<th>meja</th>
</tr>
</thead>
<tbody>
<tr>
<td>NUM</td>
<td>HEAD</td>
</tr>
<tr>
<td>&quot;one table&quot;</td>
<td></td>
</tr>
</tbody>
</table>

2. A head word can be expanded to the right by one or more other nouns (explanatory nouns/EXPN), then followed by a personal pronoun (PP), then it can be followed by a demonstrative word (DEM).

<table>
<thead>
<tr>
<th>meja</th>
<th>kayu</th>
<th>mereka</th>
<th>ini</th>
</tr>
</thead>
<tbody>
<tr>
<td>HEAD</td>
<td>EXPN</td>
<td>PP</td>
<td>DEM</td>
</tr>
<tr>
<td>&quot;this dining table of theirs&quot;</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

3. A head word can be expanded to the right by zero or more adjectives, pronouns or pronominal phrases, followed by a demonstrative.

<table>
<thead>
<tr>
<th>meja</th>
<th>biru</th>
<th>Ibu</th>
</tr>
</thead>
<tbody>
<tr>
<td>HEAD</td>
<td>ADJ</td>
<td>PP</td>
</tr>
<tr>
<td>&quot;mother’s blue table&quot;</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**3 Multi-Pass Sieve Coreference Model for Indonesian**

We design multi-pass sieve to resolve coreference problem in Indonesian text. The Multi-Pass Sieve approach works by receiving input in the form of mention pairs \((m_1, m_2)\) and classifying the correlation relationship between the two mentions according to the definition of each sieve layer sequentially and stops when the pair \((m_1, m_2)\) has been declared to have a correlation relationship or when the pair have visited the last sieve. The model is implemented in six tiers, i.e., exact string match, precise constructs, string head match, proper head word match, relaxed head match, and pronoun sieve.

Several other sieves in original Stanford model (Lee et al., 2011) are not adapted in our model due to the differences of linguistic characteristics between English and Indonesian languages. In contrast to English, demonym relation in Indonesian are not expressed by changing words. For example: "Indonesia" and "orang Indonesia" (in English: "Indonesia" and "Indonesian"). A sieve-pass using morphological properties is not included in ours. Indonesian word does not possess gender, number (singular vs. plural), and animacy attribute.

On the other hand, lexical chain sieve is not implemented due to the lack of language resources. Existing Indonesian WordNet (Putra et al., 2008)
does have neither adequate synsets nor lexical semantic relation. In addition, we do not find proper dictionary to construct alias sieve. We also exclude relaxed string match as adverb clauses are out of scope of mention detected in our coreference resolution system. Discourse processing sieve is skipped since the data used in our experiment does not contain any direct sentence.

3.1 Pass 1: Exact String Match
In this first layer of our Multi-Pass Sieve model, each pair of noun phrases is considered coherent if the two strings are the same, regardless of the difference in capitalization and punctuation.

3.2 Pass 2: Precise Constructs
The second layer of the model determines two noun phrases as coreferent if they follow a certain language structure.

**Appositive Relationship**. It is indicated by the position of the two mentions in the sentence in which a mention appears next to another mention. The second mention serves to explain the first mention, which is a proper noun in most cases. Both phrases are usually separated by a punctuation, i.e., comma, semicolon, dash, or brackets.

"[Emma Pillsbury], [salah seorang guru di SMA Ohio], mendengar berita itu."

"[Emma Pillsbury], [one of the teachers at Ohio High School], heard the news."

**Copulative Relationship**. The copulative relationship between two mentions is explanatory, in which both mentions are connected by a copula verb, e.g., "adalah", "merupakan", "yakni", "yaitu", and "ialah", (in English: "is/am/are/was/were"). Like appositive relationship, a mention explains another mention in copulative relationship.

"[Feng Yuxiang] adalah [seorang panglima perang pada masa Republik Tiongkok awal abad-20]."

"[Feng Yuxiang] was [a warlord during the early 20th century Republic of China]."

**Abbreviation Relationship**. The relationship exists when a mention is an abbreviation of another mention. As shown in Budi et al. (2006) and Lee et al. (2011), the abbreviation is detected by using a set of patterns.

"[Pekan Olahraga Nasional] (abbreviated [PON]) is a national sporting event in Indonesia which is held every four years and is attended by all provinces in Indonesia."

In aforementioned example, “PON” is detected as the abbreviation for noun phrase “Pekan Olahraga Nasional”, by matching the first letter of each word in the phrase.

3.3 Pass 3: Strict Head Match
In the third layer of our Multi-Pass Sieve model, two noun phrases are evaluated as coreferent if the head word of both phrases are the same and they also share the same lexical class. There are two variations of the strict head match. (i) **Strict head match**, looks at the similarity of core nouns consisting of one word taken during data preprocessing. (ii) **Full head match**, sees the similarity of the core nouns consisting of several words. The choice of full head in this case is to input words with the POS Tag NOUN or PROPN as the head.

There are three passes that take advantage of the head word or core noun features, i.e., the demonstrative relationship, name abbreviation, and strict head match itself.

**Demonstrative Relationship** The demonstrative relationship between two noun phrases, apart from depending on the position of the phrase in the sentence, also uses demonstrative word classes to determine the relationship. Noun phrases A and B are said to have a demonstrative relationship if one of the phrases contains a demonstrative, and after removing the demonstrative word, the phrase is a sub-phrase of another phrase.

"The Break Up" is [the fourth episode of the fourth season of the musical comedy television series Glee]. [This episode] was screenplayed by Ryan Murphy and directed by Alfonso Gomez-Rejon."
**Short Name** The short name feature sees if one mention is the short name of another mention. The implementation of this feature is as follows: given two noun phrases A and B, where B is shorter than A, B is the short name of A if every word in B is in A, and one of A or B is a proper noun. Examples of cases of short names are found in the mention of people using nicknames or last names in the article text, after the full name is mentioned at the beginning.

### 3.4 Pass 4: Proper Head Word Match

At this layer, the system looks for a specific core noun similarity for PROPN POS Tag. If given two noun phrases A and B which are identified as proper names, the system assesses the two corresponding noun phrases if A and B have core nouns with the same PROPN POS Tag and A and B have compatible attributes. The attribute used in this research is named-entity class.

*Will kemudian memberitahu tunangannya, [guru bimbingan konseling Emma Pillsbury], bahwa ia telah diterima di dewan seni pemerintah. [Emma] tidak mau meninggalkan Lima dalam waktu yang lama.*

“Will then told his fiancée, [counseling teacher Emma Pillsbury] that he had been accepted on the government arts council. [Emma] didn’t want to leave Lima for a long time.”

### 3.5 Pass 5: Relaxed Head Match

In this layer, given two noun phrases A and B, Relaxed Head Match compares whether each word in the head noun A is in the noun phrase B. The head noun A may consist of several words.

*Peternakan Nenek Bebek menjadi [pusat pertemuan keluarga], di mana [pertemuan tersebut] diatur oleh Nenek Bebek.*

“Grandma Duck’s ranch became [the center of the family gathering], where [the meeting] was arranged by Grandma Bebek.”

### 3.6 Pass 6: Pronouns Sieve

The Pronoun layer works anaphorically. If the mention is in the form of pronouns, both words and clitics, the candidate antecedents may only be the noun phrases previously mentioned. In this study, a candidate pronoun will be paired with the closest noun phrase that does not violate the following rules:

- Noun phrases identified as location are eliminated because the pronouns identified by the system are only personal pronouns.
- Noun phrases come before pronouns.
- Especially for pronouns in the form of clitic, the noun phrase attached by the clitic is not considered as a candidate.

“[Princess Stephanie] is the youngest child of Grace Kelly and Rainier III from Monaco. Sometimes [she] becomes a singer, swimsuit designer, model, and circus player.”

### 4 Data Annotation

Since there is no publicly available data of coreference resolution for Indonesian, we construct new data set in this research. We collect the data from Wikipedia in Indonesian language. We filter the Wikipedia pages that fulfill three criteria

1. The pages contain many noun phrases. We hypothesizes they are the Wikipedia pages discussing one of following topics. (i) fictional plots, e.g., subtitles for films, TV show episodes, and novel stories; (ii) biographies (incl. fictional characters); and (iii) historical events or important events.

2. The pages contain significant variation of pronoun and named-entity. We count the number of first, second, third person pronouns, and clitic pronouns in the document by applying string matching. We examine the number of named-entity using the Stanford CoreNLP NER Tagger (Manning et al., 2014) with a model trained from the Indonesian corpus taken from Alfina et al. (2016).

3. The Wikipedia texts have length of 500 to 2000 words.
BCUBED Evaluation Metrics  The BCUBED is a mention-based metric (Bagga and Baldwin, 1998). BCUBED evaluation is done by calculating precision and recall for each mention \( M \), then calculating the final result by weighted-sum of each precision and recall.

\[
\begin{align*}
\text{Precision}_M &= \frac{|M_{\text{result}} \cap M_{\text{gold}}|}{|M_{\text{result}}|} \\
\text{Recall}_M &= \frac{|M_{\text{result}} \cap M_{\text{gold}}|}{|M_{\text{gold}}|} \\
\text{FinalPrecision} &= \sum_{i=1}^{N} w_i \times \text{Precision}_i \\
\text{FinalRecall} &= \sum_{i=1}^{N} w_i \times \text{Recall}_i \\
F1 &= \frac{2 \times \text{FinalPrecision} \times \text{FinalRecall}}{\text{FinalPrecision} + \text{FinalRecall}}
\end{align*}
\]

Weight is generally defined as \( 1/N \), where \( N \) is the number of noun phrases in the document. The F1-score calculation for the BCUBED metric uses a formula that is fundamentally the same as the calculation for the MUC metric as follows:

Table 2 shows that, in general, there is an increasing trend of F1-score on the MUC metric along with the number of passes used. This is due to an increase in recall when one sieve is added one by one. However, when the system gets the best MUC F-measure value of 72.74% if all passes are implemented, the best BCUBED F-measure value is 52.18% when only the first three passes are implemented.

Based on Table 2, coreference resolution has the best precision in the implementation of Pass 1 and 2. This is different from the evaluation results of the Multi-Pass Sieve model in English and the Multi-Pass Sieve concept which depicts that the highest precision is at the top layer. This is due to cases in article text where nominal phrases with the same string refer to different entities. A common case of this allegation is generally the use of the last name to refer to a person, where people with the same surname will be considered the same entity.

Viewed from the group of features per sieve, string similarity feature is a feature that contributes the highest with a recall increase of 21.72% for MUC and 30.03% for BCUBED. The pronoun resolution is also a major contributing layer with recall increases of 33.08% for MUC and 21.99% for BCUBED, despite the decrease in precision and F1 in the BCUBED metric.

The difference in the F-measure trend of the MUC and BCUBED metrics is caused by the diff-
ference in the way the two metrics evaluate two clusters that are merged into one (over-merging). The BCUBED metric evaluates based on mentions, thus penalizing the cases of the merged cluster. The MUC metric evaluates based on mention-links, so that the number of partitions penalized for the two merged clusters is only one link, causing a fairly small penalty.

The decrease in precision in the BCUBED metric is due to the system’s inability to fully detect the antecedents of plural pronouns. Increased precision can be done by increasing the compatibility of attributes between mentions, such as the number and gender attributes which are quite difficult to identify in Indonesian. On the other hand, the head match variation feature, namely proper head match and relaxed head match, does not have much effect on system performance, because the core noun attributes are similar to the previous sieve (strict head match) but cannot take advantage of additional rules such as attribute agreement.

6 Conclusion

We conclude that the Multi-Pass Sieve approach provides a strong baseline performance for coreference resolution task in Indonesian language. The Multi-Pass Sieve approach achieves MUC F-measure up to 72.74% and BCUBED F-measure up to 52.18%. The use of the exact string match feature provides high precision for the Multi-Pass Sieve model, while the increase in recall is also influenced by the Pronoun Sieve. The highest F-measure results for the MUC metric were obtained by Multi-Pass Sieve for the combined implementation of Pass 1-6 and Pass 1-3 models for the BCUBED metric. On the other hand, the proper head match and relaxed head match features do not appear to have a major impact on system performance, contributing to a performance increase of around 1%.

There is still a lot of room to improve the coreference resolution system for Indonesian. In the future, we plan to implement an end-to-end model coreference resolution system, in which the resolved phrases or words can be detected automatically using a more perfect chunking and named-entity recognition system.

Abstract

We address the compositionality challenge presented by the SCAN benchmark. Using data augmentation and a modification of the standard seq2seq architecture with attention, we achieve SOTA results on all the relevant tasks from the benchmark, showing the models can generalize to words used in unseen contexts. We propose an extension of the benchmark by a harder task, which cannot be solved by the proposed method.

1 Introduction

Compositionality describes the property of language that the syntactic and semantic aspects of complex language units are composed of the syntactic and semantic aspects of primitive units (Fodor and Lepore, 2002). The SCAN benchmark (Lake and Baroni, 2018) has been designed to assess the ability of current neural networks to utilize compositionality of language to deal with systematic difference between the training and test data distributions (see Table 1 for examples).

We use a novel combination of existing ideas (data augmentation, adding noise and predicting outputs based only on the weighted average of input embeddings) to achieve high accuracy in all the relevant tasks of the SCAN benchmark. An approach working well for all the tasks has not been reported yet.\footnote{The model by Lake (2019) achieves very good results, but it relies on seeing test input sequences (though with modified output) during training.} Seeing the good results, we analyze some underlying assumptions of the tasks and propose a new split of the SCAN data (i.e. a new task) that proves to be more difficult for our approach.

In Section 2, we describe the SCAN benchmark for testing the systematic use of compositionality in detail. Then we present some approaches tested on the benchmark so far (Section 3), introduce our own method of solving the tasks (Section 4) and its results and analysis of some of the decisions (Section 5). In Section 6, we discuss the existing tasks and propose a new one. We conclude the paper in Section 7.

2 The tasks (SCAN dataset)

Lake et al. (2017) discussed the differences between human and machine learning and stressed systematic compositionality as an important ingredient. It makes human learning fast and data efficient, compared to slow and data-hungry training of current deep learning models. Neural networks struggle when provided with familiar concepts in new combinations, while people can use known concepts productively.

The SCAN dataset (Lake and Baroni, 2018) was designed to test this specific aspect of learning. It represents the problem of sequence transduction (sequence to sequence transformation). An agent in a grid world environment is supposed to perform a sequence of primitive actions (output) based on a sequence of commands (input). However, neither the agent nor the environment play any role in the generation of the next examples (there is no ‘state’ as known from reinforcement learning tasks) or in the interpretation of the commands. SCAN is designed to test traditional supervised learning models, namely those that translate from the “command language” into the “action language”.

Some examples taken from the dataset are given in Table 1. There are 13 input tokens (jump, look, run, walk, turn, left, right, and, after, opposite, around, twice, thrice). These are governed by an underlying non-recursive phrase-structure grammar that produces 20,910 possible input sequences in total. Each command sequence is translated into an output action sequence. The output vocabulary contains 6 tokens: (JUMP, LOOK, RUN, WALK,
As far as the training and test data are produced randomly, standard seq2seq models achieve high accuracy of 99.8% (Lake and Baroni, 2018). (The accuracy is computed over whole sequences, i.e. the models make errors in about 0.2% of the testing sequences). Once the training and test data reflect a systematic distribution change, the models struggle. In this work, we address two main sets of tasks presented by SCAN: generalization to a new primitive (JUMP) and generalization to a new combination of learned concepts (AROUND RIGHT).

We discuss them in the following subsections.

### 2.1 Generalization to a new primitive

In this scenario, a primitive command (jump) and its corresponding action are excluded from the training data except for the simplest case where the command and action stand in isolation (jump \(\rightarrow\) JUMP). The test data consist of examples with the primitive in all possible contexts (e.g. jump twice; walk opposite twice after jump around thrice). The models need to learn to generalize the information about the contextualized behavior of other primitives (run twice, walk right) and apply this information to a new primitive (jump twice, jump right).

A simplified version of the task above arises when turn left is held out from the training data instead of jump. The difference is that the corresponding output action (LEFT) still remains in the training data in different contexts: e.g. (jump left \(\rightarrow\) LEFT JUMP)

### 2.2 Generalization to a new combination of learned concepts

Loula et al. (2018) pointed out that while the tasks above are aimed at testing compositionality, there is not much information about the newly added primitives that the models are asked to utilize. We return to this argument later in Section 6. For this reason, a new set of tasks has been added to the benchmark. In these, it is a single combination of well established words that is unique to the test set. There are four such tasks, given here in increasing complexity:

- **jump around right** – unlike the jump task in Section 2.1, here jump appears during training in different contexts (e.g. jump around left; jump right; \(\ldots\)), the only instances left out from the training contain the jump around right sequence
- **Primitive right** – during training, right can only follow the two manner adverbs (around, opposite) but it never follows a verb (jump, look, run, walk, turn) directly
- **Primitive opposite right** – the models are asked to infer the meaning of this sequence (i.e. RIGHT RIGHT ACTION) from seeing examples such as (jump opposite left; look around right, walk right)
- **Primitive around right** – is analogous to the previous task, the only difference being the complexity (length) of the targeted output sequences (jump around right \(\rightarrow\) RIGHT JUMP RIGHT JUMP RIGHT JUMP RIGHT JUMP)

Table 1: Examples from the SCAN dataset (brackets are added for clarity). Each example consists of a command sequence (input) and a corresponding action sequence (output). Two horizontal lines separate the training (top) from the test (bottom) data. This particular split illustrates the jump task, where jump appears in the training data in isolation only.
3 Existing methods

We describe notable approaches to the SCAN benchmark, selected because of their good performance and/or relevance to our proposed method:

**Seq2seq** model with the LSTM encoder and decoder and the attention (Bahdanau et al., 2015) mechanism is the baseline method evaluated by Lake and Baroni (2018).

Dessi and Baroni (2019) employ convolutional neural networks (CNN) and observe substantial increase in accuracy in the SCAN tasks. This seems to support the conclusion of Bastings et al. (2018), who argue that SCAN tasks inherently prefer simpler models (mainly because of very limited temporal dependencies within the output sequences).

Andreas (2020) employs the baseline recurrent models (Lake and Baroni, 2018) together with a general data augmentation technique (GECA) to expand the training data. After the augmentation, the training set contains 5% (JUMP) and 1% (AROUND RIGHT) of the test data, which leads to an increase in performance.

Russin et al. (2020) modify the baseline model by using different attention values: in each decoding step, they keep the computation of the attention weights over the input sequence, but for attention values, the encoder hidden states are replaced with a second set of input word embeddings. These word embeddings are different from the embeddings used as the encoder input. It is an attempt to separate syntactic (computation of attention weights) and semantic (attention values) information (SyntAttn).

Li et al. (2019), in the same vein, separate the flow of information into two streams, which they call primitive (i.e. semantic) and functional (i.e. syntactic). Again, syntactic embeddings are used to determine the attention weights over the input sequence and semantic embeddings are used as the actual values the attention mechanism produces. Moreover, the approach uses regularization (adding noise to the embeddings, $L_2$ norm) leading to more stable training (and better results) compared to the previous method (Li19).

Finally, Lake (2019) uses a seq2seq model with the combination of external memory, data augmentation and meta-learning and achieves good performance on multiple SCAN tasks (MetaSeq2seq).

4 Model

Our architecture is a straightforward extension of the baseline LSTM seq2seq model with attention (Lake and Baroni, 2018). We modify the attention mechanism by using input word embeddings as the attention values (as opposed to using contextualized representations produced by the encoder). This can also be seen as a simplified version of the architectures introduced by Li et al. (2019); Russin et al. (2020). Unlike them, we train only one set of embeddings that are used both as the encoder input and as attention values. Also, we use the traditional autoregressive decoder (the previous predicted output serves as the input for the decoder at each step), which is not the case in the two cited approaches.

We added standard Gaussian noise to the input embeddings during training, as suggested by Li et al. (2019), but did not use the $L_2$ regularization.

We also experimented with weight tying, known for example, from some language modelling literature (Inan et al., 2017). We tried to avoid using a separate output layer and instead, we computed similarity (dot product) of the attention output with the output token embeddings (the embeddings used by the decoder) and used these vectors as logits.

Similarly to Lake (2019), we experiment with adding artificial primitives to the training data. We hope this would make the encoder more robust as it should recognize the syntactic patterns (X opposite right) rather than memorize each instance (walk opposite right) using the available embedding (walk).

For the jump task, we introduce artificial action commands action1, action2, action3, . . . with the corresponding actions ACTION1, ACTION2, ACTION3, . . . For all the other tasks (turn, jump around right, Primitive right, Primitive opposite right, Primitive around right), we introduce artificial directions: dir1 → DIR1, dir2 → DIR2, dir3 → DIR3 . . . Unlike Lake (2019), we are not permuting the command – action assignment during training and we do not introduce the held-out phrases to either the input or the output of the training examples.

4.1 Training details

We trained all the models using the Adam optimizer with the learning rate 0.001 exponentially decaying to 0.0001 over 60 epochs (regardless of the task). The batch size was set to 32. We experimented with different sizes of the input and output embeddings and LSTM dimensions (64, 128, 256, 512), and the

Table 2: Test accuracy (mean ± std %) on the two most challenging SCAN tasks. Results are given as reported by their authors. Seq2seq is from Lake and Baroni (2018) for the jump and Loula et al. (2018) for the around right task, CNN from Dessi and Baroni (2019), GECA from Andreas (2020), SyntAttn from Russin et al. (2020), Li19 from Li et al. (2019) and MetaSeq2seq from Lake (2019). Results are reported over 5 random seeds with the exception of GECA (10 seeds), SyntAttn (median value, 25 seeds) and ours (25 seeds).

encoder layers (1, 2). The decoder was initialized by the final hidden state of the encoder. We did not employ dropout and we clipped gradients whose norm was larger than 1. Teacher forcing was used during training. In preliminary experiments, we settled on the model with one layer bidirectional LSTM encoder, embedding size of 256 and LSTM dimension of 256. We experimented with adding 10, 50, 75 and 100 artificial command – action pairs.

5 Results and analysis

We provide the test accuracy of our model on the two most widely discussed SCAN tasks (jump and around right) in Table 2. For completeness, the results for the remaining tasks are given in Table 3. The reported model was trained using data augmentation with 75 additional command – action pairs, Gaussian noise added to the input embeddings during training and no parameter tying. Below, we investigate the effect of these choices. If not stated otherwise, we always report a mean and standard deviation computed over 25 runs with different random seeds.

5.1 Data augmentation

Arguably, the biggest benefit comes from the data augmentation. We illustrate this in Table 4, where we compare the baseline model trained with and without data augmentation on all the discussed SCAN tasks. With the exception of the jump and around right tasks, data augmentation seems to be enough to achieve good results.

5.2 Parameter tying

The effect of replacing a separate output layer with a dot product with decoder embeddings was most prominent with less intensive data augmentation. When adding only 10 additional command – action pairs to the training data of the around right task, our top model achieved the mean accuracy of 59.47% (±18.27%) with the output layer and 90.4% (±7.5%) without it. The effect disappeared with heavier data augmentation and/or with other tasks. Therefore, parameter tying was not included in the overall results.

5.3 Input embeddings as attention values

In contrast, the other architectural change with respect to the seq2seq baseline, i.e. using the input embeddings as attention values, had an effect even with stronger data augmentation. Models with modified attention trained with 100 additional command – action pairs achieved the mean accuracy of 99.44% (±0.61%) on the jump task, compared to 68.51% (±10.67%) achieved by corresponding models, where the attention values were formed by the encoder output.

5.4 Embedding noise

Adding standard Gaussian noise to the input embeddings plays also an important role by making the training more stable. Our overall best model without the noise added in training achieves only 89.12% (±12.91%) accuracy on the jump task (compared to 98.9% (±1.4%) by the same model with the noise).

5.5 Single jump proportion

During training on the jump task, the models were sensitive to the proportion of isolated jump examples in the training data. In the original dataset, such examples are upsampled so that they form about 10% of the training data (without this, models would encounter jump only once each episode). We found the best results, when these examples were treated as all the other ones, i.e. they were also eligible for command replacement with uniform probability.

6 Discussion

We show that task-specific data augmentation with simple architecture modification leads to good re-
Method | turn left | jump ar. right | right | opposite right
--- | --- | --- | --- | ---
seq2seq | 90.3 | 98.43 ± 0.54 | 23.49 ± 8.09 | 47.62 ± 17.72
SyntAttn (Russin et al., 2020) | 99.9 ± 0.16 | 98.9 ± 2.3 | 99.1 ± 1.8 | 10.5 ± 8.8

Table 4: The effect of data augmentation: the same baseline seq2seq model trained on the original data (extra0) and with 100 additional command–action pairs (extra100). Test accuracy (mean ± std %, 25 seeds)

We hypothesize that current methods (including ours) manage to solve this compositionality challenge without using much compositionality. Specifically, what is enough for all the tasks as they have been defined is to learn to attend to correct positions and then use a one to one mapping from the input to the output space. This “align and translate” approach (Bahdanau et al., 2015) approach exhibits some degree of compositionality. However, having learned somewhat complex information (say in the case of grammatical words such as around or opposite), this needs to be combined with just the identity of another word. This was actually the motivation of Loula et al. (2018) to introduce new tasks into the benchmark (e.g. around right, see Section 2.2). We believe that in this respect, the new tasks suffer from the same weaknesses as the old ones (as evidenced by the possibility of easily using data augmentation).

### 6.1 Proposed task

Based on the presented results and the discussion above, we propose another task for the SCAN benchmark: around Direction twice. ²

Here, we form the test set by selecting all the SCAN examples where the input string contains the sequence around right/left twice. Ideally, a model should be able to combine the information about doing something while turning around and doing something twice based on such examples as jump around left, jump around right thrice, jump twice, jump opposite right twice.

At face value, this task is almost identical to the tasks discussed in Section 2.2 (e.g. around right): we held out a certain combination of well established words from the training and tested on them. What we believe is the substantial difference is the fact that neither around nor twice have a direct ‘translation’ counterpart in the output ‘language’. This makes the proposed task less suitable for the above-mentioned “align and translate” approach.

Another practical effect of this is that it is not very obvious how data augmentation could be used. We would need to generate alternatives to either twice, which would quickly lead to uncomfortably long output sequences (e.g. run around right thirty-
seven times) and/or around, which seems even more obscure.

We trained 3 types of models for the new task: the baseline seq2seq architecture without modifications; our seq2seq model with added noise and modified attention values; the same model with 100 additional augmented directions (e.g. run around dir3 thrice). All the models failed with results: 10.05%(±2.30%), 8.78%(±2.48%) and 5.53%(±2.12%) respectively (each model was trained with 5 different random seeds).

7 Conclusion

The SCAN benchmark is a very accessible dataset used for investigating compositionality. Cherry-picking from previous research, we introduced the first approach that is successful in all the relevant tasks from the benchmark. Analyzing the important features defining our approach, we introduced a new task, where this approach fails. We hypothesize the new task is more challenging than the existing ones since it tests for deeper aspects of compositionality.

PyEuroVoc: A Tool for Multilingual Legal Document Classification with EuroVoc Descriptors

Andrei-Marius Avram, Vasile Păis, Dan Tufis
Research Institute for Artificial Intelligence, Romanian Academy
Bucharest, Romania
{andrei.avram,vasile,tufis}@racai.ro

Abstract

EuroVoc is a multilingual thesaurus that was built for organizing the legislative documentary of the European Union institutions. It contains thousands of categories at different levels of specificity and its descriptors are targeted by legal texts in almost thirty languages. In this work we propose a unified framework for EuroVoc classification on 22 languages by fine-tuning modern Transformer-based pretrained language models. We study extensively the performance of our trained models and show that they significantly improve the results obtained by a similar tool - JEX - on the same dataset. The code and the fine-tuned models were open sourced, together with a programmatic interface that eases the process of loading the weights of a trained model and of classifying a new document.

1 Introduction

EuroVoc\textsuperscript{1} is a multilingual thesaurus which was originally built up specifically for processing the documentary information of the EU institutions. The covered fields are encompassing both European Union and national points of view, with a certain emphasis on parliamentary activities. The current release 4.4 of EuroVoc was published in December 2012 and includes 6,883 IDs for thesaurus concepts (corresponding to the preferred terms), classified into 21 domains (top-level domains), further refined into 127 subdomains. Additional forms of the preferred terms are also available and are assigned the same ID, subdomains and top-level domains.

Multilingual EuroVoc thesaurus descriptors are used by a large number of European Parliaments and Documentation Centres to index their large document collections. The assigned descriptors are then used to search and retrieve documents in the collection and to summarise the document contents for the users. As EuroVoc descriptors exist in one-to-one translations in almost thirty languages, they can be displayed in a language other than the text language and give users cross-lingual access to the information contained in each document.

One of the most successful recent approaches in document and text classification involves fine-tuning large pretrained language models on a specific task (Adhikari et al., 2019a; Nikolov and Radevchev, 2019). Thus, in this work we propose a tool for classifying legal documents with EuroVoc descriptors that uses various flavours of Bidirectional Encoder from Transformers (BERT) (Devlin et al., 2019), specific to each language. We evaluated the performance of our models for each individual language and show that our models obtain a significant improvement over a similar tool - JEX (Steinberger et al., 2012). The The models were further integrated into the RELATE platform (Păis et al., 2020) and an API was provided through the PythonPackage Index (PyPi) interface\textsuperscript{2} that facilitates the classification of new documents. The code used to train and evaluate the models was also open-sourced\textsuperscript{3}.

The rest of the paper is structured as follows. Section 2 presents other works in the direction of EuroVoc classification. Section 3 provides several statistics with regard to the corpus used to train and test the models in the tool. Section 4 presents the approach used in fine-tuning the pretrained language models and the exact BERT variants used for each language, together with a vocabulary statistics of the model’s tokenizer on the legal dataset. Section 5 outlines our evaluation setup and the results of our experiments, while Section 6 presents

\textsuperscript{1}https://data.europa.eu/data/datasets/eurovoc
\textsuperscript{2}https://pypi.org/project/pyeurovoc/
\textsuperscript{3}https://github.com/racai-ai/pyeurovoc
the programmatic interface. Finally, the paper is concluded in Section 7.

2 Related Work

JEX (Steinberger et al., 2012) is a multi-label classification software developed by Joint Research Centre (JRC), that was trained to assign EuroVoc descriptors to documents that cover the activities of the EU. It was written entirely in Java and it comes with 4 scripts (both batch and bash) that allows a user to pre-process a set of documents, train a model, postprocess the results and evaluate a model. Each script is easily configurable from a properties file that contains most of the necessary parameters. The toolkit also comes with a graphical interface that allows a user to easily label a set of new documents (in plain text, XML or HTML) or to train a classifier on their own document collections.

The algorithm used for classification was described in (Pouliquen et al., 2006) and it consists in producing a list of lemma frequencies from normalized text, and their weights, that are statistically related to each descriptor, entitled in the paper as associates or as topic signatures. Then, to classify a new document, the algorithm picks the descriptors of the associates that are the most similar to the list of lemma frequencies of the new document. The initial release consisted of 22 pretrained classifiers, each corresponding to an official EU language.

Boella et al. (Boella et al., 2012), while focusing on the Italian JRC-Acquis-IT corpus, presents a technique for transforming multi-label data into mono-label that is able to maintain all the information as in (Tsoumakas and Katakis, 2007), allowing the use of approaches like Support Vector Machines (SVM) (Joachims, 1998) for classification. Their proposed method allows an F1 score of 58.32 (an increase of almost 8% compared to the JEX score of 50.61 for the Italian language).

Šarić et al. (Šarić et al., 2014) further explores SVM approaches for classification of Croatian legal documents and report an F1 score of 68.6. Unfortunately, this is not directly comparable with the JEX reported results since the training corpus is a different collection called NN13205. Furthermore, the categories being used for the gold annotation represent an extended version of EuroVoc for Croatian, called CroVoc.

Studies, such as in (Collobert et al., 2011), have shown that neural word embeddings can store abundant semantic meanings and capture multi-aspect relations into a real-valued matrix, when trained on large unlabeled corpora using neural networks. Considering a vocabulary $V$, an embeddings representation can be learned by means of a neural network resulting into an association of a real-valued vector $W_n$ of size $n$ to each word. Two neural network methods for automatically learning distributed representation of words from a large text corpus can be considered: Skip-gram and continuous bag of words (CBOW) (Mikolov et al., 2013). In the case of CBOW, a neural network is trained to predict the middle word given a context, while Skip-gram uses a single word as input and tries to predict past and future words. Bojanowski et al. (Bojanowski et al., 2017) introduced a method for runtime representation for unknown words by means of averaging pre-trained character n-grams, also known as subword information.

BERT has also been used to classify legal documents with EuroVoc labels, with most of the work focusing on the English language. In (Chalkidis et al., 2019), the authors studied the problem of Large-Scale Multi-Label Text Classification (LMTC) for few- and zero-shot learning and released a new dataset composed of 57k samples from EUROLEX on which several models were tested. The results showed that BERT obtained superior performance in all but zero-shot classification.

3 Dataset Statistics

The training of BERT models for the 22 languages was done using the same dataset that was used for training the JEX models. The dataset is composed of two parallel corpora from the legal domain, JRC-Acquis (Steinberger et al., 2006) and the Publications Office of the European Union (OPOCE), that were manually labeled with over 6,700 EuroVoc descriptors identifiers (ID). The EuroVoc descriptors are hierarchically organised and can be converted into higher level Microthesaurus labels (MT) and further into top-level domains (DO).

The number of documents in the dataset range from 17,858 documents in Maltese to 41,989 documents in French. Each document is labeled with multiple ID descriptors, having an average of 6 ID descriptors which can be equivalently converted to 5 MT descriptors or 4 DO descriptors. In Figure 1 we depict the distribution of the average number of ID, MT and DO descriptors per document, together with the difference between the minimum and the
maximum number of documents per descriptor.

The ID, MT and DO descriptors distributions are also highly unbalanced. Figure 2 depicts the number of documents of the most frequent ID, MT and DO descriptors, organised in groups of 50, 5 and 1, respectively. Each group contains the sum of the number of documents that are labeled with each descriptor in the respective group. As it can be observed, in each subplot, the number of documents that contain the descriptors from the first few groups is higher than the number of document that contain all the other descriptors.

4 Methodology

The proposed approach for classifying the legal documents found in the two corpora is to fine-tune a pre-trained BERT on each of the 22 languages. We follow the method introduced in (Devlin et al., 2019) where a simple feed-forward network with the weights $W \in \mathbb{R}^{E \times M}$, $E$ is embedding size of BERT and $M$ is the number of classes, and bias $b \in \mathbb{R}^M$ is put on top of the embedding of the first token $C'(\text{[CLS]})$ to create the output logits of the classification problem for the ID descriptors$^4$.

The sigmoid $\sigma$ function is then applied to produce independent probability distributions $\hat{y}$ over each class:

$$\hat{y} = P(y|x) = \sigma(C^T W + b)$$  \hspace{1cm} (1)

Additionally, a dropout of 0.1 is applied on the feed-forward layer to regularize the model.

The models are optimized by reducing the loss $\mathcal{L}$ computed as the average binary cross-entropy between the output probabilities $\hat{y}$ and the target classes $y$, over the $M$ classes (ID descriptors):.

$$\mathcal{L} = -\frac{1}{M} \sum_{i=1}^{M} y_i \log \hat{y}_i + (1 - y_i) \log(1 - \hat{y}_i)$$ \hspace{1cm} (2)

Because the flavours of BERTs vary from one language to another, the choice of the initial models for each language was made by using the following heuristic, based on the corpora used for pretraining: Legal > Monolingual (Mono) > Wikipedia (Wiki) > Multilingual (Multi). The heuristic is experimentally supported by (Chalkidis et al., 2020) that showed that language models obtain superior performance on the legal domain when they are pretrained on legal corpora and by (Pyysalo et al., 2020) that outlined the superiority of BERTs pretrained on monolingual Wikipedia over multilingual BERT (mBERT). Also, it was empirically proven that the performance of the language models improves when they are pretrained on larger

---

$^4$The MT and DO descriptors are predicted by using a direct mapping scheme
corpora (Liu et al., 2019) and for this reason we expect most of the general monolingual models to obtain better result than Wikipedia BERTs. Thus, given the existing open-sourced models for each language, we use the following taxonomy in our experiments: (Figure 3) 5:

- **Legal**: English (en) - Legal BERT (Chalkidis et al., 2020).

- **Mono**: Danish (da) - Danish BERT 6, German (de) - German BERT 7, Greek (el) - Greek BERT (Koutsikakis et al., 2020), Spanish (es) - Spanish BERT (Canete et al., 2020), Estonian (et) - EstBERT (Tanvir et al., 2020), Finnish (fi) - Finnish BERT (Virtanen et al., 2019), French (fr) - CamemBERT (Martin et al., 2020), Hungarian (hu) - huBERT (Erzsébet et al.), Italian (it) - Italian BERT 8, Dutch - BERTje (de Vries et al., 2019), Polish (pl) - PolBERT (Kleczer, 2020), Portuguese (pt) - BERTimbau (Souza et al., 2020), Romanian (ro) - Romanian BERT (Dumitrescu et al., 2020), Swedish (sv) - Swedish BERT (Malmsten et al., 2020).

- **Wiki**: Bulgarian (bg) - WikiBERT-BG, Czech (cs) - WikiBERT-CS, Lithuanian (lt) - WikiBERT-LT, Latvian (lv) - WikiBERT-LV, Slovak (sk) - WikiBERT-SK, Slovene (sl) - WikiBERT-SL.

- **Multi**: Maltese (mt) 9.

The vocabulary of BERT plays an important role in the final performance of the model. Broadly speaking, the fewer tokens each word is split into, the better the language model is expected to perform. In Table 1 we depict the average number of tokens per word and the average number of unknown (UNK) tokens per word on the legal dataset for each tokenizer of the 22 BERT models. As it can be observed, the lowest number of tokens per word is achieved by the Spanish BERT with 1.25 followed closely by the Legal BERT with 1.28. When looking at unknown tokens per word, CamemBERT tokenizer leads the leaderboard with no unknown words when tokenizing the dataset. On the other hand, the highest number of tokens and unknown tokens per word was achieved on Maltese due to use of mBERT instead of a monolingual

---

5To the best of our knowledge, not all languages have publications for their monolingual versions of BERT, so we attached a corresponding URL in these cases.

9https://huggingface.co/bert-base-multilingual-cased
model.

The legal documents in the corpus can be rather long and exceed the maximum number of tokens of 512 allowed by the BERT models. To mitigate this, we simply keep only the first 512 in the document and discard the rest. This method has been shown to lead to approximately the same performance as considering the whole document (Chalkidis et al., 2019).

5 Experiments

5.1 Evaluation Setup

Because the original splits used for training and evaluating the JEX models were not made publicly available, we united the JRC-Acquis and OPOCE datasets for each language and split it 5 times in train, validation and test sets using different seeds. Moreover, in order to preserve the class balance across the sets in one split, we employed an iterative stratification splitting approach as proposed in (Sechidis et al., 2011) and kept an approximate ratio of 80% train, 10% validation and 10% test for fine-tuning and evaluating the pre-trained language models and a ratio of 90% train and 10% test for training and evaluating the JEX models.

The pre-trained language models were fine-tuned for 30 epochs, using a batch size of 8 and the AdamW optimizer (Loshchilov and Hutter, 2018) whose learning rate was decayed by a linear scheduler peaking at 6e-5, in order to reduce the oscillations in the later stages of training due to the high values of the learning rate. We also clipped the gradients (Pascual et al., 2013) whose norm had a value over 5 and used a learning rate warm-up over the first epoch to alleviate the effects of forgetting the knowledge learned by Transformer models in the pre-training phase. The final weights of each fine-tuned language model were the ones that obtained the lowest loss on the validation set during training.

The training and evaluation of JEX models followed the approach described in (Steinberger et al., 2012). Both JEX models and the pre-trained language models were trained five times on each split with the results averaged over all test splits. We also used the validation splits for early stopping and fine-tune the hyperparameters of the BERT models.

5.2 Evaluation Metrics

Most used metrics for evaluating LMTC models are the precision ($P@K$), the recall ($R@K$) and their harmonic mean, known as F1 score ($F1@K$), over the top $K$ predicted labels. These metrics usually unfairly penalize documents that have fewer or more labels than $K$, but we still use them because they allow a direct comparison with the original results of JEX. The three metrics are defined as follows:

$$P@k = \frac{1}{k} \sum_{l \in r_k(\hat{y})} y_l$$

$$R@k = \frac{1}{n} \sum_{l \in r_k(y)} y_l$$

$$F1@k = 2 \cdot \frac{P@k \cdot R@k}{P@k + R@k}$$

where $k$ is the number of labels to be used for comparison, $n$ is the number of true labels of the respective document, $y \in \{0, 1\}^L$ is the vector of the true labels, $\hat{y} \in \mathbb{R}_L$ is the vector of predicted labels and $r_k(\hat{y})$ is a function that selects the index of the $k$th largest value in the prediction labels.

As the statistics in Section 3 have shown, the average number per document, of ID descriptors is 6, of MT descriptors is 5 and of DO descriptors is 4. Thus, we evaluate both JEX and BERT by using the F1 score for 6 labels on ID descriptors ($F1@6$), for 5 labels on MT descriptors ($F1@5$) and for 4 labels on DO descriptors ($F1@4$).

5.3 Results

The results for both JEX and the BERT models on the 22 languages by using the cross-validated dataset are outlined in Table 2. The BERT models obtained a significant improvement over JEX on each language, ranging from an enhancement of 21.54% (el), 14.85% (fr) and 9.65% (el) to an enhancement of 37.06% (sk), 25.94% (ro) and 9.65% (el) to an average number per document of 5 for ID, 63.15% for MT and 21.54% for DO descriptors, respectively. The highest F1 scores with JEX were achieved on German with 50.65% $F1@6$, 63.15% $F1@5$, 72.23% $F1@4$, and the highest F1 scores with the BERT models were achieved on Slovenian with 84.90% $F1@6$, 87.37% $F1@5$, 91.72% $F1@4$ for ID, MT and DO descriptors, respectively. On the other hand, the lowest scores were obtained on Maltese. This might be due to the low number of

documents compared to the other languages (Steinberger et al., 2012), but also because, in the case of the BERT variant, we use a multilingual model instead of a monolingual one.

Figure 4 depicts the $F1@6$-scores obtained by the BERT models on multi-label ID classification relative to the scores obtained by JEX models in the same language. One interesting aspect that can be observed in the plot is that although the mBERT used for Maltese obtained the lowest $F1$-score, its relative improvement over JEX is higher than of the other three languages that use monolingual models: Greek, Hungarian and French, mostly because the $F1@6$-score obtained by JEX on Maltese is lower when compared to the other three and thus the difference would normally be larger.

The variance of scores between languages is higher for the BERT models than for the JEX models. This happens because the BERT models were pretrained beforehand on various corpora taken from different sources and aspects like the quality of the corpus or the domain match greatly influenced the resulted fine-tuning performance. One interesting result is that WikiBERT obtained some of the highest scores and that Legal BERT also did not perform as well as expected, thus partially contradicting the heuristic introduced in the previous section. Due to time and resource constraints, we leave a detailed study of the heuristic for future work.

5.4 Comparison with State-of-the-Art

The state-of-the-art (SOTA) for EuroVoc multi-label classification was presented in (Chalkidis et al., 2019) by using the original BERT-base. The model was trained and evaluated on EUR-LEX, an English corpus introduced in the same paper. We evaluated our English model (Legal BERT), trained on JRC-Acquis and OPOCE, and report in Table 3 the R-Precision ($RP$), the normalized discounted cumulative gain (nDCG) and the F1-micro score for extracting 5 ID descriptors on the test set of EUR-LEX. Our model obtained a $RP@5$ of 81.2%,

</tbody>
</table>

Table 3: Our Legal BERT model compared with BERT-base and BIGRU-LWAN on EUR-LEX test.

Other extensive document classification experiments with BERT were conducted by (Adhikari et al., 2019a), without specific consideration to EuroVoc labels. They used a similar approach to ours by introducing a fully-connected layer over the embedding of the first token \([CLS]\). Furthermore, the paper also presents the results for a knowledge distillation process (Hinton et al., 2015) from the fine-tuned BERT-large into the previous SOTA (Adhikari et al., 2019b), a much smaller network, obtaining better results than BERT-base on the evaluated datasets, but still behind BERT-large.

5.5 Response Time

The response time of the API was tested on a CPU - Intel Xeon Silver 4210 - and on a GPU - Nvidia Quadro RTX 5000. Because the pretrained language models have mostly the same dimension, we made an inference time analysis only for the English language on CPU and GPU.

6 Programmatic Interface

To ease the loading of models and the classification of documents, we created a programmatic interface in Python that can be installed using PyPi with the command `pip install pyeurovoc`. Once the library is installed, a BERT model is simply created by instantiating the class `EuroVocBERT` with one of the 22 languages. The class will either
download the fine-tuned model from the repository or will use a local cached version of it. Finally, the classification of a document is made by calling the instantiated model with the document text.

More detailed information about the API and how custom pre-trained BERT models can be fine-tuned on the dataset can be found at the source repository. An example of API usage is presented in Appendix A.

7 Conclusion and Future Work

Document classification remains a relevant problem in nowadays society, aiding companies and government institutions to index their large textual database. This paper presented a tool for classifying legal documents with EuroVoc descriptors that use various Transformer-based language models, fine-tuned on the 22 languages that are found in JRC-Acquis and OPOCE. We thoroughly evaluated the models on multiple splits of the data and the results showed that they significantly improve the performance obtained by another similar tool - JEX. The pretrained models were made publicly available and they can be easily used to classify new documents using our API.

One direction for possible future work is to improve the inference speed of the models by either distilling their knowledge in a smaller network (Hinton et al., 2015) or quantizing their weights (Yang et al., 2019). Furthermore, we intend to include our results for legal document classification in language specific NLP benchmarks such as KLEJ for Polish (Rybak et al., 2020), LiRo for Romanian (Dumitrescu et al., 2021) or EVALITA4ELG for Italian (Patti et al., 2020).

Abstract
Sentiment analysis aims to detect the overall sentiment, i.e., the polarity of a sentence, paragraph, or text span, without considering the entities mentioned and their aspects. Aspect-based sentiment analysis aims to extract the aspects of the given target entities and their respective sentiments. Prior works formulate this as a sequence tagging problem or solve this task using a span-based extract-then-classify framework where first all the opinion targets are extracted from the sentence, and then with the help of span representations, the targets are classified as positive, negative, or neutral. The sequence tagging problem suffers from issues like sentiment inconsistency and colossal search space. Whereas, Span-based extract-then-classify framework suffers from issues such as half-word coverage and overlapping spans. To overcome this, we propose a similar span-based extract-then-classify framework with a novel and improved heuristic. Experiments on the three benchmark datasets (Restaurant14, Laptop14, Restaurant15) show our model consistently outperforms the current state-of-the-art. Moreover, we also present a novel supervised movie reviews dataset (Movie20) and a pseudo-labeled movie reviews dataset (moviesLarge) made explicitly for this task in English language and report the results on the novel Movie20 dataset as well.

1 Introduction
Online reviews and tweets play an essential role in consumer decision making. Hence, it becomes crucial to efficiently and effectively extract user opinions from an unstructured text (user review, tweet). Aspect-Based Sentiment Analysis is a fundamental task in mining opinions and sentiment analysis (Pang and Lee, 2008; Liu, 2012). This task requires detecting the aspects of the target entities mentioned (Aspect Extraction) and detecting the sentiment attached, i.e., the polarity of the target entity (Sentiment Classification). Hence, it is more challenging than the traditional sentence-level sentiment analysis (Lin and He, 2009; Kim, 2014), where we predict the text’s polarity as a whole. As shown in Table 1, given a sentence, the task is to extract the aspects “acting” and “editing” and predict the corresponding polarity, which is positive, negative, respectively.

Table 1: Example Sentence

Most of the previous works treat this Aspect-Based Sentiment Analysis (ABSA) task as a combination of two different subtasks, namely, Aspect Extraction (AE) and Sentiment Classification (SC). Researchers often treat these two subtasks as independent and work on both of them individually, or some even tried to combine the two and propose a joint model that can extract the targets and predict the polarity. Much work has been done in the field of AE. Jakob and Gurevych (2010); Liu et al. (2015); Wang et al. (2016a); Poria et al. (2016); Shu et al. (2017); He et al. (2017); Xue and Li (2018); Fan et al., (2018) formulate AE as a sequence tagging problem. In sequence tagging, the task is to mark each word with a set of tags (e.g. B, I, O). The second subtask, SC, i.e., marking each extracted target term as Positive, Negative, or Neutral, has also been widely studied (Tang et al., 2016; Wang et al., 2016b; Chen et al., 2017; Xue and Li, 2018; Fan et al., 2018). The main issue with most of these sentiment classifiers is that, they assume the target is already given.

Zhang et al. (2015) and Li et al. (2019) tried to combine the two subtasks and solve the task in a more integrated way by jointly extracting targets and predicting their sentiments. The main idea
here is either jointly marking the words with a set of tags for the task of AE (e.g., B, I, O) and also marking them as Positive, Negative, Neutral for SC or use a more collapsed version of marking (e.g., B-Sentiment, I-Sentiment, O).

There are many disadvantages to the above BIO annotation scheme. As shown by Lee et al. (2016), using BIO tags for extractive question answering (in our case extracting opinion terms) have issues like colossal search space since the model must consider the power set of all words in a sentence. This results in it being less effective, and in the case of polarity classification, sequence tagging is not optimal because tagging the polarity over each word fails to capture the semantics of the entire opinion-target. Moreover, there could be sentiment inconsistencies in a multi-word target-term as predicted polarities over different words in a target could be different.

In this paper, we make the following contributions:

1. We propose TEASER, a span-based labeling scheme methodology exploiting the extract-then-classify framework for aspect-based sentiment analysis that reduces the search space while dealing with half-word coverage issues and overlapping spans.

2. We conduct extensive experiments that demonstrate our model to consistently outperform the current state-of-the-art in Aspect Extraction and overall ABSA task on the three benchmark datasets (Restaurant14, Restaurant15, Laptop14).

3. We also present two novel datasets\(^{1}\) in the domain of movie-reviews. The Movie20 dataset is a Supervised dataset of 1162 sentences made explicitly for this task, and movies-Large is a Pseudo-labeled dataset of 14373 sentences.

2 Related Work

Hu and Liu (2004) proposed Aspect-based Sentiment Analysis for the first time. Since then, it has been widely studied, especially in recent years (Zhang et al., 2018).

Most existing works treat this as a combination of Aspect Extraction and Sentiment Classification.

A joint modeling approach for AE and SC was proposed by Goldie et al. (2019). They used a BiLSTM with attention mechanism to capture the relationship between the two tasks.

For AE, there are various methods tried and tested for this task. Jakob and Gurevych (2010); Wang et al. (2016a); Shu et al. (2017) made use of Conditional Random Fields (CRFs) for prediction. Poria et al. (2016) tried a deep learning approach for this task of AE for the first time. They proposed a CNN based model to tag words in sentences as an aspect or non-aspect. Xu et al. (2018) Used a double embedding Mechanism with Convolutional Neural Networks (CNNs) to solve this task. Liu et al. (2015) tried to tackle this with Recurrent Neural Networks (RNNs). Similar to AE, the subtask of SC has been widely studied (Jiang et al., 2011; Vo and Zhang, 2015; Wang et al., 2018; Zhu and Qian, 2018; Chen and Qian, 2019; Zhu et al., 2019). Dong et al. (2014) proposed an RNN based approach, Chen and Qian (2019) attempted to solve this using Transfer Capsule Network, and Li and Lam (2017) used Memory networks.

Few works tried to propose a joint (unified) model for both the tasks of AE and SC. There are mainly two ways: Joint training and Collapsed tagging. In the former, a multi-task learning framework is built where both the subtasks, AE and SC have individual tags and are trained independently, and they may have some shared features. Then the two models are combined during inference. Meanwhile, in the latter, a collapsed set of tags e.g. B-Sentiment, I-Sentiment, O are used, and then a single model is trained combinedly for both the tasks.

Mitchell et al. (2013) formulated this task as a sequence tagging model and proposed a model using CRFs for the same. Li et al. (2019) made use of the collapsed tagging scheme, involving two stacked RNNs and a gate mechanism to maintain sentiment consistency. Zhou et al. (2019) proposed a span-based joint model using BiLSTMs and an attention mechanism to compute the sentiment information towards each span. Hu et al. (2019) proposed a pipelined span-based extract-then-classify framework using BERT (Devlin et al., 2018) as a backbone network jointly trained on AE and SC. Chen and Qian (2020) tried to exploit the interactive relation between the two subtasks by constructing a multi-layer multi-task framework with a relation propagation mechanism and thereby boosting the performance of both the subtasks.

Table 3: Half Word Coverage and Overlapping spans

3 Methodology

3.1 Preliminaries

Hu et al. (2019) proposed a span-based labeling scheme, as shown in Table 2, i.e., annotating each opinion target with its span boundary followed by its sentiment polarity. While this model reduces the search space marginally, the approach has issues like overlapping spans, half-word coverage.

As shown in the example in Table 3, the sub-word [waiter] is being predicted twice; i.e., it is part of two different predicted spans ([waiter] and [waiters]). This is a case of overlapping spans as each sub-word should be a part of no more than one span, and since this output will then be sent to the sentiment classifier, there could be a problem of sentiment inconsistency for the word “waiters”. Also, half-word coverage is evident here as “waiter” should not be considered as an aspect, instead, “waiters” is more appropriate, because if “waiter” is considered as an aspect it will lead to having two different tags for the word “waiters” (one tag for “waiter” and one tag for “s”) which is incorrect. Though the work clearly states that they remove redundant spans with the word-level F1 function but since BertTokenizer tokenizes the words into sub-words (e.g. Waiters being tokenized to “waiter” and “s”) the redundancy issue persists.

3.2 Supervised Method

We formulate ABSA in a different way as compared to most of the previous works which treat ABSA as a sequence-tagging problem. As shown by (Lee et al., 2016), it is more beneficial to predict the two endpoints of a span as compared to sequence-tagging (BIO prediction). Hence, we use a similar approach of predicting the two endpoints. Similar to (Hu et al., 2019), we make use of span-based labeling scheme which is as follows: given an input sentence \( x \) of length \( n \) i.e. \( x = \{x_1, x_2, \ldots, x_n\} \), we make three different lists, \( \text{start\_positions} \), \( \text{end\_positions} \) and \( \text{polarities} \), each of length \( m \) where \( m \) is the number of targets in the sentence. \( \text{start\_positions} \) is a list containing the start position of each target in a sentence. Similarly, \( \text{end\_positions} \) is a list containing the end position of each target and \( \text{polarities} \) is the list containing the polarities (Positive, Negative, Neutral) of each target.

We build two different models for the two sub-tasks of Aspect Extraction and Sentiment Classification. These two models are separately trained and combined as a pipeline during inference. The pre-trained BERT model can be finetuned with just one additional layer to create state-of-the-art results in many tasks (Devlin et al., 2018). Therefore we use the BERT encoder as the primary network in both the subtasks. Using the pre-trained transformer blocks (Vaswani et al., 2017), the word embeddings are mapped to contextualized token representations. An Aspect extractor is used to extract the multiple possible targets from the sentence. Then, a polarity classifier (Hu et al., 2019) is used to predict the polarity of each extracted target using the summarized span representation.

3.2.1 BERT

Bidirectional Encoder Representations from Transformers (BERT) can achieve state-of-the-art results in a lot of NLP tasks (Devlin et al., 2018) and hence we use it as our main network. Given a sentence \( x \), we first tokenize the sentence using BertTokenizer(based on wordpiece) with a vocabulary of 30522 tokens. Then we put a [CLS] token at the start and [SEP] token at the end of the tokenized sentence to form a new sentence \( y \) of length \( n + 2 \)
(considering \( n \) as the length of \( y \)). For each token \( y_i \in y \), its input representation is constructed by summing the corresponding token, segment and position embeddings (Devlin et al., 2018). Now the input representation is passed to the series of \( L \) stacked transformers blocks(\( L = 12 \) for BERT-base and \( L = 24 \) for BERT-Large) to get the contextual representations. It has been used in various downstream tasks including GLUE (Devlin et al., 2018), subjective bias detection (Pant et al., 2020), and sarcasm detection (Pant and Dadu, 2020). We suggest readers go through (Devlin et al., 2018) and (Vaswani et al., 2017) to get an in-depth understanding of BERT and the transformer block architecture, respectively.

### 3.2.2 Aspect Extractor

The aim of Aspect extractor is to extract all possible opinion targets from a given sentence. Instead of tagging the sentence sequentially, we detect the target by predicting the start and end positions of the targets (Hu et al., 2019). We add another layer on top of the BERT model. Using this, we get the confidence score for the start and end position as shown in Equation 1, where \( h \) is the contextual representation of the input (Output of BERT) and \( w_s, w_e \) are trainable weight vectors.

\[
\begin{align*}
    c_s &= w_s h, \quad p_s = softmax(c_s) \\
    c_e &= w_e h, \quad p_e = softmax(c_e)
\end{align*}
\]

(1)

For training, we then generate two lists, a list of \( \text{starts} \) and a list of \( \text{ends} \), each of length \( n + 2 \). Each position in the \( \text{starts} \) signifies if any span in the training sentence starts at the given position. Similarly, the list of \( \text{ends} \) signifies if any span in the training sentence ends at the given position. And the probabilities \( p_s \) and \( p_e \) are calculated as shown in Equation 1. The training objective is the sum of the negative log probabilities of the true start and end positions on the two predicted probabilities (Hu et al., 2019). The training objective is shown in Equation 2 where \( y_s \) and \( y_e \in \mathbb{R}^{n+2} \), and each element \( y_s^i \) indicates whether the \( i \)-th token starts a target and \( y_e^i \) indicates whether the \( j \)-th token ends a target(Hu et al., 2019).

\[
L = - \sum_{i=1}^{n+2} y_s^i \log(p_s^i) - \sum_{j=1}^{n+2} y_e^j \log(p_e^j)
\]

(2)

Once we get the confidence scores \( c_s \) and \( c_e \), the objective is to choose the non-overlapping spans ensuring no half-word coverage that has maximum value of \( c_s^i + c_e^j \) such that \( i <= j \). As shown by (Hu et al., 2019), choosing the top \( k \) spans could lead to overlapping spans. Hence, we present a TEASER’s heuristic for Aspect Extraction as shown in Algorithm 1. The algorithm helps remove the overlaps as well as half-word coverage. Firstly, we choose top \( M \) indices from both the confidence scores\( (\text{starts}, \text{ends}) \). For each pair \( s_i, e_j \) such that \( s_i \in \text{starts} \) and \( e_j \in \text{ends} \), \( s_i <= e_j \) and \( s_i \) is a start of a word and \( e_j \) is an end of a word, The heuristic score is defined as \( c_s^i + c_e^j - \sqrt{\text{length of the target}} \). It is inter-

**Algorithm 1: TEASER’s Heuristic for Aspect Extraction**

**Input:** \( c_s, c_e, \alpha, K \)

\( /* c_s: \) score of start position */
\( /* c_e: \) score of end position */
\( /* \alpha: \) threshold value */
\( /* K: \) maximum proposed targets */

1. \( P, \text{Out}, H = \{\}, \{\}, \{\} \)
\( /* P: \) preliminary predictions */
\( /* \text{Out}: \) output list */
\( /* H: \) heuristic score */

2. \( \text{selected} = \{\} \)

3. \( \text{starts}, \text{ends} = \text{Top-M indices of } c_s, c_e \)

4. \( \text{for } s_i \in \text{starts} \text{ do} \)

5. \( \text{for } e_j \in \text{ends do} \)

6. \( \text{if } s_i < e_j \text{ and } c_s[i] + c_e[j] \geq \alpha \) then

7. \( \text{target} = [s_i, e_j] \)

8. \( \text{score} = c_s[i] + c_e[j] - \sqrt{\text{length of target} + 1} \)

9. \( P = P \cup \text{target} \)

10. \( H = H \cup \text{score} \)

11. \( P.\text{sort()} /* \) sort based on Heuristic score in reverse order */

12. \( \text{for } \text{pred} \in P \text{ do} \)

13. \( \text{if } \text{size}(\text{Out}) < K \text{ then} \)

14. \( s_i, e_i = \text{pred.start.position}, \text{pred.end.position} \)

15. \( \text{if } \forall i \in \{s_i, e_i\} \notin \text{selected} \) then

16. \( \text{Out} = \text{Out} \cup \text{pred} \)

17. \( \text{selected} = \text{selected} \cup [s_i, e_i] \)

18. else

19. \( \text{break} \)

20. \( \text{return Out} \)
testing to note that, the heuristic score is a function of the length of the target and this is very important for the performance of the model as the targets are usually short entities. If the heuristic score of these two indices is greater than a certain threshold (manually tuned), we add it to the list of preliminary predictions. preliminary predictions is a list of predictions which follow the heuristic condition but it also has overlapping targets. To remove the overlaps we maintain another list of selected tokens, selected, which helps in identifying if a token was a part of a better prediction.

We sort the preliminary predictions in reverse order with the most confident prediction being in the first place and so on. We then iterate through the list, let the start position and end position of the current prediction we are looking at be \( t_s, t_e \) respectively. If any token \( e \in [t_s, t_e] \) was already present in a previous prediction (which is calculated using the selected list), we discard the current prediction. If no token is present in the selected list, we add the prediction to the list of targets and mark all tokens \( e \in [t_s, t_e] \) as selected.

We repeat this until we reach the end of preliminary predictions or the maximum number of targets are extracted. The pseudocode of the algorithm is as shown in Algorithm 1.

### 3.2.3 Polarity Classifier

Instead of using sequence tagging methods, we calculate a summarized vector from the contextualized sentence vectors according to the span boundary (Hu et al., 2019). The summarized vector is calculated using attention mechanism (Bahdanau et al., 2015) and the sentiment polarity is predicted with the help of feed-forward neural networks.

We obtain the polarity score by applying a linear transformation followed by a Tanh activation and another linear transformation which is then normalized using the softmax function as shown by (Hu et al., 2019).

\[
\begin{align*}
g^p &= W_p \tanh(W_v v) \\
p^p &= \text{softmax}(g^p)
\end{align*}
\]

where \( W_v \in \mathbb{R}^{h \times h} \) and \( W_p \in \mathbb{R}^{k \times h} \) are two trainable parameter matrices.

We minimize the negative log probabilities of the true polarity on the predicted probability. We calculate the polarity probability for each candidate target span present in the set \( \mathbf{O} \) during inference and choose the sentiment class with the highest \( p^p \).

## 4 Semi-Supervised Learning

### 4.1 Dataset Creation

We scrape the 15535 sentences from 3200 movie reviews from a leading movie review website. Users rate a movie on a scale of 1 (very bad) to 10 (very good). To avoid any potential bias, we chose the most popular movies with the most reviews, and the reviews were chosen uniformly on a rating scale of 1 to 10. We then divide the dataset into two parts: 14373 sentences (moviesLarge) for training the semi-supervised model and 1162 sentences (Movie20) to validate the semi-supervised model.

Two human annotators with proficiency in English and linguistic background performed the annotation of the dataset’s validation split (Movie20). The annotation was performed according to the original guidelines as set in (Pontiki et al., 2014b) on the following aspects:

1. **Opinion Targets**: Given a sentence, identify all the aspect terms present in the sentence. e.g., “Stunning visuals, amazing storyline.” The aspect terms in the sentence are “visu- als”, “storyline”.

2. **Target Sentiment**: Assuming that we know the aspect terms beforehand, determine the sentiment attached, i.e., the polarity of each term (Positive, Negative, Neutral). e.g., visuals - Positive, storyline - Positive (Considering the example mentioned above.)

Table 4 shows a few example instances from the novel Movie20 dataset.

For validating the quality of the annotation process, we use the Inter-Annotator Agreement of both the tasks through Cohen’s Kappa Coefficient (Fleiss and Cohen, 1973). We obtain a Kappa score of 0.8326 for the annotation process. The Kappa score implies that the annotation process is of high quality, with the annotators showing a high degree of agreement.

### 4.2 Pseudo-Labeling

The moviesLarge dataset has 14373 sentences. Since human annotation to such a large dataset is very time-consuming and complex, we use the Pseudo-Labeling technique. In Pseudo-Labeling, instead of manually annotating the dataset, we approximate labels to the dataset based on available labeled data.
It has very good cinematography shots and it is very entertaining. [cinematography shots] POS

I like it but the beginning was very long and slow while the end was all over the place trying to explain everything. [beginning], [end] NEG, NEG

It is action packed, fantasy filled and thoroughly exciting. [action], [fantasy] NEU, NEU

Great Acting dreadful editing. [Acting], [editing] POS, NEG

the whole cinematic experience is not there. [cinematic experience] NEG

Table 5: The statistics of the three datasets

Figure 1 shows the Pipeline of Semi-Supervised Learning. As shown, it can be divided into two parts: Pseudo-Labeling (1a) and final Model Training (1b). In case of pseudo-labeling, we combine all the three existing datasets, Laptop14, Restaurant14, and Restaurant15 and using this as our training data, we train our model TEASER. We then make use of the trained model to predict the labels of the unlabeled moviesLarge dataset. Since these labels aren’t manually annotated, these are the approximate labels and hence the process is called pseudo-labeling.

Once we have the pseudo-labeled moviesLarge dataset, we combine moviesLarge and the labeled datasets Laptop14, Restaurant14, and Restaurant15 and train the model using this as our training data. Finally, we test this model on our novel Movie20 dataset and derive the results. The details are discussed in subsection 6.2.

5 Experiments

5.1 Datasets

For all the experiments, we use the three benchmark datasets from various domains. The datasets were taken from SemEval 2014 (Pontiki et al., 2014b) and SemEval 2015 (Pontiki et al., 2014a) tasks which include 2 datasets from restaurant domain, Restaurant14 and Restaurant15. Moreover, we use another dataset Laptop14 made by using customer reviews from the laptop domain. The statistics of the datasets are as shown in the Table 5.

5.2 Metrics

We use the F1 score as the evaluation metric for the ABSA task. To analyze our TEASER’s heuristic for Aspect Extraction’s performance, we also compare using an F1 score between various models for the subtask of Aspect Extraction.

5.3 Experimental Settings

We use the pre-trained BERT-Large model for all the experiments. It has 24 layers (transformer blocks), 16 attention heads. For more details about BERT-Large parameters, readers can refer to (Devlin et al., 2018). The batch size is 32, \( M \) (number of candidate spans) is set to 20, while \( K \), the maximum number of proposed targets is 10, and the threshold is manually tuned. We use Adam optimizer with a learning rate of 2e-5.

\( ^2 \)We do not use the erroneous rest, total dataset as prescribed by the authors of Li et al. (2019).

5.4 Baseline Methods

We compare our proposed model with the following approaches:

1. MNN (Wang et al., 2018) - This work proposed a unified (collapsed) tagging scheme for both the tasks of Aspect Extraction and Sentiment Classification.

2. SpanABSA (Hu et al., 2019) - It is a pipelined model with a multi-target extractor and a polarity classifier. It uses BERT-Large as the backbone network for both the subtasks.

3. E2E-TBSA (Li et al., 2019) - It has two stacked RNNs(Recurrent Neural Networks) with multi-task learning over a collapsed tagging scheme.

4. DE-CNN (Xu et al., 2018) - It is a model exclusively for Aspect Extraction, which uses a double embedding mechanism with CNNs(Convolutional Neural Networks).

5. RACL-BERT (Chen and Qian, 2020) - This is the current state-of-the-art method that proposes a Relation Aware Collaborative Learning (RACL) framework which allows the subtasks to work coordinately via the multi-task learning and relation propagation mechanisms in a stacked multi-layer network.

6 Results

6.1 Supervised Model

The Table 6 shows the comparison for all the methods. For the task of Aspect Extraction, our model achieves 2.05%, 5.15%, 4.82% absolute gains over the three benchmark datasets, which proves the efficacy of our model. Also, for the overall ABSA task, our model achieves 0.09%, 1.29%, 5.43% absolute gains, which is significant. The AE results prove that span-based extraction performs better than any of the other methods proposed. The overall ABSA results suggest that it is better to use two different models for the two subtasks and then combine via pipeline over jointly learning to predict them simultaneously. This further concretizes the fact mentioned by (Hu et al., 2019) that Target Extraction and Sentiment Classification are loosely coupled, i.e., there is a weak connection between them.

6.2 Semi-Supervised Model

As shown in Table 7, we report the Precision, Recall, and F1-score of the model on our novel Movie20 dataset for the AE and ABSA task. The F1 score for AE is 63.74% and 58.23% for ABSA. Through this, we set a strong benchmark for semi-supervised aspect-based sentiment analysis on a movie-based dataset. We further analyze the model’s predictions and discover the following patterns in the errors made by the model:

1. The model usually failed to mark aspects preceded by rare adjectives (i.e., adjectives that occurred in the dataset with less frequency). For example, in the following sentence, “Great Acting dreadful editing”, the words “acting” and “editing” are the targets with polarities Positive and Negative respectively. However, the model recognized “acting” but failed to recognize “editing” because the word “dreadful” occurs very rarely in the dataset. Fewer examples in the dataset could have caused the model to fail in such cases.

2. The model also failed to mark sentences where specific experiential knowledge about a movie’s good and bad aspects was required (usually in the absence of any clear adjec-

tives). For example, in the following sentence, “We know the bliss can’t last. Thus, tears stream down your face during the third act”; the phrase “third act” should be marked as an aspect with a positive sentiment since movies that can connect with the audience’s emotions are considered good. However, the model does not have this experiential knowledge and hence failed to recognize the aspect. A similar example is the following sentence, “I could not relate to any character and did not care about the outcome.”, where the model failed to mark “character” as an aspect with negative sentiment since the model does not have the experiential knowledge that relatable characters make for a good movie.

7 Conclusion

In this work, we proposed TEASER, an extract-then-classify network for Aspect-based Sentiment Analysis with pre-trained BERT-Large as the main network. We also presented an Aspect extractor with a novel heuristic, which helps extract all the targets of a given sentence. Experiments show that our method consistently outperforms the current state-of-the-art in the task of AE and also in ABSA. We also presented two datasets, Movie20, a supervised dataset of 1162 sentences with a Cohen Kappa Score of 0.8326, and moviesLarge, a pseudo-labeled dataset of around 14373 sentences. Lastly, using Semi-supervised learning, we benchmarked TEASER on the Movie20 dataset. We analyzed the model to reason where the model failed to perform, and according to the findings, aspects preceded with rare adjectives and aspects with an absence of a clear adjective were the primary reasons for the failure.

Interactive Learning Approach for Arabic Target-Based Sentiment Analysis

Husamelddin A.M.N Balla, Marisa Llorens Salvador and Sarah Jane Delany
School of Computer Science
Technological University Dublin
Dublin, Ireland
{husamelddin.balla,marisa.llorens,sarahjane.delany}@tudublin.ie

Abstract

Recently, the majority of sentiment analysis researchers focus on target-based sentiment analysis because it delivers in-depth analysis with more accurate results as compared to traditional sentiment analysis. In this paper, we propose an interactive learning approach to tackle a target-based sentiment analysis task for the Arabic language. The proposed IA-LSTM model uses an interactive attention-based mechanism to force the model to focus on different parts (targets) of a sentence. We investigate the ability to use targets, right and left contexts, and model them separately to learn their own representations via interactive modeling. We evaluated our model on two different datasets: Arabic hotel review and Arabic book review datasets. The results demonstrate the effectiveness of using this interactive modeling technique for the Arabic target-based sentiment analysis task. The model obtained accuracy values of 83.10 compared to SOTA models such as AB-LSTM-PC which obtained 82.60 for the same dataset.

1 Introduction

Sentiment analysis (SA) is one of the most prolific research areas in computer sciences, which aims to identify and extract user opinions from reviews. This technique has become an essential part of a wide range of applications in the areas of politics, business, advertising and marketing as it can help in identifying people's opinions towards related targets (Tang et al., 2015). Arabic is considered among the top 4 languages in terms of internet usage (Boudad et al., 2018). With the rapid growth of Arabic web content and low resources for analyzing Arabic opinion mining, the need for accurate Arabic sentiment analysis tools is very necessary.

There are three main classification levels in sentiment analysis: document-level, sentence-level, and target-level. Document-level SA aims to classify the sentiment expressed in the whole document. It considers the whole document as a basic information unit (talking about one topic). Sentence-level SA aims to classify the sentiment expressed in each sentence. In traditional sentiment analysis, the detailed opinions of all targets of the entity (which are required in many applications) are not provided. To acquire these details, we need to use the target level. Target-based sentiment analysis (TBSA) aims to classify the sentiment with respect to the specific targets of entities. The opinion holders can give different opinions for different targets of the same entity, like in this sentence: “The hotel is clean with good services, but the room was too small”. Target-based sentiment analysis is a fine-grained task in sentiment analysis. This kind of fine-grained target-based analysis generally relies on machine learning techniques that require large domain-specific datasets with manual training data (Hu and Liu, 2004).

Target-based sentiment analysis has become more popular in recent research as it delivers more accurate results compared to traditional sentiment analysis. Given a plain text, the trained model is able to detect the targets that were seen in the training set; the context is simply the sequence of words or tokens around the targets. Referring to the previous example, Target1: hotel, Context: clean, good service, Polarity: positive; Target2: room, Context: too small, Polarity: negative. In traditional sentiment analysis (non-target-based SA), this detailed level of analysis is not possible as the analysis is performed at sentence level and hence the entire sentence is classified as either positive or negative.

The research area of Arabic SA is relatively new. Recently, the work on Arabic SA has received a lot of attention and a number of papers on traditional SA have been published in the last couple of years (Shoukry and Rafea, 2012; Duwairi and El-Orfali, 2014; Nabil et al., 2015; Al-Rubaiee et al., 2016). However, research work on Arabic TBSA has not been addressed in depth yet. Most of the existing
TBSA research focuses on English (Xue and Li, 2018; Mowlaei et al., 2020; Ma et al., 2018) with very little work on other languages such as Arabic. In this paper, we address the task of TBSA in Arabic. The proposed model uses a neural network with an attention mechanism to force the model to attend to the important parts of a sentence. To achieve that, an interactive attention-based long short-term memory network (IA-LSTM) with an interaction technique is used to capture important information related to a given target.

Previous work in Arabic target-based SA used deep learning represented in Recurrent Neural Network (RNN) and LSTM models and developed several methods aiming to model contexts through the generation of target-based representations (Ruder et al., 2016; Tamchyna and Veselovská, 2016; Al-Smadi et al., 2019). However, the modeling of interactive targets with contexts using attention mechanisms was not addressed.

The model proposed in this paper (IA-LSTM) is based on a model (IAN) proposed for English language TBSA in a previously published paper (Ma et al., 2017) that addresses the separately modeled targets and contexts that jointly interact with each other with an attention mechanism. However, the left context was ignored in the previously proposed approach in (Ma et al., 2017). Given the fact that Arabic language is written from right to left, the addition of the left context may improve the performance as the most of the opinionated words come after the target (left context). The proposed model (IA-LSTM) is obtained by adding the left context to the IAN model from (Ma et al., 2017), to end up with a model that considers the three main elements (left context, target, and right context). Code for the proposed model is publicly available on Github 1.

The rest of this paper is organized as follows: section 2 presents the related work of SA and TBSA in English and Arabic. Section 3 discusses the methodology used for the proposed model in this paper. Section 4 describes the datasets used for evaluations. Section 5 explains the baselines, evaluations, the experimental results and analysis. Section 6 concludes this paper.

2 Related Work

The research work on Arabic TBSA has few examples as the published papers are limited, so, the first subsection of related work mainly focus on traditional SA approaches. While the second subsection covers the published work on TBSA on both Arabic and other languages.

2.1 Arabic SA

The early attempts on Arabic SA relied on the methods applied for English SA as it is more mature with rich resources in terms of SA. An example of this, Ahmad (2006) employed a rule-based approach that was originally designed for English. Almas and Ahmad (2007) modified the approach to accept other languages such as English and Urdu. Those two attempts used financial news datasets. The results from these experiments were similar across all of languages tested.

Continuing in a business-oriented and rule-based approach, Elhawary and Elfeky (2010) performed experiments on Arabic SA. The authors addressed the problem of SA using large data and MapReduce in an attempt to enhance the performance. Another work following a similar approach was proposed by Farra et al. (2010), which used a pre-compiled lexicon to improve the performance on both sentence-level and document-level SA. However, there were no significant improvements in general performance, except at sentence level SA with slight improvement.

Work on Arabic SA or any other language always requires datasets to test the used approach. As Arabic is a language with low resources, very few datasets have been created for Arabic SA over the past years. AWATIF Abdul-Mageed and Diab (2012) is one example of the existing datasets.

2.2 Target Based Sentiment Analysis (TBSA)

One of the earliest papers in TBSA was for English, and used a frequency-based approach proposed by Hu and Liu (2004). The basic idea behind this approach is counting the nouns in the text and considering the most frequently mentioned ones as targets. The authors also tried to avoid the error of incorrectly identifying infrequent nouns as targets by using the nearest opinion words. This approach was also used in several other papers (Qiu et al., 2009; Zhuang et al., 2006). To enhance this approach, Popescu and Etzioni (2007) proposed using a technique named “part of relationship” to eliminate the frequent nouns that are incorrectly identified as targets.

TBSA is more challenging than the traditional task of sentiment analysis (non-target-based) be-
cause the model needs to include the impact of the context words on the target. A deep learning approach in this task can be performed by representing context, generating a target representation, and then detecting the important parts of the sentence (i.e. the targets). Again, RNNs have proven their competitive performance in this task in terms of capturing long-term dependency in sentences and general semantic classification. Moreover, the best RNN performers are the ones that include attention or memory networks. This shows that the models can learn how to concentrate on different parts of the sentence with an attention weight aggregated from a lower level to classify targets and opinion words and the link between them. Several researchers adopted an attention mechanism for this task in English (Gers et al., 2000; Song et al., 2019; Li et al., 2018). In general, there are not many techniques using deep learning for Arabic sentiment analysis and, in particular, TBSA (Dahou et al., 2016; Ruder et al., 2016; Tamchyna and Veselovská, 2016; Al-Smadi et al., 2019).

The International Workshop on Semantic Evaluation (SemEval), one of the most significant events in natural language processing (NLP) research, is concerned with the evaluation of computational semantic analysis systems. A special event focused on TBSA was organized in 2014, 2015 and 2016. In this workshop, Al-Smadi et al. (2018) proposed Arabic TBSA paper which performs a comparison between a deep neural network and SVM models. The authors used an RNN framework named Deeplearning4j that provides a set of implementations for different deep neural network algorithms. They evaluated their models on the Arabic hotel review dataset (Mohammad et al., 2016). Their deep neural network model outperformed the SVM model in accuracy of sentiment polarity while SVM outperformed the deep learning model in target extraction. They also proposed another study (Mohammad et al., 2016), which was part of the SemEval-TBSA 2016 competition. In this study they created a hotel review dataset with baselines obtained by using the SVM model with only unigram feature.

Focusing on Arabic TBSA and using the same dataset that this research is using (Arabic hotel reviews), three papers were recently published (Ruder et al., 2016; Tamchyna and Veselovská, 2016; Al-Smadi et al., 2019). Ruder et al. (2016) proposed a deep learning-based approach (INSIGHT-1) for multi-lingual TBSA as one of SemEval-2016 participants, which used a convolutional neural network for target extraction and sentiment analysis. Using the Arabic hotel review dataset their model outperformed the other participants in the workshop. Another approach proposed by Tamchyna and Veselovská (2016) for the same task used an RNN-based binary classifier for the task of target-category identification. Their model was trained using word embedding features and achieved good performance as the second rank after (Ruder et al., 2016).

A recent attempt by Al-Smadi et al. (2019) used targets and context embeddings in their proposed model (AB-LSTM-PC). The approach models the context words via LSTM networks and then combines the word’s hidden states with target embeddings to generate the attention vectors. In addition, to further strengthen the effect of target embeddings, the model appends target embeddings, with each word embedding vector forming the context. This is used to produce the final representation for TBSA. Their model performance was the highest among all previously published papers evaluated on the same dataset we are using in this research.

An approach (IAN) for English TBSA using interactive targets and context representations was proposed in Ma et al. (2017). The model uses attention mechanisms to concatenate the separately modeled targets and context as final representation before it is fed to the softmax layer. This model only considers the right context of targets, ignoring the left context.

All the research mentioned in this section ignores the the left and right context of targets and the interactions between them. Using these extra features can increase the amount of information about the context by providing a more comprehensive approach to context. In this paper, we propose an interactive learning approach based on (Ma et al., 2017) to tackle sentiment polarity identification for the Arabic language which includes the use of left and right context.

3 Proposed Approach

Recurrent neural networks (RNNs) are deep learning neural networks designed specifically to learn sequences of data and are mainly used for textual data classification. The learning process is done at hidden recurrent nodes depending on their previous layers of nodes. However, RNNs suffer from the
vanishing gradient problem when handling long sequences of data. Bi-directional long short-term memory (Bi-LSTM) (Schuster and Paliwal, 1997) was proposed as a solution for this problem and have proven to be efficient in many NLP-related problems. In contrast to the standard RNNs, Bi-LSTM units have a major role in extracting and learning important features out of the input or computed data and keeping the computed values as long as they are needed in the memory vector.

In this research, we focus on target-based sentiment polarity classification considering the right and left contexts. The enhancement of sentiment classification performance can be achieved by considering the targets and their contexts. The good performance relies on simultaneously modeling targets and contexts precisely. Targets and contexts can influence the representation of each other. For example, the target word “hotel” can be naturally associated with the context word “clean” and vice versa. Therefore, targets and contexts can be modeled individually but learn from their interactions. In the input text, each word usually has its own contribution or importance, which is different from other words in the final representation for sentiment analysis. For instance, the importance of the word “room” is higher in the representation of the target “room price”, which is described by “expensive”. Therefore, in the proposed model, the attention weights for both targets and contexts are computed to respectively capture their important information.

The proposed model is an interactive attention LSTM-based (IA-LSTM) model which employs long short-term memory networks (LSTM) and attention mechanisms. To get important information from the left and right context, the model uses an attention mechanism associated with a target then computes context representation for sentiment polarity identification. In addition, the proposed model makes use of the interactive information from the word’s context to supervise the target modeling. Finally, the model concatenates the attended left context representations, target representations, and right context representations, then uses them to predict the sentiment polarity (see Fig. 1).

Following the model notation in Fig. 1, assume that a left context consists of k words \( [w_{LC1}, w_{LC2}, ..., w_{LCk}] \), a target consists of \( m \) words \( [w_1, w_2, ..., w_m] \), and a right context consists of \( n \) words \( [w_{RC1}, w_{RC2}, ..., w_{RCn}] \). We use pre-trained word embeddings for word representation of contexts and targets. Then, since there is a strong dependence between words in a sentence, the LSTM network is used to learn the hidden word semantics as LSTM is good at learning long-term dependencies. Next, LSTM produces the hidden states \( [h_{LC1}, h_{LC2}, ..., h_{LCk}] \) for the left context words, \( [h_1, h_2, ..., h_m] \) for the target words, and \( [h_{RC1}, h_{RC2}, ..., h_{RCn}] \) for the right context as word representations. Then, the model calculates the average of the hidden states to get the initial representations of the contexts and target.

The attention mechanism in the proposed model is adopted by using the initial representations of the contexts and target as input to help in selecting important information for classifying the sentiment polarity. To form the attention mechanism, we use the average as well as the last hidden state output of target and contexts to capture an abstract representations of the input sequence. The use of the average value is to form the initial representation of the other component (target or context) and combine it with the last hidden state of the current component. We found this is the best way to form the attention mechanism and it help to reduce the noise and the sparse information associated with the Arabic language (ElNagar et al., 2020).

The attention process is described by considering the left context, target, and the right context, as shown in Fig. 1. Using the left context words representation \( [h_{LC1}, h_{LC2}, ..., h_{LCk}] \) and the average of hidden states of target representation \( T_{avg} \), the model computes the left attention vector \( L_{Oi} \). Similarly, the model computes the target attention vector \( \beta_i \) by using the average of left context words \( L_{avg} \), the target words representation \( [h_1, h_2, ..., h_m] \), and the average of the right context vector \( R_{avg} \). The same technique is followed for the right attention vector \( R_{Oi} \) obtained using the right context words representation \( [h_{RC1}, h_{RC2}, ..., h_{RCn}] \) and the average of hidden states of target representation \( T_{avg} \). Then, the attention vectors \( L_{Oi}, \beta_i \), and \( R_{Oi} \) are used to obtain the word attention weights and concatenated as one vector before being fed to the softmax classifier.

Formally, given the word embeddings of the contexts and target, the hidden state representations of the contexts (left and right) and target are \( [h_{LC1}, h_{LC2}, ..., h_{LCk}], [h_{RC1}, h_{RC2}, ..., h_{RCn}] \) and \( [h_1, h_2, ..., h_m] \) respectively. The initial representation of contexts (left - equation (1) and right - equation (2)) and targets equation (3) is obtained by calculating...
the average of each as follows:

\[ LC_{\text{avg}} = \frac{1}{k} \sum_{i=1}^{k} h_{LC}^i \]  

(1)

\[ RC_{\text{avg}} = \frac{1}{n} \sum_{i=1}^{n} h_{RC}^i \]  

(2)

\[ T_{\text{avg}} = \frac{1}{m} \sum_{i=1}^{m} h_{T}^i \]  

(3)

To make the model focus on the important parts of the representations, an attention mechanism that employs the initial representations of the contexts and target is used. The target influence on the left context and the influence of the left context on the target is considered, as well as the influence of the target on the right context and the influence of the right context on the target. The left attention vector \( L\alpha_i \) is generated using both the left context and target representations as in equation (4):

\[ L\alpha_i = \frac{e^{\gamma(h_{LC}^i, T_{\text{avg}})}}{\sum_{j=1}^{k} e^{\gamma(h_{LC}^j, T_{\text{avg}})}} \]  

(4)

Where \( \gamma \) is a score function that computes the importance of \( h_{LC}^i \) and \( h_{RC}^i \) in the left and right context respectively. This function is defined as equation (5):

\[ \gamma(h_{LC}^j, T_{\text{avg}}) = \tanh(h_{LC}^j \cdot w \cdot T_{\text{avg}}^t + b) \]  

(5)

Where \( w \) is a weight matrix, \( b \) is a bias, and \( T_{\text{avg}}^t \) is a transpose of \( T_{\text{avg}} \). The right attention vector \( R\alpha_i \) is generated using both the right context and target representations as equation (6):

\[ R\alpha_i = \frac{e^{\gamma(h_{RC}^i, T_{\text{avg}})}}{\sum_{j=1}^{n} e^{\gamma(h_{RC}^j, T_{\text{avg}})}} \]  

(6)

Similarly, the target attention vector \( \beta_i \) is calculated using all of the right context, left context, and the target as (7):

\[ \beta_i = \frac{e^{\gamma(h_{T}^i, LC_{\text{avg}})}}{\sum_{j=1}^{m} e^{\gamma(h_{T}^j, LC_{\text{avg}})}} + \frac{e^{\gamma(h_{T}^i, RC_{\text{avg}})}}{\sum_{j=1}^{m} e^{\gamma(h_{T}^j, RC_{\text{avg}})}} \]  

(7)

The representations of the left context, target, and right context are computed as in equations (8), (9), (10) respectively:

\[ C_l = \sum_{i=1}^{k} L\alpha_i h_{LC}^i \]  

(8)
\[ T = \sum_{i=1}^{m} \beta_i h_{RC}^i h_{LC}^i \tag{9} \]
\[ C_t = \sum_{i=1}^{n} R\alpha_i h_{RC}^i \tag{10} \]

The final representation is done by concatenating the representations of the three components of the left context, target, and the right context (\( C_1 \), \( T \), and \( C_r \) respectively) as one vector \( (F) \). Finally, the prediction of sentiment polarity (positive, neutral, negative) is done by using the softmax layer as in equation (11):

\[ x = tanh(w_1 F + b_1) \tag{11} \]

Where \( w_1 \) is the weight matrix and \( b_1 \) is the bias.

### 3.1 Hyperparameters and Model Training

The pre-trained Arabic word embeddings “AraVec” (Soliman et al., 2017) was used for the target and the context word embeddings with a dimension of 300 nodes. AraVec is an open-source project which provides free-to-use Arabic word embeddings trained on more than 3 billion words from web pages and Wikipedia. A uniform \( \beta \) distribution \( U(0:1; 0:1) \) was used to initialize all out-of-vocabulary words and weights. The model employs the momentum optimization algorithm (Qian, 1999) to train the parameters, which adds a fraction of the update vector in the preceding step to the current update vector. The dropout rate is set to 0.5, and the normalization coefficient \( L2 \) in the objective function is set to \( 10^{-5} \).

### 4 Datasets

There are two benchmark datasets were used to evaluate the proposed approach, Arabic hotel reviews and Arabic book reviews datasets.

#### 4.1 Arabic Hotel Reviews

This dataset was part of the work proposed in task 5 of the Sem-Eval 2016 workshop on target-based sentiment analysis (Pontiki et al., 2016; Mohamad et al., 2016). The dataset contains the 24,028 TBSA annotated tuples provided (19,226 tuples for training and 4,802 tuples for testing). For the sake of generalization and to avoid the single dialect problem, the original dataset was collected from well-known different Hotels’ booking websites such as Booking.com, TripAdvisor.com. The selected reviews in the datasets belongs to Hotels from different Arabian cities in different countries such as Dubai, Beirut, Amman, Mecca, etc. In addition, the dataset was annotated on both text-level (2,291 reviews’ texts) and sentence-level (6,029 annotated sentences). In this research, we consider only the sentence-level tasks. This is a manually annotated dataset, whereas, for each sentence, a tuple of target category, opinion target expression, and target polarity were annotated. The sentiment polarity labels (positive, negative, neutral) were used to annotate the polarity of each target or category.

#### 4.2 Arabic Book Reviews

This dataset was provided by (Al-Smadi et al., 2015) as a benchmark Human Annotated Arabic Dataset (HAAD). HAAD is a book review dataset in Arabic, which has been constructed and annotated by humans, taking into account the target terms and their polarities. For each review sentence, a tuple consisting of an target-category, target-category polarity, target-term, and target-term polarity was extracted and annotated. A sentiment polarity (positive, negative, conflict, neutral) was used to represent both the target-category and target-term sentiment polarity based on the annotated sentences. This dataset consists of 1513 Arabic book reviews annotated with aspect terms, aspect term polarity, aspect category, and aspect category polarity. In our experiments, we considered the labels positive, negative, and neutral excluding conflict label.

Lastly, both datasets were proposed as three separated machine-readable XML format files annotated training, test, and gold test with polarity distribution in Table 1. In addition, one sentence can contains more than one target which can be assigned with different polarity label. SemEval-TBSA designed a specific way of evaluations for all of the models evaluated on the associated datasets. F1 score is usually used as a metric for category and target execration. However, the metric used for sentiment polarity in the literature review is the accuracy of each model. A sample of Arabic hotel reviews dataset is shown in Fig. 2.

### 5 Evaluation

We evaluated the proposed model on the Arabic hotel review and the Arabic book review. The evaluation is done by computing the accuracy of the polarity. The used accuracy metric defined as the
number of correctly predicted polarity labels of the (gold) targets, divided by the total number of the gold targets. The test set contains sentences without polarity labels which is expected to be predicted by the model and compared with the labels in the test gold set containing the same sentences. We compared the proposed model performance with the related work and SOTA approaches stated as LSTM (Gers et al., 2000), IAN (Ma et al., 2017), INSIGHT-1 (Ruder et al., 2016), and AB-LSTM-PC (Al-Smadi et al., 2019) evaluated on the same Arabic hotel review dataset. For the Arabic book review dataset, the proposed model is compared with a subset of these approaches: LSTM (Gers et al., 2000) and IAN (Ma et al., 2017). In addition, the baselines labelled as “Baseline” in Table 2 are the baselines provided with the published work of dataset creation. The baseline for the Arabic hotel review dataset was obtained by using SVM with N-grams as features. The baseline for the Arabic book reviews was obtained by using a frequency approach.

5.1 Compared Models

The models used in the comparison in this paper are as follows: (i) LSTM uses one LSTM network to model the context and get the hidden state of each word. The average value of all the hidden states is obtained as the final representation and fed to a softmax function to estimate the probability of each sentiment label (Gers et al., 2000). (ii) IAN uses an interactive attention-based LSTM considering the target and right context only (ignoring the left context) (Ma et al., 2017). (iii) INSIGHT-1 uses a convolutional neural network (CNN). The model concatenates the target vector with each word embedding and then applies a convolution over it to identify the sentiment polarity (Ruder et al., 2016). (iv) AB-LSTM-PC uses an attention-based LSTM by adding the target embedding in the input. To generate the attention vectors, the approach models the context using LSTM networks and combines the hidden states with the target embeddings (Al-Smadi et al., 2019).

For INSIGHT-1 and AB-LSTM-PC, we report the previously published results without implementing the models as they were evaluated on the same dataset. The rest of the compared models (LSTM and IAN) were implemented and evaluated on the datasets.

5.2 Experimental Results and Analysis

Table 2 shows the proposed model’s performance compared with other models. The worst performance in this table was for the LSTM model. This is most likely due to the fact that it does not make use of the attention mechanism, confirming findings in previous research (Jiang et al., 2011). Both the AB-LSTM-PC model (SOTA) and INSIGHT-1 have similar performance and outperform the LSTM model, confirming that the attention mechanism enhances the ability to identify sentiment polarity. Unlike IAN in (Ma et al., 2017), our proposed IA-LSTM model (represented by “IA-LSTM” in the table) takes a further step towards confirming the importance of considering the targets and contexts in the learning process interactively. As shown in Table 2, the IA-LSTM model achieved the highest performance, outperforming all baselines and the other approaches. This enhancement can be explained by the fact that our model uses three connected attention networks to model the target and contexts. Using such a design, the model can effectively learn the representations of targets and contexts, which can jointly enhance the overall performance of target-based sentiment
Table 2: Accuracy comparison between the proposed IA-LSTM model performance for the TBSA task and the baseline results based on SVM along with n-gram features and approaches from related work.

<td>65.82</td>
</tr>
</tbody>
</table>

different approaches show that the more attention that is paid to targets, the higher the accuracy.

As we can notice for Table 1, the class distribution is imbalanced in both Hotel review and Book review datasets. Therefore, we calculate the accuracy for each polarity class in Table 3. A lower accuracy obtained by class "Neutral" as it has the lowest amount of data and a higher accuracy obtained by class "Positive".

Lastly, we verified the effectiveness of using targets and interaction with the left and right contexts in modeling the attention mechanism and the results are displayed in Table 4. The first model (labelled No-interaction) completely ignored the interaction between the targets and contexts. This model uses three LSTM networks to learn the representations of the left context, target, and right context in their own local attentions without any interaction. In the second model (labelled Right-side interaction), we showed the impact of using the right-side of the interaction mechanism that enables the target to interact with the right contexts. This model uses two LSTM networks to learn the representations of the target and right context and interact with the right context only. Similarly, in the third model (labelled Left-side interaction) the target interacts with the left context only. The fourth model (labelled Full-model) uses the target interaction with both left and right contexts. As shown in Table 4, a lower performance was achieved by the No-interaction model. Using two-side interaction showed some improvement in the performance specially the left-side as Arabic is written from right to left which means most of the opinion words comes on the left-side after the target. The best performance was achieved by the Full-model, as we expected, where using the target interactions with the left and right contexts is fully considered, which enhances the overall model performance. Therefore, from this table, we can observe that the interaction of the target between the left and right contexts can contribute greatly in enhancing TBSA. The performance investigation of using target-attention only was well represented by the AB-LSTM-PC model in Table 2 which we avoid to repeat it in our comparison in Table 4.

6 Conclusion

In this paper, we proposed a deep learning-based approach to tackle Arabic TBSA. The proposed model “IA-LSTM” uses an interactive attention-based technique for the task. The main idea of the proposed IA-LSTM model is to use three attention networks to interactively model the target and contexts (left and right). It is based on previous work in English that uses only the right context but given the way Arabic is written from right to left, the addition of the left context provides important context information. The model can focus on the important parts in the sentence and identify the sentiment polarity. The proposed approach was evaluated on two different datasets: Arabic hotel reviews and book reviews. Experiments verify that the proposed approach outperforms the baselines and other approaches evaluated on the same datasets. Implementing the interactive attention-based model demonstrated that the model can learn effective features for targets and contexts (left and right) and enhance the performance of Arabic TBSA.

Abstract

Best-worst Scaling (BWS) is a methodology for annotation based on comparing and ranking instances, rather than classifying or scoring individual instances. Studies have shown the efficacy of this methodology applied to NLP tasks in terms of a higher quality of the datasets produced by following it. In this system demonstration paper, we present LITESCALE, a free software library to create and manage BWS annotation tasks. LITESCALE computes the tuples to annotate, manages the users and the annotation process, and creates the final gold standard. The functionalities of LITESCALE can be accessed programmatically through a Python module, or via two alternative user interfaces, a textual console-based one and a graphical Web-based one. We further developed and deployed a fully online version of LITESCALE complete with multi-user support.

1 Introduction

Annotation is a cornerstone of Computational Linguistics and Natural Language Processing (NLP). Much of modern NLP is based on machine learning, and in particular on supervised machine learning. As a consequence, large amounts of manually annotated data are constantly in high demand, and the quality of the annotation directly influence the predictive capability of models trained on them.

The annotation of natural language resources comes in many forms of varying complexity and levels of abstraction. However, it is possible to categorize most of the approaches in three main families. Categorial annotation is perhaps the most common approach, whereas each instance of a dataset is associated with a label from a fixed set of options. Annotation can also consist of scalar values, that is, numeric values on a predetermined scale. Finally, ranking is a type of annotation where multiple instances are put in a certain order by the annotator, who therefore does not make judgments on instances in isolation but rather on groups of them.

Recent literature highlights the advantages of the ranking strategy, in terms of the quality of the annotation produced with it, in particular when dealing with subjective aspects of natural language (Yannakakis et al., 2018). The Best-Worst Scaling model (BWS) is a ranking-based annotation process developed by Louviere et al. (2015). BWS has been proved to be beneficial to the quality of the resulting gold standard data for subjective-related tasks such as emotion detection (Kiritchenko and Mohammad, 2017) and hate speech detection (Piletto et al., 2019). The recent work of De Bruyne, Luna and De Clercq, Orphée and Hoste, Veronique (2021) further proved the validity of BWS as a method of annotation for sentiment-related tasks, dominance in particular.

Several general-purpose annotation tools have been proposed in the literature. Among the most popular, WebAnno (Eckart de Castilho et al., 2016) and Brat (Stenetorp et al., 2012) both provide Web-based interfaces and the possibility to implement rich annotation schemas, including annotation at the word and span level, and links between annotations. A number of online services are also available to perform linguistic annotation, especially in a crowdsourced fashion, such as Amazon Mechanical Turk1, Appen2, or LightTag3. All these systems, however, allow the user to devise schemas that associate labels or scores to individual units of text, whether words, spans, sentences or others. In other words, they natively give the possibility of implementing categorial or ranking annotations. To our knowledge, there is no publicly available system

2 Best-worst Scaling Annotation

In Best-worst Scaling (BWS) annotation, the annotator is shown a tuple consisting of a fixed number of instances, and a phenomenon to annotate. The annotator is then asked to select the instance from the tuple which expresses the phenomenon to the maximum extent, and the one that expresses it to the least extent. For example, in a sentiment polarity annotation task, the annotator may be asked to select the sentences conveying the most positive and the most negative sentiment.

Starting from the set of instances to annotate, tuples must be created such that:

- The instances appear in tuples in a random order.
- Each instance appears in a predetermined number of tuples.
- The same pair of instances never appears in the same tuple more than once.

The size of the tuples and the number of tuples in which each instance appears are parameters to be determined at the time of the creation of the tuples. The ratio between the values of these two parameters determines the number of tuples with respect to the number of input instances. In particular, if the two parameters are equal, then the number of tuples will be approximately the same as the instances to annotate.

Since the number of tuples where any individual instance appears equals the size of the tuples (four items), the number of final questions for the annotators is roughly equivalent to the number of items to be annotated.

Once the annotation is complete, a score is computed for each instance as the difference between the number of times the instance was selected as “best” and the number of times it was selected as “worst”. The score can easily be normalized to fit a \([-1, 1]\) or \([0, 1]\) interval, depending on the needs of the downstream application.

Since the tuples are computed once, at the beginning of the annotation process, every annotator is presented the same set of instances. It is therefore possible to compute standard measures of inter-annotator agreement such as Fleiss’ Kappa or Krippendorf’s Alpha (Artstein and Poesio, 2008).

3 Litescale

In this section, we introduce LITESCALE, a free and open source software package that implements the Best-worst Scaling annotation framework. LITESCALE is composed of a core Python library implementing the core functions, and two alternative interfaces, a console-based textual one and a Web-based graphical one. The user can create annotation projects by providing a tab-separated text file, and obtain a similarly formatted file at the end of the annotation. A diagram depicting the information flow and the modules of LITESCALE is in Figure 1.

3.1 Core Functions

The core library of LITESCALE implements a series of functions to create and manage BWS annotation tasks, called projects. A project is created starting from a simple text file, where each line is a tab-separated pair of an instance identifier (which can be any string) and its textual content. Upon the creation of a new project, a JSON file is created representing all the information relative to the project.

Tuple creation. The function to create a new project takes five inputs: a name, the label for the phenomenon to annotate, the file containing the instances, and two parameters for the creation of the tuples from the set of input instances. Such parameters are the size of the tuples to create (tuple size) and the number of tuples in which a single instance will occur (instance replication). Given these two parameters, the system implements the three constraints described in Section 1 by leveraging Gauss’ modular arithmetic. More precisely, calling \( s \) the tuple size and \( r \) the replication factor, and \( n \) the
total number of instances, tuple are composed of instances with indexes in the form:

\[(xs^{j+1} + is^{j}) \mod n\]

\[0 \leq x < \lfloor n/s \rfloor\]
\[0 \leq i < s\]
\[0 \leq j < r\]

This formula ensures that the BWS conditions are met, by “wrapping up” the indexes in an appropriate way. For instance, with \(s = 4, r = 4,\) and \(n = 101,\) the first tuples are identified by the following indexes: \((1, 2, 3, 4), (5, 6, 7, 8), \ldots\) However, once the indexes exceed \(n,\) the modular arithmetic recombinates them: \((1, 5, 9, 13), \ldots, (81, 85, 89, 93), (97, 101, 4, 8),\) and so on. While this method ensures to fully include all the input instances into the tuples, due to the inner working of the modular arithmetic the formula works correctly under the condition that \(n\) (the number of instances) and \(s\) (the size of the tuples) are be co-primes, i.e., they need not have common divisors other than 1. As a workaround, the LITESCALE library automatically exclude a number up to \(s – 1\) of instances from the process, to prevent the formula to run into a corner case. Furthermore, for some combinations of parameters it is mathematically impossible to have all the instances appear in exactly \(r\) tuples. More precisely, there will be up to \(s – 1\) instances that occur \(r – 1\) times, i.e., a considerably small set of instances will lack exactly one annotation at the end of the process.

**BWS annotation.** The library creates a directory to store all the annotations for a project as a series of JSON files, one for each user participating to the annotation task. The `next tuple` function checks the current status of the annotation and returns the first non-annotated tuple to be presented to the user. The `annotate` function takes a pair of tuple indexes indicating the “best” and the “worst” and updates the annotation JSON correspondingly. The `progress` function returns the number of currently annotated tuples by a given user and the total number of tuples in the project, in order to compute the advancement status of the project as a percentage or progress bar.

**Gold standard.** The other key function in the LITESCALE core library is the one that computes the gold standard. This function collects all the annotations provided by the users for a specific project, and computes the gold standard according to the BWS methodology. For each instance, library counts the number of times it was judged “best” and the number of times it was judges “worst”, and computes the difference between these numbers. The result is then normalized using the minimum and maximum values of the differences across all instances, in order to return a score between 0 and 1, indicating the relevance of the phenomenon object of the annotation project in each instance. The gold standard dataset is finally written out to a text tab-separated file consisting of three columns, namely instance ID, text, and score.

### 3.2 Command-line Interface

The command-line interface (CLI) of LITESCALE is implemented with the [PyInquirer](https://github.com/CITGuru/PyInquirer) Python library. It makes use of the functions provided by the LITESCALE core library and exposes an interactive, menu-based interface to easily navigate through its functionalities.

![Figure 2: LITESCALE command-line interface: login and start menu.](image1)

Upon starting, the CLI asks for a username to log in, and keeps memory of the last user that has logged in previous sessions. No password is requested, since the application is intended to be for single user interaction in individual installations. After logging in, a menu with a few options is proposed to the user, as shown in Figure 2.

![Figure 3: LITESCALE Command-line interface: creation of a new annotation project.](image2)

- **Start/continue annotation**: lists the available annotation projects, and start the annotation of the selected project.
- **Generate gold standard**: lists the available annotation projects, and creates the gold stan-
The creation of a new annotation project involves a small set of questions for the user. These include a name for the project, a label for the phenomenon to annotate, values for the two parameters for the creation of the tuples (tuple size and instance replication), and the path to a tab-separated file from which the instances will be read.

For the BWS annotation, the CLI shows two questions in sequence to the user, in the form “which is the MOST label?” and “which is the LEAST label?”, followed by the list of the instances in a tuple, where label is the label of the phenomenon for the selected project. An example of the annotation interface is shown in Figure 4. At any moment, the user can select PROGRESS to check how many instances are left to complete the task (Figure 5), or EXIT to return to the main menu.
of LITESCALE is shown, initially prompting for a username, exactly as its CLI counterpart. Once the user has logged in, the main menu is displayed as in Figure 6.

The Web-based interface provides the same functionalities as the CLI, and the annotation workflow is identical (Figure 7). Furthermore, the two interfaces are by default part of the same installation of LITESCALE and make use of the same core library. Therefore, an annotation task can start with one interface and switch seamlessly to the other and back at any time. The annotations created with the two interfaces are exactly in the same format, and can therefore be merged without any extra work.

4 Multi-user Online Platform

Despite being a standalone application, LITESCALE is natively multi-user, because the annotations produced by different users are represented as different JSON files. These files can reside on the same machine, or different machines if multiple installation of LITESCALE took place. In the latter case, it is sufficient to copy the annotation files of a project from one installation to another to generate a gold standard comprising all the annotations. This process, however, can be tedious and error-prone. Moreover, the version of LITESCALE presented so far needs to be executed as a series of Python scripts, therefore requiring at least a minimal amount of skill in such technology from the annotators. To overcome these issues, and provide an even easier and more accessible user experience, we developed a fully online, multi-user version of LITESCALE, described in this section.

The online version of LITESCALE offers the same functionalities as the standalone version described in the previous section, with a user interface very similar to the Web-based interface in Section 3.3. The front-end was however implemented from scratch, while retaining the core library for the basic functions, although with some modifications. LITESCALE online is a Web application implemented with the Flask Python framework. More precisely, the software is designed in a modular way. A RESTful HTTP API is provided in order to expose the core library functionalities, and a Web application provides the user interface by connecting to the API. Figure 8 shows the modular architecture of this version of LITESCALE.

The RESTful API is intended as a layer of abstraction to facilitate the future development of tools that access the core library functions remotely, or application that provide alternative interfaces, such as mobile applications. The RESTful API is implemented with the Flask-RESTful extension of the Flask framework. The HTTP verbs and their semantics are summarized in Table 1.

In order to make LITESCALE online ready to scale up the number of users and projects, the core library has been modified. In particular, the inner representation and persistence of instances, projects, tuples, and annotations, does not rely on JSON files but rather on a SQL database.

The workflow in the online version of LITESCALE is substantially the same as the standalone version, including the interface to create new projects (Figure 9) and the annotation interface itself. However, additional functionalities were implemented to account for the online multi-user envi-

environment. The users can sign up with a valid email address and set up proper log in credentials after receiving a confirmation by email. The user authentication features are managed by the Werkzeug\(^8\) Python library, including the storage of encrypted passwords in the database. Moreover, the association of users to projects is also managed through the Web application. By default, when a project is created, the user who created it assumes the role of owner of that project. The owner of a project can invite other users to join their projects, by indicating a valid email address (Figure 10). The recipients of such invitation will receive an automated email notification, inviting them to sign up to LITESCALE if they are not already registered.

5 Evaluation

We conducted a pilot test in order to evaluate the efficacy of Litescalse in supporting the Best-worst Scaling annotation of datasets for NLP tasks. We extracted a sample of short hotel reviews in English from the list of 1,000 hotels and their reviews provided by Datafiniti’s Business Database\(^9\). We selected the 20 shortest reviews for each of the five ratings (1 to 5 stars) for a total of 100 instances, shuffled then randomly and created an annotation task in Litescalse. Three annotators were asked to perform the annotation and record the times spent annotating each 10 annotations (pairs of best/worst judgments). We computed the Pearson correlation between the scores resulting from Litescale and the original ratings associated to the reviews, obtaining a score of 0.77, indicating strong correlation with the ground truth. The agreement between the annotators is relatively high, considering the subjectivity of the sentiment polarity annotation task. Interestingly, the three annotators agreed more on the worst judgments (two annotators agreed 91% of the times, all three agreed 66% of the times) than on the best ones (two annotators agreed 88% of the times, all three agreed 58% of the times).

The annotation took about 43 minutes on average. However, the average time spent annotating tends to decrease consistently as the annotation task progresses, as shown in Figure 11. This is not surprising, considering the nature of the BWS annotation, where the same instance is shown multiple times, and therefore the annotator gains familiarity with the instances over time.

6 Conclusion and Future Work

We introduced LITESCALE, a flexible software tool to create and manage linguistic annotation tasks based on the Best-worst scaling methodology. LITESCALE is easy to use, free and open source\(^10\), and ships with different user interfaces. Moreover, a multi-user online version of LITESCALE is also presented\(^11\), which runs entirely in a Web browser.

---

\(^8\)https://werkzeug.palletsprojects.com
\(^10\)The source code of LITESCALE is available on the Github repository https://github.com/valeriobasile/litescale
\(^11\)LITESCALE online is available at http://lite-env.eba-jhijbmtj.eu-west-3.elasticbeanstalk.com/home
and provides all the functionalities of the original software.

While the BWS methodology has been thoroughly tested in the literature, this particular tool has not been systematically tested for its usability (but it is being used at the moment for the creation of several language resources). Although all the main features are implemented, there is always room to add extra functionalities and improving the existing ones.

A short video describing the main functions of LITESCALE is available on YouTube: https://youtu.be/SozWDMH2ah0

Abstract

Emotion Classification is the task of automatically associating a text with a human emotion. State-of-the-art models are usually learned using annotated corpora or rely on hand-crafted affective lexicons. We present an emotion classification model that does not require a large annotated corpus to be competitive. We experiment with pretrained language models in both a zero-shot and few-shot configuration. We build several of such models and consider them as biased, noisy annotators, whose individual performance is poor. We aggregate the predictions of these models using a Bayesian method originally developed for modelling crowdsourced annotations. Next, we show that the resulting system performs better than the strongest individual model. Finally, we show that when trained on few labelled data, our systems outperform fully-supervised models.

1 Introduction

A large part of Natural Language Processing (NLP) research is focused on building technology to automatically extract information from large collections of texts. However, text contains often not just mere factual information, but also opinions, attitudes and emotions. Applications of emotion-aware NLP models range from established tasks such as analysis of product reviews (Blitzer et al., 2007) and development of “emotional” chatbots (Chatterjee et al., 2019) to less obvious tasks such as the analysis of developer experience on Stack Overflow (Novielli et al., 2018), author profiling (Rangel and Rosso, 2016) and the prediction of mental health disorders (Uban et al., 2021).

In this work, we focus on the fine-grained emotion classification task (Strapparava and Mihalcea, 2007): given a document, an emotion label must be provided. For example, the sentence The angry wolf ate the happy boy could be associated with fear or sadness if the emotion is being modelled from the reader’s perspective; alternatively, it could be associated with anger or joy considering the text’s perspective. In the emotion classification literature, the targeted emotion perspective is rarely made explicit (Bostan et al., 2020), which — in addition to the subjectivity involved in the annotation task — makes it difficult to obtain large amounts of high quality data (Bobicev and Sokolova, 2017; Troiano et al., 2021). Furthermore, with few exceptions (Mohammad et al., 2018; Lamprinidis et al., 2021), most of the research has been conducted on English corpora: most of the other languages can be considered low-resourced with respect to affective corpora.

In this work, we aim to minimize the amount of annotated data needed to obtain competitive performance in the task of emotion classification. Several emotion theories exist, which differ on the emotion inventory and representation type (categorical vs. continuous): in this work we focus on the categorical paradigm, using the mix of different inventories available from the Unify Emotion dataset (Bostan and Klinger, 2018).

We describe the use of pretrained language models (PLMs) for emotion classification in both few-shot and zero-shot scenarios (Section 4). Few-shot models are supposed to solve a task using only few annotated instances; zero-shot models are supposed to use none. These models have been shown to perform well in different tasks (Yin et al., 2019; Schick and Schütze, 2021b; Wang et al., 2021). However, in a real unsupervised scenario (i.e., without...
an evaluation split), their performance is by definition unknown. To mitigate the risks involved in deploying such models, we experiment with a probabilistic ensemble that combines the individual – and potentially biased and noisy – outputs of those models. We use the Multi-Annnotator Competence Estimation model (Hovy et al., 2013), a Bayesian method designed to deal with noisy crowdsourced annotations (Section 5). Experimental results (Section 6) show that our ensemble performs better than the strongest individual model. In addition, we show that just fine tuning with few labeled data, our system outperforms fully-supervised models.

2 Related Work

Attempts to minimize the amount of hand-labelled data required to train emotion-aware NLP models have mostly focused on using distant supervision (Go, 2009) to collect large amounts of silver labels for training models in a supervised fashion: emoji (Felbo et al., 2017), emoji description (Eisner et al., 2016), and hashtags (Mohammad, 2012) have been shown to be good proxies for emotion classification. The idea of using label templates for unsupervised classification can be traced back at least to Hearst patterns (Hearst, 1992). Within the neural paradigm, Cloze (Taylor, 1953) label templates are used by Schick and Schütze (2021a), who obtain strong results on few-shot classification. Yin et al. (2019) and Wang et al. (2021) use templates to generate synthetic data for framing text-classification as entailment. An alternative neural approach to unsupervised classification embeds both the input sequence of text and the set of possible label names in the same semantic space and selects the one which maximizes a defined similarity metric (Gabrilovich and Markovitch, 2007). Pushp and Srivastava (2017) concatenates both input and label embeddings and classify their relatedness. A recent survey of template-based or “prompt-based” learning can be found in Liu et al. (2021). Perhaps the closest work to ours is Yin et al. (2019), who evaluate zero-shot text classification on the Unify Emotion dataset (Bostan and Klinger, 2018).1 Our main contribution with respect to Yin et al. (2019) is the suggestion of a principled way for a) aggregating multiple predictions without having any access to a model’s performance and b) inferring the most probable emotion label given multiple models.

An overview of Bayesian models of annotation can be found in Paun et al. (2018). The idea of using a generative model to infer a latent label from multiple signals has recently been presented in a unified framework by Ratner et al. (2016). An alternative to Bayesian models for aggregating predictions can be found in Poerner and Schütze (2019), who apply Generalized Canonical Correlation Analysis to build an ensemble of unsupervised BERT models for Duplicate Question Detection in a low-resource scenario.

Table 1: Overview of the dataset.

For all our experiments we use a section of the Unify Emotion dataset (Bostan and Klinger, 2018) which aggregates several annotated corpora in a common format. Specifically, we use the following datasets: Grounded-Emotions (Liu et al., 2007), CrowdFlower (Crowdflower), DailyDialog (Li et al., 2017), TEC (Mohammad, 2012), Electoral-Tweets (Mohammad et al., 2015), ISEAR (Scherer and Wallbott., 2017), Emotion-Stimulus (Ghazi et al., 2015), Tales-Emotion (Alm et al., 2005; Alm and Sproat, 2005; Alm, 2008), and EmoInt (Mohammad et al., 2017). We aggregate all the corpora and then sample from each class 60% of the data for the train split, and 20% for the Emotion dataset, the actual instances and label set used are different.

1We don’t compare our results directly to Yin et al. (2019): even though both datasets stem from the Unify
development and the test split, respectively. The annotation quality, domain, annotation procedure (manual vs. semi-automatic), and topic differ among the various datasets. We refer to (Bostan and Klinger, 2018) for additional details about the specific datasets.

Table 1 highlights the label distribution in the dataset. As it is the case for most available emotion corpora, the labels are heavily unbalanced.

4 Entailment as Zero-Shot and Few-Shot Learning

Given two sentences, a premise and a hypothesis, they can be related by an entailment, contradiction or neutral relation. The task of Natural Language Inference (NLI) (Dagan et al., 2005) aims at predicting such relations. Recently, the creation of large NLI datasets (Bowman et al., 2015; Williams et al., 2018; Thorne et al., 2018; Conneau et al., 2018) has allowed deep learning methods to achieve state-of-the-art performance on the NLI task, outperforming logic-based approaches. The high performance of BERT-like models (Devlin et al., 2019) on NLI tasks can be exploited to successfully tackle general classification tasks by recasting them as entailment problems: pre-trained language models can be finetuned on NLI datasets and these finetuned models can be then re-purposed to attack different problems (Wang et al., 2021). For modelling the emotion classification problem, we follow Yin et al. (2019) and given a text to classify (the hypothesis), we build pseudo-sentences to serve as premises, one for each target label. For instance, the input sentence “John said he loved the pizza” can be classified as JOY, if an NLI models predicts that it entails the artificial sentence “This person expressed a feeling of pleasure”. We can substitute pleasure with other emotion-expressing words and map them to specific target labels (e.g., pleasure to JOY, sad to SADNESS, etc.) to build a system for zero-shot, multi-label emotion classification.

Following Yin et al. (2019), in this work we explore two options to formulate the hypotheses: based on the label’s name and on the label’s WordNet (Fellbaum, 1998) definition. We show the details about our hypotheses for emotion classification in Table 2.

We experiment with six different pretrained NLI models that differ in terms of the underlying pretrained language model (BART (Lewis et al., 2020), RoBERTa (Liu et al., 2019) and XLM-RoBERTa (Conneau et al., 2020)) and NLI dataset used for training (Multigenre NLI (MNLI) (Williams et al., 2018), Adversarial NLI (ANLI) (Nie et al., 2020) and XNLI (Conneau et al., 2018)). In Table 3.B of Section 6 we include the details about our models. The zero-shot setup motivates the usage of a variety of pretrained NLI models: given that in a true zero-shot scenario no development dataset is available, assessing how different NLI training data and pretrained language models impact the performance is of crucial importance.

We conduct the few-shot learning experiments by fine-tuning a pretrained entailment model. To build the training data, we fill the templates used in the zero-shot setup with the gold labels and training follows the standard sentence pair classification task used to train the original entailment model.

5 A Probabilistic Ensemble

In a true zero-shot classification scenario, no development set is available and therefore a method for estimating the performance of the model on the specific input data is required. In this work, we propose to use several different models and to infer the best possible answer using a probabilistic model. Such a model has two advantages over a simple majority voting strategy: first, it has been shown to outperform majority voting (Snow et al., 2008); second, it provides a confidence value for each instance and estimates the models’ accuracy.

To aggregate the predictions from the different unsupervised models, we use the Multi-Annotator Competence Estimation (MACE) model (Hovy et al., 2013). This model has been originally developed to analyse crowdsourced annotations for both identifying unreliable annotators and retrieving the true labels. Figure 1 shows the plate diagram of the model and we refer to the original publication for further details. Algorithm 1 describes the generative process.

We generalize the notion of annotator to also

\quad \quad \text{else} \\
\quad \quad \quad \left[ y_{i,n} \sim \text{Multinomial} \left(\xi_j\right) \right] \\
\]

Figure 1: The MACE model. Given \( I \) instances and \( N \) annotators, the observed label \( y_{i,n} \) is dependent on the gold label \( G_i \) and \( B_{i,n} \), which models the behaviour of annotator \( n \) on instance \( i \). The model parameters \( \theta \) and \( \xi \) are left out.

6 Evaluation

We evaluate the unsupervised models in a zero-shot configuration against two supervised baselines. We then experiment with adding increasing amounts of supervision to both the baselines and the entailment model in a few-shot setting. We conduct all the evaluation using the standard classification metrics: precision, recall, and macro-averaged f1-score.

Baselines As upper-baselines for our experiments, we train two supervised models on all the available training data: we train both a neural network based on RoBERTa-base (Liu et al., 2019) and a linear SVM using character n-grams as representations (henceforth referred to as Char-SVM).  

Entailment Models We assemble 12 different unsupervised zero-shot classification models finetuned on the NLI task. The models differ in terms of the pretrained language model, label template and NLI finetuning data. Yin et al. (2019) a) explore two different evaluation scenarios: label-partially-unseen and label-

----
3The original Java implementation can be found at https://github.com/dirkhovy/MACE

4We use a custom implementation of a RoBERTa and use the pretrained model from https://huggingface.co/models. For the SVM model, we use the LinearSVM implementation contained in scikit-learn (Pedregosa et al., 2011).
fully-unseen. In the partially-unseen setup, a model is trained on a subset of the label set and then evaluated on the full dataset; in the fully-unseen setup, no labelled data is shown to the model. In this work we do not take into account the label-partially-unseen because, as stated by Yin et al. (2019), this is a restrictive definition of the zero-shot paradigm, unlike the label-fully-unseen scenario. For the few-shot evaluation, we only train the best-performing model (distilbart-mnli-12-1). Information about the used hyperparameters can be consulted in A.

**Probabilistic Ensemble** We train a MACE model using Variational-Bayes on the predictions of the 12 zero-shot entailment models. We train the model for 100 iterations and 50 restarts; we use the default values (0.5) for the $\alpha$ and $\beta$ parameters.

**Results** As reported in Table 3, emotion classification is a challenging task even for fully-supervised models trained on large annotated datasets. Interestingly, RoBERTa-base, a large neural model, outperforms the CharSVM model only by few points. The battery of zero-shot models shows a large variation in terms of performance, ranging from 8.01% f1-score for XLM-RoBERTa-large with WordNet-based hypothesis to 20.12% for distilbart with label names. The performance of that distilled entailment model is remarkable, considering that bart-large uses twice the number of parameters of its distilled version. On average, name-based templates outperform WordNet-based ones. Aggregating the predictions of the zero-shot models using MACE leads to a much higher f1-score when compared to majority voting. The MACE-based ensemble outperforms the strongest zero-shot model in terms of f1-score by a small but statistically significant margin (+0.84% f1-score). However, in a true zero-shot scenario, where no evaluation

Table 3: Overview of the evaluation results. Scores are macro-averaged. L: embedded label name for hypothesis representation; W: WordNet definition for hypothesis representation. [ ]: distilled model. Rows in A: fully supervised. Rows in B: zero-shot. Rows in C: aggregations. Rows in D: few-shot learning, each row denotes the number of training instances; the results are averaged over three runs and the standard deviation is shown in subscript. Statistically significant results according to a $\chi^2$ test, per sub-table, are highlighted in bold. Significant results between Zero-shot and the aggregations (B and C sub-tables), are highlighted with *.
set is available, simply discarding the predictions from weak, unfit models and selecting the best ones available, is crucial for deploying zero-shot models in a production environment. Our results show that for emotion classification, the model-based aggregation can not only automatically select the best available model, but also improve its performance.

When few annotated instances are available, our results show that entailment models perform notably better than supervised models: Figure 2 shows that a finetuned entailment model outperforms by a large margin not only a linear baseline model using shallow features but also a strong neural LM-based model. The RoBERTa-base model is outperformed by the entailment model by a large margin (+6.98% f1-score) when trained on the full dataset. This highlights a key advantage of few-shot learning for under-resourced scenarios.

Given the diverse nature of the data that compose the Unify Emotion dataset, we evaluate four different models on the individual datasets contained in Unify Emotion: Table 4 highlights the results. As shown already in Bostan and Klinger (2018), some datasets are easier to model than others. CrowdFlower and DailyDialog are relatively noisy datasets and all the models struggle on them. Datasets containing noisy text written in non-canonical language (e.g., Electoral-Tweets, Grounded-Emotions), seem to challenge the zero-shot models more than corpora like ISEAR and Tales-Emotion which contains more standard text. ISEAR’s annotation format is particularly close to the pseudo-sentences that we used (i.e., “This person feels [...]”), which can explain the high performance achieved by the zero-shot model.

7 Conclusions

In this work we presented an emotion classification model that does not require large annotated data to be competitive on the Unify Emotion dataset. We experimented with pretrained language models in both the zero-shot and few-shot settings. We aggregated the predictions of these models using MACE, a Bayesian method developed for modelling noisy, crowdsourced annotations. Experimental results showed that the resulting system performs better than the strongest individual zero-shot model. When evaluated on a diverse dataset, our zero- and few-shot models behave in a comparable way to fully-supervised models, without requiring the same amount of annotated data. Noisy text seems to challenge the NLI models trained on canonical text, while zero-shot models perform well when the annotation scheme matches the pseudo-sentences used for building the synthetic data: this suggests that different domains might need different templates that take into account elements like vocabulary or stylistic variation. Finally, we showed that when the MACE and the few-shot systems are trained...
on few labelled data, they outperform fully-supervised models.

In future works we will further explore how to apply zero and few-shot learning for text classification tasks, and how to better aggregate the outputs of different models in an unsupervised manner.

A Appendix

A.1 Hyperparameters

Training the Entailment model in a few-shot scenario was carried out using a single NVIDIA GeForce GTX 1080 Ti, which allows to allocate up to 11GB of RAM. This has constraint some of the hyperparameters we have chosen to try.

Aside from that, we have also followed the recommendations shared by Wang et al. (2021) because our experiments with few-shot learning were very similar to theirs.

**Batch size and Maximum Length** A batch size of 8 samples was used. The maximum length was adapted to the maximum number of tokens seen when encoding the whole Unified dataset with the corresponding tokenizer of the chosen model (distilbart-mnli-12-1). When computing this, it was also taken into account the fact that, for the entailment approach, the label description or hypothesis is encoded as an additional input to the model. The final selected value was 286 tokens.

**Learning Rate** Typical learning rate values recommended for fine tuning an Adam optimizer are: 5e-5, 3e-5, 2e-5 (Devlin et al., 2019). Following the implementation of Wang et al. (2021), we used a constant and smaller value of 1e-5.

**Epochs** As a practical consideration we decided to train just 1 epoch because we observed that training on more steps reduced the overall performance.

**Number of trials** In order to avoid instability among reported results, mainly caused by the small number of samples used in few-shot experiments (Wang et al., 2021; Gao et al., 2021), the metrics measuring the performance of the model are averaged among 3 different runs that are trained over its corresponding randomly sampled training sets from the whole Unified dataset.
Cross-Lingual Wolastoqey-English Definition Modelling

Abstract

Definition modelling is the task of automatically generating a dictionary-style definition given a target word. In this paper, we consider cross-lingual definition generation. Specifically, we generate English definitions for Wolastoqey (Malecite-Passamaquoddy) words. Wolastoqey is an endangered, low-resource polysynthetic language. We hypothesize that sub-word representations based on byte pair encoding (Sennrich et al., 2016) can be leveraged to represent morphologically-complex Wolastoqey words and overcome the challenge of not having large corpora available for training. Our experimental results demonstrate that this approach outperforms baseline methods in terms of BLEU score.

1 Introduction

Definition modelling, introduced by Noraset et al. (2017), is the task of automatically generating a dictionary-style definition for a given target word. Definition modelling can provide more-transparent, human-interpretable representations of the information in embeddings. Definition modelling could also potentially be applied to automate, or semi-automate, the constructing or updating of dictionaries, for example, by generating draft definitions for newly-emerged words that are not yet listed. Although there has been a range of work on definition modelling (e.g., Ni and Wang, 2017; Gadetsky et al., 2018; Chang and Chen, 2019) the focus has been on monolingual definition modelling, with the target word and generated definition being in the same language.

Malecite-Passamaquoddy (also Maliseet-Passamaquoddy, Passamaquoddy-Maliseet) is an Eastern Algonquian language spoken in regions of what is now New Brunswick and Quebec, Canada, and Maine, United States. Malecrite and Passamaquoddy are dialects of this language. However, Malecite is a Mi’kmaq exonym, with Wolastoqey being the term this speech community uses to refer to their language. We therefore use the term Wolastoqey throughout this paper.

Wolastoqey is an endangered language, with roughly 300 remaining first language speakers in Canada (Statistics Canada, 2017). Moreover, children are typically not learning the language proficiently. Wolastoqey is also a low-resource language, with no large corpora or annotated datasets available for training natural language processing (NLP) systems. However, the Passamaquoddy-Maliseet Dictionary (Francis and Leavitt, 2008) is available online through the Passamaquoddy-Maliseet Language Portal. This dictionary includes roughly 19k entries with Wolastoqey headwords and English definitions. Many entries also include parallel Wolastoqey-English example sentences. There has been very little prior computational work on Wolastoqey, with Farber (2015) presenting a preliminary finite-state model of nouns.

Wolastoqey, like other Algonquian languages, is polysynthetic. Verbs in particular have rich morphological structure, and often include several roots (Leavitt, 1996). Consider the example gloss below for paskoloqessu:

<table>
<thead>
<tr>
<th>pask-oloq-ess-u</th>
</tr>
</thead>
<tbody>
<tr>
<td>breaking-ice-move.quickly-s/he</td>
</tr>
</tbody>
</table>

‘She or he moves quickly across ice as it cracks’

The root *oloq* can be seen in various other words, such as ’*ketoloqtehmon* ‘s/he chips it out of ice’, *sahsoloqe* ‘it is slippery, is icy’, and *supoloqe* ‘there is smooth ice (on lake, etc.)’. There is, however, ambiguity in that the character sequence *oloq* does not always correspond to this morpheme. For example, in *oloqapeku* ‘s/he crawls in that direction’ *oloq* has the meaning of ‘in that direction’.

All examples are taken from the Passamaquoddy-Maliseet Language Portal.

In this paper we propose a model for cross-lingual Wolastoqey-English definition modelling. We hypothesize that sub-word representations of Wolastoqey words based on byte pair encoding (BPE) tokenization (Sennrich et al., 2016) can be leveraged to generate English definitions. We propose a sequence-to-sequence model (Sutskever et al., 2014) in which the encoder operates over Wolastoqey words segmented via BPE, and the decoder generates English definitions. We show that our proposed model is able to outperform baseline systems in terms of BLEU score.

Wolastoqey speakers regularly create new words by creatively combining roots (Leavitt, 1996). As such, not all words can be expected to be included in a dictionary. Cross-lingual Wolastoqey-English definition modelling could therefore be helpful for Wolastoqey learners.

2 Related Work

The task of definition modelling is to learn to generate a dictionary-style definition for a given input word. This task was initially described by Noraset et al. (2017), who focused on generating English definitions for English words. Noraset et al. proposed a word-to-sequence neural language model, composed of a two-layer LSTM and a parallel CNN, to generate a definition given an initial input word and its embedding. This language model-based approach generates definitions by iteratively predicting the next occurring word given some prior history. In this model, different inputs were given to each of the sub-components. The LSTM component was initially given the embedding for the word being defined, but also considered the embeddings of its previous output in the form of context at a given timestep. The CNN sub-network, on the other hand, was used to extract character-level information about the word and, as such, was given the characters of the word being defined. The CNN was included because the word-level LSTM has no knowledge of sub-word information. Manual analysis of the proposed system’s performance considered seven types of errors that were observed to occur in the generated definitions. These include redundancy, self-reference, wrong part-of-speech, under-specification, opposite definition, close semantic errors, and incorrect definition generation. Out of all these errors, incorrect definition generation was observed to be the most common. This paper further found that high-quality word embeddings were crucial for definition modelling to be successful.

One challenge for our work is that we do not have a large corpus available from which to learn high-quality Wolastoqey word embeddings. We propose to use BPE segmentation to overcome this. Specifically, we hypothesize that sub-word representations based on BPE can be leveraged to represent morphologically-complex Wolastoqey words without requiring a large corpus to be available for training word-level embeddings.

The approach of Noraset et al. (2017) is context-agnostic; i.e., the model generates a definition for a target word without any specific context of usage for the target. Other context-agnostic approaches to definition modelling include Yang et al. (2020) who incorporate knowledge of Chinese sememes (minimum semantic units) for Chinese definition modelling, and Balachandran et al. (2018) who propose a domain-specific definition generation model for the software domain. In line with these previous studies, we also propose a context-agnostic approach.

Contrasting with context-agnostic approaches, context-aware approaches to definition modelling have also been considered (e.g., Ni and Wang, 2017; Gadetsky et al., 2018; Mickus et al., 2019). In these approaches a definition is generated for a target word used in a specific context. Some context-aware methods have used a sequence-to-sequence model (Ni and Wang, 2017; Mickus et al., 2019) as does our proposed approach. Ni and Wang propose a sequence-to-sequence model to generate definitions for non-standard English words. Their encoder uses a character-level LSTM to represent the target word and a word-level LSTM to represent the context. An LSTM is also used for decoding. Our proposed approach is similar to that of Ni and Wang, but we do not use an LSTM to encode context, and our LSTM which encodes the target word operates over BPE tokenization as opposed to characters.

An alternative line of research considers definition extraction (e.g., Navigli and Velardi, 2010) in which sentences containing terms and their corresponding definitions are automatically identified in corpora. We focus on definition modelling, as opposed to extraction, because there are very few corpora containing English definitions of Wolasto-
key words on which to apply a definition extraction method, and because Wolastoqey is a polysynthetic language and as such many possible words would not be expected to be found in corpora.

3 Model

Cross-lingual definition modelling can be seen as a machine translation task which involves translating a word in a source language to a definition in some target language. We therefore consider using a network architecture proposed for the task of translation rather than a word-to-sequence model proposed in previous work on monolingual definition modelling (e.g., Noraset et al., 2017). Specifically, we consider a sequence-to-sequence model that makes use of an attention decoder (Bahdanau et al., 2014). We base our model on a sample sequence-to-sequence translation model.\(^2\)

3.1 Encoder Architecture

For our encoder model’s architecture, we use a simple recurrent neural network consisting of an embedding layer followed by a long-short term memory (LSTM) layer. The structure of the encoder is shown in Figure 1.

The embedding layer of our model serves the purpose of representing the meaning of the sub-word tokens that compose our vocabulary. To obtain the embeddings used by our encoder, we consider the approach of initializing the weights of our embedding layer to zeroes as well as the approach of first pretraining our embeddings on a corpus of example sentences extracted from the Passamaquoddy-Maliseet Dictionary. While training, we allow the weights of the embeddings to be updated through gradient descent, but also consider freezing these weights in the case of pretrained embeddings. This is done to further analyze the effects pretraining has on system performance.

At a given timestep, input is passed into our encoder in the form of a sequence of indices corresponding to sub-word representations in our input vocabulary. At a given time-step, the encoder will consider a given input subword. For this subword, the encoder will start by looking up its embedding using the embedding layer. This embedding will then be passed to the LSTM layer. From here, the LSTM layer will use this embedding, the hidden layer of the previous time-step and the context from the previous time-step layer to calculate the value for the current hidden layer which acts as the decision at the current timestep. The context is then updated with the information regarding the current decision, and then passed forward with the output at the current time-step. Once all of the outputs have been calculated, we pass the encoder outputs to the decoder.

3.2 Decoder Architecture

The decoder architecture is shown in Figure 2. Rather than relying on a single vector to contain all information about the input sequence, we instead use an attention decoder to consider the encoder outputs more holistically. Our decoder consists of an embedding layer, two intermediary linear layers, a recurrent LSTM layer and a final linear layer.

\(^2\)https://github.com/spro/practical-pytorch
which we then softmax over to get the output at a given timestep. We apply dropout regularization to the embedding layer in an effort to avoid overfitting.

At a given timestep, input is given to our decoder in the form of the decision made at the previous step, or, in the case of the first decision, a start of sequence token, and will take the form of an index of a token contained within our output vocabulary. We then use this index to look up the embedding for the word through the embedding layer. From here, we concatenate the embedding with the hidden state from the previous decision. We pass this value to the first linear layer which will give us weights we can then compare to the encoder outputs through batch matrix multiplication. This product will then be passed to another linear layer with a ReLU activation function which will set all negative values to 0. This value is then passed as input to our LSTM layer, which will also consider the previous hidden layer and the context from the previous time-step. This will give us updated context and hidden states, which we will pass forward to the next timestep. However, to get the current output, we will need to pass the resulting vector from the recurrent component of our system to another linear layer. The results from this layer will then be softmaxed to give us the final output, and our decision for the current timestep.

3.3 Model Variations

In addition to the base model described above, we also consider two architecture variations designed to analyze the effect of model complexity on performance. Specifically, we consider replacing the unidirectional LSTM layers used in both the encoder and decoder with comparatively simpler GRU layers, and comparatively more complex bidirectional LSTM layers. We consider this because we have a relatively small training corpus which might not be large enough to adequately train more complex models. Although bidirectional LSTMs have been shown to perform better than GRUs and unidirectional LSTMs when sufficient training data is available, they generally perform worse when insufficient training data is available. By considering these model variations, we can attempt to determine whether we have enough training data to justify the use of more complex models.

4 Experimental Setup

In this section, we describe the dataset constructed for these experiments, the evaluation methodology used, and implementation details for our proposed model.

4.1 Dataset

Wolastoqey is a low-resource language. As such, we are limited in regards to our choice of dataset. For cross-lingual Wolastoqey-English definition modelling we require a dataset consisting of Wolastoqey headwords and their corresponding English definitions. The Passamaquoddy Maliseet Dictionary consists of Wolastoqey head words and their corresponding English definitions. Many entries also include parallel Wolastoqey-English example sentences. We use the headwords and definitions to construct our dataset. We use the example sentences to train embeddings, as well as our BPE tokenizer in the case of Wolastoqey.

The Passamaquoddy-Maliseet Dictionary is available online. There is, however, no publicly available download for the contents of this dictionary. We therefore use Selenium, a web automation tool, to crawl the dictionary and extract the entries.

After scraping the dictionary content, we normalize the text. For this, we remove any entries containing errors such as #NAME? as a headword. As each headword can have multiple definitions associated with it, we split definitions on semi-colons as they are used as the primary definition delimiter. We perform a similar operation for the headwords themselves, as an entry can include multiple word-forms for the headword. We split the headword text on commas, with each extracted headword being used to create word-definition pairs with respect to all available definitions for a given word.

Wolastoqey has four parts-of-speech (POS): nouns, pronouns, verbs, and particles (Leavitt, 1996). For this dataset we only include headwords that are nouns, verbs, and particles because there are relatively few entries that are pronouns.

This extraction method produces a dataset that contains 22.5k headword-definition pairs from 19k valid entries. We then split these pairs into training, development, and test sets. To do this, we first group the data based on headwords to prevent any headword with the same form from appearing in more than one of the sets. Once we have grouped the headwords, we then split the data by headword with 80%, 10%, and 10% of headwords in the train-
ing, development, and test sets, respectively. The training set is used for training our model. The development set is used for model tuning. The test set is held out for final evaluation.

In addition to the dictionary headwords, we also extract 18.6$k$ Wolastoqey-English sentence pairs pulled from all valid dictionary entries containing example sentences. As we use these example sentences to train our embeddings, we split this parallel corpus into separate monolingual Wolastoqey and English corpora consisting of 80.5$k$ and 181.9$k$ tokens, respectively.

4.2 Evaluation

Following previous work on definition modelling (Noraset et al., 2017; Ni and Wang, 2017; Gadetsky et al., 2018) we use BLEU score (Papineni et al., 2002) for evaluation. At test time, we generate an English definition for each Wolastoqey headword (in either the development or test set) and calculate the BLEU score between this generated definition and the gold-standard reference definition for this headword.

We compare our proposed model against a baseline that outputs a randomly selected definition from the development set for any input. This baseline will always produce a syntactically well-formed definition, but the definition is unlikely to be semantically appropriate. We consider two variations of this baseline, POS-aware and POS-agnostic, which differ with respect to knowledge of the POS of the input. The POS-agnostic baseline simply outputs a randomly selected definition. The POS-aware baseline outputs a randomly selected definition corresponding to a headword with the same POS as the input. 3

We implement our proposed model using PyTorch 1.7.1. We use a hidden layer size of 256 for each layer in both the encoder and decoder sub-models. Our decoder sub-model’s dropout layer uses a dropout rate of 0.1. To train our model, we use an Adam optimizer with a learning rate of 5e-4. We train all our models for a total of 15000 iterations. We use teacher forcing as our training regimen.

To obtain sub-word representations we use the Huggingface Tokenizers 0.10.1 library. For English, we use the pretrained word-piece DistilBERT (Sanh et al., 2019) tokenizer. For Wolastoqey, we train a BPE tokenizer on the Wolastoqey exam-

ple sentences extracted from the Passamaquoddy-Maliseet Dictionary.

To learn pretrained embeddings we consider both word2vec skip-gram with negative sampling (Mikolov et al., 2013) and fastText (Bojanowski et al., 2017). We use the Gensim version 3.8.3 implementations of skip-gram and fastText. We use the default parameter settings (i.e., a window size of 5 sub-word tokens and 100 dimensional embeddings) except for the minimum frequency to be included in the embedding matrix, which we set to 1 (as opposed to the default of 5) because of the small size corpora we use for training.

We calculate BLEU score using the implementation available in NLTK 3.5 (Bird et al., 2009).

5 Results

In this section we first consider tuning the vocabulary size for the Wolastoqey BPE tokenizer in experiments on development data (Section 5.1). We then present our main results on test data, including an analysis of the impact of pretraining embeddings (Section 5.2) and results for the model variations presented in Section 3.3 (Section 5.3). We then present a qualitative evaluation of the model (Section 5.4).

5.1 Tuning Vocabulary Size

We conduct a grid search to find the optimal vocabulary size for our Wolastoqey BPE tokenizer. The BPE vocabulary will directly affect how our Wolastoqey input words are tokenized and could potentially drastically impact the performance of our proposed model. As we are investigating whether sub-word representations can be leveraged for Wolastoqey-English definition modelling, it is important to determine the optimal vocabulary size.

We consider vocabulary sizes from 2500 to 15000 in increments of 2500. Results on development data are shown in Figure 3. We observe that the optimal vocabulary size is 7500 sub-word tokens. We also observe a steep drop-off in performance when using a vocabulary size that exceeds 7500 tokens. We further observe that the relative performance across parts-of-speech is similar regardless of vocabulary size. We use a vocabulary size of 7500 for the Wolastoqey BPE tokenizer for the remainder of the experiments. At this vocabulary size, each Wolastoqey verb, noun, and particle in the development data is represented by an average of 3.21, 2.56, and 1.93 sub-word tokens,

3 Although we compare against a POS-aware baseline, the proposed model itself has no knowledge of POS.
Figure 3: BLEU score for various Wolastoqey BPE vocabulary sizes on development data.

Table 1: BLEU score for each model overall and for each POS.

respectively.

5.2 Effects of Pretraining

Results on test data for the proposed model and the baselines are shown in Table 1. We first consider the baselines. The POS-aware baseline, as expected, outperforms the POS-agnostic baseline, overall and for each POS.

The base model (i.e., the model proposed in Sections 3.1 and 3.2) outperforms both baselines. This finding demonstrates that sub-word representations of Wolastoqey words based on BPE can be leveraged to generate English definitions. We note that the performance is much better on verbs, which are the most common POS in our datasets, than other parts-of-speech. We hypothesize that this is because Wolastoqey verbs often consist of multiple morphemes, and indeed are on average split into more sub-word units than other parts-of-speech in the analysis in Section 5.1, whereas other parts-of-speech often correspond to a single morpheme, and are split into fewer sub-word units. We consider training the base model on only verbs, shown as “Base Model (Verbs Only)” in Table 1. Here we see a slight improvement in performance over the base model on verbs, and a corresponding reduction in performance on other parts-of-speech.

The base model does not use pretrained embeddings. We now consider experiments using pretrained embeddings, in which we allow the embeddings to be adjusted through updating during training (“Adjustable Pretrained” in Table 1). We consider word2vec and fastText embeddings trained on the Wolastoqey and English corpora built from the example sentences in the Passamaquoddy-Maliseet Dictionary (“word2vec (Examples)” and “fastText (Examples)”, respectively). Both of these approaches improve over the base model in terms of overall BLEU score. For English, because it is a high-resource language, we have access to many sources of embeddings which are pretrained on much larger corpora. We therefore consider using English word2vec embeddings pretrained on text from Google News, shown as “word2vec (News)”. This requires switching from word-piece tokenization to word-level tokenization for English. For Wolastoqey, we still use BPE tokenization and train on the corpus of Wolastoqey example sentences. Although these English embeddings are trained on a much larger corpus, this does not yield an improvement over using embeddings pretrained on the English example sentences.

Finally, we consider the impact of allowing the embeddings to be updated during training. We again consider word2vec and fastText trained on the corpora of Wolastoqey and English example sentences, but here we freeze the embedding weights when training the model (“Frozen Pretrained” in Table 1). These methods perform poorly compared to the base model, and compared to the case where the embeddings are updated during training. In particular, here the word2vec embeddings perform roughly on par with the POS agnostic baseline. These findings indicate the importance of allowing the embeddings to be updated during training.

The base model substantially outperforms both baselines considered. In the following subsection we consider further variations on the base model.

5.3 Model Variations

Table 2 shows results on test data for the base model using a (unidirectional) LSTM (i.e., the base model
presented in Table 1) and GRU, and a bidirectional LSTM. We observe that using a GRU in-place of an LSTM gives a better overall BLEU score. Despite being more powerful, the bidirectional LSTM performs worse overall than the unidirectional LSTM base model. We hypothesize that, because of the relatively small size of the training data, simpler models, such as a GRU, can be more effectively trained. This finding, combined with the findings from Section 5.2, suggests that there could be scope for further improvement through the use of pre-trained embeddings with a GRU.

5.4 Qualitative Analysis

While BLEU score provides a method of empirically evaluating our system, we also wish to perform a qualitative analysis of our system’s outputs. For this analysis, we generated definitions for 20 randomly-selected test set Wolastoqey words and manually compared the generated definitions to their ground-truth reference definitions. This analysis was carried out by the first author of this paper, an English first language speaker and Wolastoqey learner. We analyzed the definitions with respect to both semantics and syntax.

For semantics, we considered whether the generated definitions were topically-related to the reference definitions. Of the 20 definitions, 10 were determined to have little to no topical relatedness to the reference definition, 8 showed some level of topical relatedness to their ground truth reference, and 2 were determined to be reasonable definitions for their respective words. For this analysis, we consider reasonable definitions to be definitions that contain few or no syntactic errors and do not significantly vary in meaning when compared to their ground truth references. An example of a word our system is able to reasonably define with little error is ‘t-uwapolokehkimal, which the Passamaquoddy-Maliseet Dictionary defines as ‘s/he instructs h/ incorrectly; s/he teaches h/ incorrect information, etc.’ For this word, our system generates the definition ‘s/he teaches h/ incorrectly’. An example of a generated definition that shows some level of topical relatedness to the reference definition can be seen for the verb kcitawse, for which our system generates the definition ‘s/he walks without walking, walks in’ whereas the reference definition is ‘s/he walks far into or sinks into, s/he gradually works way into’. In this example, both definitions share some reference to the action of walking; however, the meaning of the generated definition deviates from its ground truth reference.

Considering syntax, we observed that 13 out of the 20 definitions generated demonstrated correct syntactic form and were overall comprehensible output sequences.

6 Conclusions

In this paper, we considered cross-lingual Wolastoqey-English definition modelling, in which we automatically generate English definitions for Wolastoqey words. Our work is in contrast to most prior work on definition modelling which has been monolingual, i.e., the word being defined and its definition are in the same language. In further contrast to most prior work on definition modelling, where Wolastoqey is a low-resource language, we do not have access to a large Wolastoqey background corpus for training. We showed that a sequence-to-sequence model that represents morphologically-complex Wolastoqey words at the sub-word level using BPE segmentation outperforms baseline approaches. We further demonstrated that the proposed approach can be improved by pretraining on small Wolastoqey and English monolingual corpora built from dictionary example sentences and by using a GRU instead of LSTM. Qualitative analysis revealed that the generated definitions are often syntactically well-formed and topically related to the gold-standard reference definitions.

In future work we plan to investigate alternative strategies for representing Wolastoqey words in the encoder, including character-level approaches and segmentations based on unsupervised approaches to learning morphology (Creutz and Lagus, 2002). We also plan to explore alternative model architectures, including transformer-based models (Vaswani et al., 2017) and models that incorporate large pre-trained English language models (e.g., Lewis et al., 2020).

Ethical Considerations

Wolastoqey is an Indigenous language and natural language processing can reinforce colonialist views
(Bird, 2020). The first author of this paper is Wolastoqew. The Passamaquoddy-Maliseet dictionary can be used for research purposes. We obtained permission to scrape the dictionary content for use in natural language processing research.

Abstract
This paper presents a global summarization method for live sport commentaries for which we have a human-written summary available. This method is based on a neural generative summarizer. The amount of data available for training is limited compared to corpora commonly used by neural summarizers. We propose to help the summarizer to learn from a limited amount of data by limiting the entropy of the input texts. This step is performed by a classification into categories derived by a detailed analysis of the human-written summaries. We show that the filtering helps the summarization system to overcome the lack of resources. However, several improving points have emerged from this preliminary study, that we discuss and plan to implement in future work.

1 Introduction
In this paper, we propose a new approach for sport commentary summarization. This approach is still an ongoing work, and the results presented here are preliminary. Sport commentaries represent an interesting resource, as the live commentaries we work on are associated with a summary written by an expert: the commentator himself. Indeed, the commentator writes a summary at the end of every game. Automatically generating a game summary would release the commentator from a part of his heavy workload and thus would free up his time for more complex and rewarding tasks, such as game in-depth analysis.

Summarizing live sport events commentaries is a challenging task. First of all, they are live written; new commentaries can conflict with or complete former ones. For example, if a soccer player scores two goals, the live commentaries about each goal are relevant information. However, extracting the live commentaries about each goal will not be sufficient in order to generate a good summary. It would indeed lead to producing redundant summaries.

Moreover, if you consider a game as an event, it is composed of several subevents. Some of them are deemed important enough to be commented. However, most of those commented subevents are not important enough to appear in a summary. So, live commentaries are mostly made up of noise: in a soccer game, there will be more shots than goals, even more substitutions than goals, which are the most important information of a game. This noise has to be filtered. Therefore, studies have to be carried out about the relevance of an information in the game summarization context.

The style of human-written summaries differs from the one of live commentaries. For all these reasons, statistical extractive summarization models are not relevant for this kind of data. Extractive models consist in fact in extracting relevant sentences from source corpora and put them together in order to build a summary. The difference in style between summaries and commentaries and the noise in commentaries are a substantial hindrance to building live commentaries summaries with extractive models. As for neuronal abstractive models, fast-growing these past few years, they need huge training corpora to be efficient: several hundreds of thousands of documents associated to their summary. However, we can only assemble a corpus that covers five years of a national championship – approximately 1700 game commentaries associated with their summary.

Moreover, neural abstractive summarizers are mostly designed for news summarization. News summarization fits well neural summarizers as neural models can only take a limited number of words for input. Journalists use an inverted pyramid structure, so the most important information is packed in the first paragraph. Taking the first n words as input ensures that a neural model will work only with
important information. Live commentaries do not have such a hierarchical structure, and commonly used statistical indicators do not seem to be useful. Therefore, selecting the input of a neural model is a challenge in our application.

In order to overcome these obstacles, we need to train our own abstractive summarization model. We have to reduce the data noise in order to allow the abstractive model to converge quickly with a limited amount of data. We hypothesize that the human summaries variability is low enough to make it possible for the model to learn despite having a small corpus as input.

We propose a global summarization method that aims to lower the input data entropy in order to enhance the automatic summaries quality. This method relies on an information selection prior to learning in order to shorten the input texts and thus get rid of data that are useless to the summary generation.

The paper is structured as follows: in a first part, we present the related work. In a second part, we introduce our corpus and its features. Then we describe our method, followed by the experiments and the results. We end by discussing the results and exposing our perspectives.

2 Related Work

The automatic generation of sports commentary summaries is, to our knowledge, a subject that is very little discussed in the literature.

We can mainly cite the work of (Zhang et al., 2016) which, from game commentaries available online, generates an extractive summary. The method consists of three main steps: a first step of modeling sentences according to surface clues defined empirically as the sum of the \( tf-idf \) sentence words, the presence or absence of important words in the sentence such as “red card”, ”goal”... Then, from a set of reference sentences, a learning step predicts the sentences ROUGE score according to these surface clues. Finally, a last ranking step allows the sentences with the best scores to be incorporated into the summary. According to these authors, however, the approach suffers from several limitations. Since the process is sentence-centered, the summaries generated have a lot of redundancy between sentences. Furthermore, learning tends to penalize short sentences that are sometimes wrongly considered less informative because their direct contribution to the ROUGE score is lower.

On this same task, we can also cite the work of (Bouayad-Agha et al., 2012) whose particularity is to propose a system of generative summary based on the definition of a specialized ontology for soccer games. Thus, from the data extracted from commentaries in an ontology, handwritten rules are triggered in order to rephrase the information and generate a summary. The main limitations of the approach are the need for an exhaustive ontology population (players, teams,...) as well as a generation of stereotypical summaries because they are built from the same rules.

On the same issue but from a very different angle, the work of (Corney et al., 2014) starts from the comments of twitter users during games and produces subjective summaries. For each official commentary related to an event during the game, the supporters’ comments on twitter are analyzed on a 4 minutes window, the goal being to extract the most representative tweet of this event from the subjective point of view of the supporters of each team. For that purpose, the tweets are first distributed between the two teams. A user is defined as a supporter of a team if in his comments the team is overrepresented compared to other teams. In a second step, for each team, the most important topics are detected using a variant of the \( tf-idf \). Finally, for each team, the most representative tweet of the subjects found is selected, without further processing.

More recently, the work of (Li et al., 2019) presents a model able to produce NBA games summaries. Based only on game statistics, it can generate a summary composed of two parts: a game overall summary and a player centered summary. This model uses latest deep learning techniques with a Wasserstein generative adversarial networks (WGAN) proposed by (Arjovsky et al., 2017). However, despite the model used, the method only generates stereotyped summaries filling a fixed template. For the overall summary, the template is defined as follows:

\[
\text{On [Date], [Team(A)] made a [Score(A)]-Score[B] [learned phrase] [Team(B)].}
\]

Except for the learned phrase, all elements in [ ] are directly assigned from game statistics. The learned model will only affect the learned phrase used to characterize with words to which degree team A wins or loses against team B.
To avoid the pitfall of generating stereotypical summaries, given the difference in style between the summaries and the live commentaries, the high noise level in the commentaries and the low volume of data, we choose to stand out from previous methods by taking advantage of recent advances in neuronal generation. To do so, we approach the problem from the perspective of neuronal generation preceded by a noise reduction step in the source texts to allow the generative model to converge quickly.

3 Live Commentaries Corpus

We extracted all the available Ligue 1 soccer games commentaries and their associated human-written summary from L’Equipe website (http://www.lequipe.fr). The archived games with live commentaries cover a five seasons period from 2014 to 2019. Game commentaries are 8000 words long on average and 80 interventions of the commentator. Live commentaries about the game are interspersed with facts about the game players: information about a recent trade, an ongoing goals streak... Manual summaries are 55 words long on average (cf. Figure 1). Therefore, live commentaries are significantly longer than 400 words which is the length commonly used by most neuronal summarization models in order to reduce their complexity (Rush et al., 2015; See et al., 2017).

The complexity of automatic summarization based on such live commentaries is thus far too important, especially given the small amount of documents we can use to learn.

Figure 1 shows the three last minutes of Paris vs Lille commentaries. It displays the noise in these documents. One can especially notice a poll posted by the commentator between 90+1’ and 90+2’ minutes, and three commentaries that one can consider as noise for the purpose of generating a short summary: extra time announcement and three missed actions. One can also notice the difference in style between the summary and the commentaries.

The specificities of these documents force us to rethink the automatic summarization process by first filtering only relevant information, then generating a summary in order to mimic manual summaries style.

4 Our Model

Automatically summarizing soccer game commentaries presents a major difficulty: standard frequency-based techniques for evaluating the importance of a word or sentence are ineffective due to the source documents specificity: the most important information about a game is often the rarest one – result, expulsions, goals. This, combined with the style of the summary which is radically different from the commentaries, led us to abandon the extractive methods for an abstract method. However, the small number of documents that can be used for learning is very restrictive1.

1Even if we had summaries over twenty years, we would have 500 times fewer documents than the CNN/Dailymail Corpora used in most abstractive neural summarization research works.
We hypothesize that, given the small average size of summaries and their low linguistic variability, the decoder part of an encoder/decoder model can learn how to generate a summary using style elements of manual summaries. On the other hand, the relatively large size of the commentaries makes the encoding task more complicated, if not impossible given the small size of the learning corpus.

Therefore, we choose to reduce the entropy of the source texts in order to allow an encoder/decoder to learn how to generate summaries with a restricted corpus size. The simplest idea is to keep in the input commentaries only those that are deemed relevant for the development of a summary, before learning an automatic summary model based on these filtered commentaries. We detail both steps here.

4.1 Sentence filtering

In order to filter the input sentences, we need to characterize the sentences that carry important information, and those that do not. To this end, we decided to rely on the manual summaries written by the game commentators. We assume that these summaries contain only relevant information.

4.1.1 Manual corpus annotation

We analyzed an entire year of League 1 (so 380 pairs of live commentaries / summary) and typed the information found in the summaries. The presence of a particular information within a summary is a sign of its relevance. We therefore identified the types of information, then counted the occurrences of the different types of information and kept the most frequent ones.

This led us to the following list of information categories, summarized in Table 1.

Table 1: Information categories and the percentage of summaries in which they are represented (based on an entire League 1 season)

<table>
<thead>

</table>

Then, we systematically searched for this information in the live commentaries and annotated them according to the type of information they conveyed. For example, the figure 1 does not contain a relevant commentary, but the game summary contains important information: Neymar’s return, PSG’s efficiency (“surgical, the Argentinians...”), Icardi’s goal, Di Maria’s goal, PSG’s victory (resulting from the half-time win and subsequent management). In this summary as in many others, information is implied and derived from other information, which has made the task of defining types of information particularly complex. Thus, we have an annotated corpus to learn to categorize commentaries according to the information they carry.

4.1.2 Categorizing Commentaries

We kept only the 17 most frequent classes, considering that below a certain threshold – empirically set – the frequency of a type of information within the summaries was too low for it to be considered important.

Before proceeding with the sentences classification, we trained a language model (Bengio et al., 2003) (Sundermeyer et al., 2015) on the commentaries corpus in order to take into account the specificities of this particular corpus (specific vocabulary, different style from the general language). This model, represented in figure 2 learns word embeddings thanks to a neural network of bi-LSTM (Graves and Schmidhuber, 2005) units which aims at improving the next-word probability prediction.

Figure 2: Language model architecture

We then proceeded to train a binary classification model of commentaries on a one-year sample of annotated commentaries. The model used represented in figure 3 is a Bi-LSTM (two successive layers of LSTM, one proceeding from the beginning to the end of the sentence, the other from the end to the beginning of the sentence). This bi-directional architecture allows better results in
language processing tasks. The input layer takes a game commentary and the output layer a binary value. The commentary is classified as relevant if it covers one of the 17 selected categories, otherwise the game is classified as irrelevant.

![Figure 3: Classification model architecture](image)

We applied this model to all commentaries outside the learning corpus. As a result, we can filter and present to a neural summary model only the commentaries deemed relevant, and thus improve the model response by reducing the entropy of the input data. The results of the binary classification are presented in Table 2.

4.2 Generative summary model

We used a pointer-generator network (See et al., 2017). We trained it on two different datasets: a Raw corpus and a filtered corpus (binary classes). Pointer-generator is a supervised learning method derived from sequence-to-sequence translation models (Bahdanau et al., 2014) with an attention mechanism (Nallapati et al., 2016).

5 Experiments

To test our approach, we compare two automatic summary models: an extractive method, TextRank (Mihalcea and Tarau, 2004) as well as a generative method, pointer-generator on the sample of the last 167 League 1 games that were not used during any learning step.

**Experimental Setup:** Both methods are tested with and without prior filtering of the sentences judged relevant, according to the method presented in §4.1.2, in order to validate the hypothesis that reducing entropy in source texts has a positive effect on model convergence and on the quality of the summaries produced. The workflows for generative methods with and without pre-filtering are shown in Figures 4 and 5.

![Figure 4: Pipeline architecture without classification](image)

The language model uses a word embedding layer of dimension 64. The recurrent cells of the encoder and decoder are of dimension 64. The size of the output layer is the size of the vocabulary, which is 4480.

The classification model uses the same word embedding layer that it retrieves from the language model after training and two layers of LSTM (bi-LSTM) each of size 16, the output layer is of size 2 (0 or 1 for important and unimportant).

The pointer-generator model uses an encoder and a decoder with bi-LSTMs of dimension 128. The vocabulary size of the model is 50000. During training, the model takes texts truncated to 400 words and produces summaries of no more than 100 words, which is much more than the number...
of words used in human summaries. In order to reduce the size of the problem and speed up training, we have a batch size of 4. Error backpropagation is done with the Adam optimizer with a learning rate of 0.15. The models were learned over 30000 iterations (80 epochs). It takes fewer iterations than the See et al. (2017) model to get results because our training set is much smaller.

**Evaluation Metric:** Summaries are evaluated with the commonly used ROUGE package (Lin, 2004). The ROUGE-N score is a metric that compares the N-grams in common between the reference summary and the summaries to be evaluated. We took as a reference summary the summaries written by the commentator at the end of the game.

We use the specific configuration that showed the best correlation with human evaluations in Graham (2015) (a ROUGE-2 precision score).

**Baselines:** We compare the generative method to two extractive methods: one without, and one with filtering commentaries. We use TextRank (Mihalcea and Tarau, 2004), a method comparable to (Radev, 2004) but designed for mono-document summarization. It is a graph-based method that considers summarization as the extraction of the most central sentences in a graph. The implementation used is the one of Nyzam and Bossard (2019), freely available online\(^2\). Even if TextRank method was designed in 2004, it was shown in (Zheng and Lapata, 2019) that it still compares to more recent methods when there is no correlation between sentence position and centrality.

### 6 Results

The results are presented in the table 3. We observe a consequent improvement in the ROUGE scores of the extractive and generative models when run on filtered commentaries.

We also find that extractive models are better in recall but less accurate than generative models. The extractive model used here indeed maximizes the number of words in the abstracts, unlike the generative model. As a result, extractive summaries are composed of 69 words on average compared to 44 words for generative summaries, so they can carry more information.

It is also noted that while the generative summaries present relevant information, it is often poorly expressed. Figure 6 shows an example of a summary generated by our system (we try to retranscript syntactic errors in our translation in italics)

**Table 3:** ROUGE-2 Scores of the different summary systems. The best score obtained with Graham (2015)’s configuration is in bold.

Extractive summaries contain a great deal of redundancy and irrelevant information. Using surface clues other than purely frequency clues, such as (Zhang et al., 2016), would surely partly solve this problem. Figure 8 presents an extractive summary for the same game as the summaries of Figures 6 and 7.

### 7 Discussion

Our model offers relevant information, but with an approximate linguistic quality. We assume that

---

**Figure 6:** Example of a summary generated by our generative system (we try to retranscript syntactic errors in our translation in italics)

**Figure 7:** Example of a manual summary written by L’Equipe’s commentator (our manual translation in italics)
Figure 8: Example of an extractive summary (manual translation in italics)

Sala scores a brace! Thomasson keeps pushing on the left of the box but gets blocked by a LOSC player. Lucas Lima gets the ball and crosses with his left foot. Free at the 6-yard line, Sala heads the ball and beats Maignan on his left side. Sala forward. © L’Equipe Thanks to his scorer Sala (9th goal in L1 this season), the FC Nantes leads unsurprisingly after the first half as they were solid and efficient. Sala scores! He crosses for Thomasson who passes towards Sala. Sala forward

this lack of linguistic consistency is mainly due to the lack of training data; it prevents the model from capturing language features despite the low linguistic variability displayed in human-written summaries due to document specialization.

As we assumed, the extractive model results in very noisy juxtapositions of commentaries that contain a lot of irrelevant information. The results are therefore far away from human summaries. This is shown on the one hand by reading the summaries produced and on the other hand by the evaluation of the ROUGE score.

Commentary filtering prior to learning does improve the quality of the generated summaries. Learning is simplified by reducing noise and the size of the input data.

We did not perform a manual evaluation of the summaries, because the work is still in its early stages and the time needed for a manual evaluation, e.g. pyramid (Nenkova and Passonneau, 2004) is better spent in late stages. However, we analyzed the automatic summaries produced by our method, and we made the following observations:

- they are close to be grammatically correct;
- even if their ROUGE-2 scores are twice as good as TextRank model, they lack some major information;
- linguistic quality of the results with pre-filtering is far better than without pre-filtering (observation that needs to be confirmed by an accurate evaluation).

This can be due to several causes: first, even if we filtered the commentaries, they are still longer on average than the 400 words commonly used as input of neural summarizers (and used by our summarizer as well). Given the small amount of data available for training and the fact that information is cut from the input texts, it can explain that major information is missing.

Second, the filtered commentaries are still noisy. Instead of using filtering techniques, information extraction techniques could be used to fill predefined templates for the 17 important information categories we defined in §4.1.1. This would lead to more concise input texts, focusing on the core of each relevant information only.

Third, some information cannot be found in the commentaries. We think of championship ranks, ongoing streaks, which are rarely raised in pre-game commentaries, or the overall technical quality of a game, which can be derived from game statistics (percentage of completed passes). However, these statistics can be extracted and given as input of the pointer-generator decoder. This way, the pointer-generator would have access to the information needed to generate sentences conveying what our analysis of the data considered as major information.

8 Conclusion

In this paper we presented a model that allows the generation of abstractive summaries of specialized documents with limited data in French language. Our goal was to show that for summary generation and in specific contexts, abstract models could converge more quickly by reducing the entropy of the input data. Our preliminary results show that after having filtered the input texts and even with a small amount of data, the neural summarizer reaches a much higher precision, and also a better linguistic quality.

We found that much of the information needed to manually generate summaries is not present in the live commentaries. Indeed, many important facts: absence of a player, efficiency, domination of a team, balanced game, are often only deductible from non textual data. Systematically providing this input data to a generative system can help it to improve summary generation. In this way, we plan to add to the text sequences the relevant statistics for the generation of summaries. We also plan to provide more focused and concise texts as input to a neural generative summarizer in order to improve its summaries even with a limited amount of data. We could also improve a language model by using extra texts about soccer games, and thus improve the linguistic quality of the generated summaries.

Abstract

Split-and-rephrase is a challenging task that promotes the transformation of a given complex input sentence into multiple shorter sentences retaining equivalent meaning. This rewriting approach conceptualizes that shorter sentences benefit human readers and improve NLP downstream tasks attending as a preprocessing step. This work presents a complete pipeline capable of performing the split-and-rephrase method in a cross-lingual manner. We trained sequence-to-sequence neural models as from English corpora and applied them to predict the transformations in English and Brazilian Portuguese sentences jointly with BERT’s masked language modeling. Contrary to traditional approaches that seek training models with extensive vocabularies, we present a non-trivial way to construct symbolic ones generalized solely by grammatical classes (POS tags) and their respective recurrences, reducing the amount of necessary training data. This pipeline contribution showed competitive results encouraging the expansion of the method to languages other than English.

1 Introduction

Text Simplification (TS) is the process of modifying natural language to reduce complexity and improve both readability and understandability (Shardlow, 2014). A simplified vocabulary or a simplified text structure can benefit people with limited language skills, such as those with low education levels, children, non-native speakers, and individuals with learning impairments (e.g., autism, dyslexia, or aphasia) (Štajner et al., 2015; Guo et al., 2018). Furthermore, when applied as a preprocessing step, TS may also improve the performance of several natural language processing (NLP) tasks, such as parsing, machine translation, semantic role labeling, text summarization, information extraction, among others (Niklaus et al., 2019a; Štajner and Popović, 2019).

Most work on TS has concentrated on analyzing specific characteristics at the sentence level, fashioning the task of sentence simplification (SS) (Alva-Manchego et al., 2020). SS applications aim to identify and solve two main aspects: lexical complexity, which refers to difficult words or expressions in the text (e.g., non-frequent words, specific terminologies, foreign words, etc.) (Štajner et al., 2020; Narayan and Gardent, 2014); and syntactic complexity, which refers to the length of the sentences and their grammatical complexities (e.g., number of subordinate or coordinate clauses, unusual sentence structures, depth of the syntactic tree, among others) (Štajner et al., 2020; Rebello et al., 2019).

Split-and-rephrase, proposed by Narayan and co-authors (Narayan et al., 2017), is a novel sentence simplification task that has attracted much research interest in the NLP field. Its goal is to split and rephrase a complex input sentence into shorter sentences that retain equivalent meaning (see examples in Figure 1). Neither deletion nor lexical/phrasal simplification is intended. The core of this process is to properly make the syntactic transformations required by the split action (e.g., turn a relative clause into a main clause).

Figure 1: Basic split-and-rephrase examples highlighting the transformations promoted by the split action.

This bottle was used until 2002 when it was dropped in favor of a traditional bottle.

He sought medical care in Rome, but it was unsuccessful, and he died at the age of 42.
This work innovates from previous split-and-rephrase methods. We present a complete pipeline capable of performing the split-and-rephrase challenge by combining trained sequence-to-sequence neural models that rely on symbolic vocabularies accompanied by BERT’s masked language modeling. The main contribution is to construct a cross-lingual solution that deals both with English and Portuguese sentences. In addition, we enhanced a preliminary work (Berlanga et al., 2020) promoting analysis against complete reference test sets and comparing results to similar models/pipelines. To the best of our knowledge, this is the first complete pipeline to address split-and-rephrase in a cross-lingual manner, encouraging the expansion of the method to languages other than English.

2 Related Work

As discussed by Narayan and colleagues (Narayan et al., 2017), split-and-rephrase method must be distinguished from other sentence rewriting tasks, such as sentence compression, sentence fusion, and sentence paraphrasing. Furthermore, in contrast to the conventional sentence simplification task, split-and-rephrase does not entail loss of information, thus targeting the meaning preservation despite the split behavior (Alva-Manchego et al., 2020).

In an observational study, Gasperin and colleagues (Gasperin et al., 2009) stated that sentence splitting was the most frequent syntactic simplification operation used by an annotator when creating simplified texts. Among the techniques to perform the transformations required by sentence splitting, Niklaus et al. (Niklaus et al., 2019a) segregates them into three classes: (a) Syntax-driven rule-based approaches that use a set of hand-written rules to detect points where sentences may be split (Siddharthan and Mandya, 2014; Ferrés et al., 2016); (b) Semantic parsing based approaches that aim to decompose sentences into minimal semantic units that may be split into individual output sentences (Narayan and Gardent, 2014; Sulem et al., 2018); and (c) Data-driven approaches where the splitting point and transformations are learned automatically from training in aligned corpora of complex-simple sentences (Narayan et al., 2017; Aharoni and Goldberg, 2018).

Concerning split-and-rephrase previous works, Narayan et al. (Narayan et al., 2017) recently presented data-driven baseline models to help with some insights about the task, together with the WebSplit benchmark corpus. After that, Aharoni and Goldberg (Aharoni and Goldberg, 2018) established more robust baselines augmenting sequence-to-sequence neural models with copy-mechanism (Gu et al., 2016), and also released an updated version of WebSplit to reduce overlap in the data splits. Given the small vocabulary and the unnatural linguistic expressions present in WebSplit corpora. Botha et al. (Botha et al., 2018) compiled the WikiSplit corpus uniting more than one million naturally occurring sentence rewrites obtained from mining English Wikipedia’s edit history. Later, Niklaus et al. (Niklaus et al., 2019b) constructed the MinWikiSplit corpus running DisSim framework (Niklaus et al., 2019a) over the WikiSplit data and applied a set of 35 handwritten transformation rules to decompose source sentences in more split simplified counterparts.

As for the Portuguese language’s split-and-rephrase task, based on the literature surveyed, we found no specific corpus built for this purpose. However, Leal et al. (Leal et al., 2018) made available the PorSimplesSent data set, a Brazilian Portuguese corpus to study sentence readability assessment, which we incorporated into this work to further test our pipeline.

3 Methodology and Data

We define the split-and-rephrase task as follows. Given a complex sentence \( C \), the goal is to produce a simplified text \( T \) consisting of a sequence of sentences \( T_1, T_2, \ldots, T_n, n \geq 2 \), in such a way that \( T \) preserves the meaning of \( C \).

In this section we specify the details about the implementation of our proposed pipeline and all the above mentioned split-and-rephrase corpora employed in this work.

3.1 Pipeline Specification

Our complete pipeline is composed of two main elements: (1) one trained sequence-to-sequence neural model that relies on a given custom symbolic vocabulary explained ahead; and (2) the BERT’s masked language modeling. The overview of the pipeline is illustrated in Figure 2. Below we present these elements and how they are integrated.

**Sequence-to-sequence neural models** Our constructed models were based on the conventional encoder-decoder architecture composed of Gated Recurrent Unit (GRU) neural networks with attention mechanism (Bahdanau et al., 2014; Cho et al.,
Figure 2: Illustration of our complete pipeline. To perform a prediction in the pipeline, the complex input sentence (A) passes through a preprocessing step to convert the text into symbolic vocabulary (B). This converted symbolic sequence is given to a sequence-to-sequence neural model that produces an output based on the learned knowledge on how to split such items (C). The model’s output symbolic sequence is then reconverted to genuine text (D) and fed into BERT’s masked language modeling to generate the simplified output sentences filling eventual gaps (E).

2014). Such mechanism makes it possible to establish references at particular points in original sequences, and enable the transmission of these instances to the decoder outputs. This approach is known to be an appropriate strategy for training models in aligned corpora and has shown excellent results for text-to-text NLP tasks (Raffel et al., 2019). The attention layer is connected to the encoder-decoder GRU layers, both composed of 100 units. We employed a batch size of 200 and the training process lasts 10 epochs in Training Setup 1 and 40 epochs in Training Setup 2. These two distinct setups are further discussed in Section 4. We used categorical-cross entropy loss function and applied Adam optimization algorithm (Kingma and Ba, 2014) to update the networks’ weight iteratively.

Symbolic vocabulary Contrary to traditional approaches that seek training models with extensive genuine vocabularies, we feed our sequence-to-sequence neural models with custom symbolic ones generalized uniquely by the concatenation of grammatical classes (POS tags) and their respective recurrences (indexes) observed in the aligned sentence pairs from the training data sets. The wildcard character ‘*’ is used for padding. The custom implementation to build such vocabulary is illustrated in detail in Figure 3. We found this strategy drastically reduced the vocabulary size to only a few items optimizing training process times.

This symbolic vocabulary approach is the key factor that enables our models to work in a cross-lingual manner: instead of dealing with genuine texts, they are capable to understand items in common gained from sentences of different languages, namely English and Portuguese, given that features such as grammatical classes are standard across these languages (Stodden and Kallmeyer, 2020). In addition, due to the existence of syntax-based patterns behind splitting in both languages, the specific knowledge on how to split the sentences may be captured accordingly thanks to the sequential observation nature of sequence-to-sequence neural models with attention mechanism.

BERT’s masked language modeling Since our models are trained with alignments of symbolic sequences (such the example in Figure 3), they may predict symbolic sequences of items that need to be reconverted to genuine texts. But such predicted items are not always present in the complex input sentence to be converted back (see example in Figure 4). To fill this gap, we employed BERT’s masked language modeling (MLM) (Devlin et al., 2018). BERT is proposed to train deep bidirectional language representations based on the Transformer architecture (Vaswani et al., 2017). Instead of predicting the next word in a sequence given the history, MLM predicts missing tokens in a sequence given its left and right context (Qiang et al., 2020). For the English language, we adopted the pre-trained model on English Wikipedia and Book Corpus. For the Brazilian Portuguese language, we employed the large trained model from BERTimbau work (Souza et al., 2020).
Anaya was born in Palencia, Spain, and is the youngest of three children.

The building was then turned into a railway heritage centre in 1979 by the Butetown Historic Railway Society.

In 1994 the railway started to run steam hauled passenger services up 500 m of track.

WebSplit v0.1 Narayan et al. (Narayan et al., 2017) launched this corpus as the first data set to address the split-and-rephrase task. It is composed of 1,100,166 sentences written from RDF tuples. Due to the fact that one single complex sentence may map to a set of \( S_n \) structurally simplified references, the actual number of distinct complex sentences, \( |C| \), is in the order of 4,5K;

WebSplit AG18 Aharoni & Goldberg (Aharoni and Goldberg, 2018) arguing they could achieve more robust results from their split-and-rephrase models, proposed a new train-development-test data split corpus. They randomly divided the distinct complex sentences from the original WebSplit corpus across the TDT sets to ensure that every possible RDF relation is represented in the training set, and every RDF triplet is conferred in only one of the splits;

WikiSplit Botha and colleagues (Botha et al., 2018) introduced this corpus presenting a language-agnostic method for extracting split-and-rephrase rewrites from Wikipedia edit histories. Each single complex sentence maps to a single simplified reference containing only one split. Compared to WebSplit versions, this data set has a more rich and varied vocabulary over naturally expressed sentences, despite being slightly noisy. The authors showed that models trained on this data set produced dramatically better results;
## MinWikiSplit
This corpus is composed of 203K sentences whose referred simplified references are composed of shorter, syntactically simplified counterparts. As they specify, these are clauses with a 'minimal semantic unit that cannot be further decomposed into meaningful propositions' (Niklaus et al., 2019b). For this reason, the main contribution of this corpus is to possibly enable models to learn to perform more than one single split per complex input sentence. The authors did not state any division in train-development-test sets;

## PorSimplesSent
This is a corpus for sentence-based readability assessment in Portuguese. It is constructed from the PorSimples text simplification corpus (Caseli et al., 2009) and combines three levels of simplifications: from Original to Natural; from Natural to Strong; and from Original to Strong pairs (Leal et al., 2018). In this work, we employed the specific version of from Natural to Strong pairs that, in our view, better reflects a split-and-rephrase corpus. We selected only pairs with splits in the simplified side of the alignments, extracting 719 sentence pairs to test the pipeline in Brazilian Portuguese language.

For training purposes, we used both WikiSplit and MinWikiSplit training sets as they contain more rich and varied vocabulary with diverse syntax (see Section 4). The validations throughout implementation were performed using WebSplit v0.1, WebSplit AG18, and WikiSplit development sets. At last the results were obtained from WebSplit v0.1, WebSplit AG18, WikiSplit test sets, and PorSimplesSent (see Section 4.1). Table 1 summarizes the number of involved alignments from each corpus/set considering distinct complex sentences.

### 4 Experiments
We assembled two different training setups concerning the sequence-to-sequence neural models attending different corpora as follows.

#### Training Setup 1
From WikiSplit (Botha et al., 2018) training corpus, we selected aligned sentence pairs formed only by alphanumerical characters, commas, periods and whitespaces, eliminating any foreign/special characters as this corpus is slightly noisy as admitted by the authors\(^2\). This cut extracted 485,120 alignments, consolidating the training set for this first setup. We then executed our aforementioned custom implementation to construct the symbolic vocabulary and obtained 247 different items to train the first model;

#### Training Setup 2
From MinWikiSplit (Niklaus et al., 2019b) corpus, we first established a limit to select aligned sentences with a maximum length of 100 tokens, due to the fact that this corpus has few long sentences that would lead to long padding. This first cut extracted 197,496 alignments. We then repeated the prior setup selecting aligned sentence pairs formed only by alphanumerical characters, commas, periods and whitespaces, finally consolidating a training set of 122,104 alignments. The symbolic vocabulary obtained by our custom implementation was composed of 230 different items to train the second model.

#### 4.1 Results
Following Narayan et al. (Narayan et al., 2017), Aharoni and Goldberg (Aharoni and Goldberg, 2018) and Botha et al. (Botha et al., 2018) reference works, we report the results in sentence-level through BLEU (Papineni et al., 2002), BiLingual Evaluation Understudy, which is a primarily known metric borrowed from machine translation. It calculates modified \(n\)-gram precision as follows:

\[^2\text{Despite this training selection, the final predicted sentences by the pipeline can normally still have special characters assigned by the reconversion process.}\]
count the maximum number of times that an n-gram occurs in any of the references; (ii) clip the total count of each candidate n-gram by its maximum reference count; and (iii) add these clipped counts up, and divide by the total (unclipped) number of candidate words (Alva-Manchego et al., 2020). Also following reference works, we report the average number of simplified output sentences per complex input sentence (#S/C); and the average number of tokens per simplified output sentence (#T/S). Lastly, following Niklaus et al. (Niklaus et al., 2019b) we report the percentage of simplified output sentences that were totally copied from the complex input sentence without any modification (%SAME).3

Table 2 reports the obtained results against the full test sets when performing the complete pipeline with both trained models, considering the aforementioned different setups. Our best BLEU score was obtained with the model built by the Training setup 1 in the WikiSplit test set, closely followed by the score in the PorSimplesSent data. We also highlight the #S/C and #T/S features obtained with model from Training setup 2, pointing that this fashion attempts to split complex input sentences into shorter ones than the model from Training setup 1. The %SAME column values in turn illustrate our proposal’s low conservatism, tending to virtually intercept all the input sentences to perform the split-and-rephrase rewriting transformations (see detailed discussion in Section 5).

As expressed by the scores in Table 3 alongside other approaches scores (Copy512 and DisSim) in the WikiSplit test set, we established our pipeline as a competitive method. Copy512 is the strongest baseline reported by Aharoni and Goldberg (Aharoni and Goldberg, 2018) work. It is a sequence-to-sequence neural model augmented with a copy-mechanism (Gu et al., 2016) that bias the model towards copying tokens from the complex input sentences, taking into account that many of them should appear in the simplified output sentences. DisSim framework, by Niklaus et al. (Niklaus et al., 2019a), is a recursive sentence splitting approach, that applies a set of 35 hand-written rules to decompose a wide range of linguistic constructs, more oriented to generate simple and regular structures to support downstream semantic applications and faster generalization in machine learning tasks.

To encourage further research analysis, our complete logs containing all the predictions from Training setup 1 in the WikiSplit test set are publicly available4. One may notice many sentences achieved meaning preservation and perfect matches against the expected references.

5 Discussion

To achieve a detailed analysis, we manually inspected some of the predictions from the pipeline with the two built models bringing some examples to help explain the scores illustrated in Tables 2 and 3. These extracted examples are in Table 4 and show general patterns with some of the exciting behaviors produced by our method.

In Example 1, the same complex input sentence is transformed into different simplified outputs according to their training setups: Output 1 performed a single split whereas Output 2 performed two splits. This different behavior explains the higher numbers in the #S/C column and the lower numbers in the #T/S column from Training setup 2. These two measures confirmed the hypothesis that models trained in MinWikiSplit might capture the tendency to split source sentences into multiple output ones. Such multiple sentences may not be good for humans readers, but may benefit NLP downstream tasks.

In Example 2, even though both setups generated perfect outputs in terms of meaning preservation, only the Output 2 achieved maximum BLEU score since it is the unique that matched perfectly against one of the references. This brings the evidence that BLEU requires high-quality data to produce more precise outcomes, ideally with multiple correct references (Martin et al., 2019). Another limitation from BLEU is the low correlation with simplicity when sentence splitting is performed, but it still holds the high correlation with human assessments of grammaticality and meaning preservation (Alva-Manchego et al., 2020).

In Example 3, we note interesting contrasts produced by the models from the distinct training setups. While Output 1 retained the same structure from the complex input sentence, Output 2 promoted the reordering of the words preserving equivalent meaning and showing low conservatism. The only little mistake is observed by the repetition of word “was” in the Output 2.

3The metrics/quality estimation features were achieved with EASSE package (Alva-Manchego et al., 2019).

Table 3: Scores alongside other approaches in the WikiSplit test set.

Lastly, Example 4 illustrates the pipeline working in a cross-lingual manner. *Output 1* produced a pronoun “Ele” (He) instead of repeating “O projeto Gemini” (The Gemini project), as observed in *Output 2*. It is exactly the same behavior seen in the English Example 2 reflected for Brazilian Portuguese sentences. Recent studies that analyze eye movements of human readers interestingly reveal that they quickly retrieve information upon finding pronouns when referred to a close syntactic antecedent (Rebello et al., 2019).

Our detailed inspection together with the prediction logs confirmed that the pipeline could split complex input sentences into shorter simplified ones, often preserving equivalent meaning successfully. More than that, it showed ability to perform equivalent syntax transformations for different languages (English and Portuguese). On the other hand, some of the predictions reveal common mistakes from sequence-to-sequence models, such as repetition or omission of tokens and “hallucination” of new unwanted information. Another limiting factor is the noise from unsupported or missing statements observed in the referred test data sets. The low quality references eventually harmed the BLEU scores in those cases.

6 Conclusion

Split-and-rephrase task conceptualizes that shorter sentences are generally better processed by humans and by NLP downstream applications. We presented a complete pipeline for the split-and-rephrase method that attends in a cross-lingual manner English and Portuguese languages, by integrating sequence-to-sequence neural models and BERT’s masked language modeling. In contrast to conventional approaches, we train models making use of symbolic vocabularies defined by a custom implementation. This approach speeds up the training process and enables the models to acquire specific knowledge on how to split symbolic sentences, then demanding only a little step to convert them back to genuine texts in respective languages. Furthermore, the pipeline is capable to foster new words to rewrite the complex input sentence, thanks to BERT’s MLM predictions. Unlike most previous works on split-and-rephrase, we employed the four state-of-the-art corpora for the task and also a Brazilian Portuguese corpus, showing competitive results to equivalent approaches.

As future work, we plan to exploit our pipeline in more languages. We should also inspect the effectiveness of the Transformer architecture in replacement of the sequence-to-sequence models. Moreover, we intend to promote an extrinsic evaluation of the benefits of the split-and-rephrase method in NLP downstream applications.

---

3We refrain from report SARI and SAMSA scores. The first metric is more reliable to evaluate lexical (not structural) simplicity, and the second heavily relies on linguistic resources making the application in Portuguese language unfeasible.

Abstract

We introduce a multi-label text classifier with per-label attention for the classification of Electronic Health Records according to the International Classification of Diseases. We apply the model on two Electronic Health Records datasets with Discharge Summaries in two languages with fewer resources than English, Spanish and Swedish. Our model leverages the BERT Multilingual model (specifically the Wikipedia, as the model have been trained with 104 languages, including Spanish and Swedish, with the largest Wikipedia dumps¹) to share the language modelling capabilities across the languages. With the per-label attention, the model can compute the relevance of each word from the EHR towards the prediction of each label. For the experimental framework, we apply 157 labels from Chapter XI – Diseases of the Digestive System of the ICD, which makes the attention especially important as the model has to discriminate between similar diseases.

1 Introduction

Electronic Health Records (EHRs) are classified by clinical experts for documentation, reporting global health vital statistics, insurance billing, etc. International Classification of Diseases (ICD) is used world-wide to define diagnostic terms and procedures and serves to encode EHRs. There are thousands of terms encoded within the ICD WHO (2016). For medical experts, reading EHRs, lengthy and technical documents, finding explicit and implicit mentions of diagnoses and procedures for then assigning standard ICD codes is cumbersome and requires specific training. In fact, it is well-known that manual encoding is not error-free, as an example, Jacobsson and Serdén (2013), estimated that 20% of them were either incorrect or were missing. In this context, natural language understanding brings opportunities to bridge the needs of the society in terms of computer aided coding approaches.

In 2006, it was argued that Natural Language Processing (NLP) tools could quickly help identify codes in discharge summaries Kukafka et al. (2006). Today NLP tools for classifying clinical documents written in English are widespread. Even more, languages with scarce resources for biomedical NLP like Spanish, Italian, Swedish, etc., are in the limelight in the last years to develop codification systems as has been done for English. In the context of working towards the codification of documents, in languages with a small number of resources for NLP, different tasks have been addressed. In 2018 CLEF Névéol et al. (2018b) worked with Italian, French and Hungarian for the automatic codification of death certificates. Each death certificate consisted of a few words (on average 20 words) with at least one main diagnosis. In 2020 the CodiEsp task at CLEF Miranda-Escalada et al. (2020) consisted on the automatic assignment of ICD-10 codes to Spanish Clinical Records with 350 tokens on average. For Swedish Henriksson et al. (2011) the authors mentioned that the corpus was compiled with documents that on average had a length of 96 words.

Admittedly, multi-label classification is challenging, particularly with extensive label-sets (as it is the case of the ICD) and domain-specific corpora, and even more when it comes to dealing with clinical information extraction on languages other than English Névéol et al. (2018a). Spanish and Swedish researchers are striving to bridge this gap, indeed, as the first and relevant step, they gathered corpora conveying patient records Oronoz et al. (2015); Dalianis (2018). Previous works showed that the multi-label classification problem of EHRs coded with ICD-10 can be tackled with an adapted

¹https://github.com/google-research/bert/blob/master/multilingual.md#list-of-languages
BERT architecture Amin et al. (2019); Zhang et al. (2020).

Moreover, we focused just on a sub-set of the ICD, i.e. the Diseases of the Digestive System (the ICD codes starting with the letter K). Focusing on semantically related diseases poses an added challenge, since the Natural Language Understanding (NLU) in charge of encoding the input EHR must be able to cope with the nuances inherent to the distinction of similar diseases. Unarguably, it is easier to distinguish two diseases each belonging to a different body-part than two diseases within the same body-part (as it is this case distinguishing diseases all within the digestive system). In summary, distinguishing semantically different diseases (e.g. gastrointestinal vs cardio-pulmonary) would be easier than distinguishing two diseases within the same speciality. To that end, the LM and the attention mechanisms play the most critical role, so we opted for the transformers models. BERT-based approaches have been tested in this context, with attention mechanisms as a strength towards finding relationships between input text with output ICD codes. The attention is a mechanism whose effectiveness has also been shown with other architectures such as RNNs with LSTM units Hochreiter and Schmidhuber (1997) or Convolutional Neural Networks Du et al. (2017).

Nevertheless, in this context we are dealing with scarce resources and relatively similar codes. In this line, the main scientific contribution of this paper rests on the implementation of a head adapted for BERT with multiple label attention mechanisms (instead of a generic one) in order to delve deeper into the nuances of the understanding module. In this work, we have implemented a per-label attention mechanism, and given that regular BERT models also have the self-attention mechanism, it allowed us to compare the effect of different attention mechanisms. The per-label attention mechanism allows the model to give a different relevance to each word and ICD code pair, contrary to the regular attention mechanism. The experimental results support the approach’s acceptable performance, so we decided to release the head for the scientific community.

2 Corpora

We have applied two datasets of languages with scarce resources for this work, i.e., languages with fewer resources than English, specifically, Spanish and Swedish. Both datasets are Electronic Health Records containing Discharge Summaries from patients. The Spanish EHRs are from the Emergency Services of the Basque Health Public System, conveying records, and therefore labels, from all the medical specialities Oronoz et al. (2015). However, the Swedish EHRs are only from the gastro-surgery medical specialisation and comes from the research infrastructure Health Bank - Swedish Health Record Research Bank², at Stockholm University. Therefore, to have equal label sets, we have selected the ICD codes shared between both datasets to carry out the experiments, obtaining 157 codes, all from the Chapter XI of the ICD-10, i.e., Diseases of the Digestive System. By selecting the codes of some specialities the number of available EHRs is reduced but the label sets are easier to handle. Training specific models on EHRs of specialities improves the performance against training general models Blanco et al. (2020). For the Swedish ICD-10 corpus data set the Swedish KB-BERT model Malmsten et al. (2020) has been applied with good results, see (Remmer et al., 2021).

Here we present a quantitative description and comparison between both datasets. Regarding the input, the Swedish dataset is more than twice larger in number of EHRs, with 8,909 records in contrast to the 3,891 available Spanish EHRs. Nevertheless, the vocabulary (i.e., number of unique words) is around three times bigger for the Spanish dataset. One explanation is that the Spanish EHRs come from several specialities, and therefore there is a higher lexical variability due to the specific terms of each medical specialisation. Also, the Spanish EHR contains lab tests, which could increase the number of unique words significantly.

Regarding the output, both datasets are equivalent, with the same set of 157 gastrointestinal ICD-10 codes. Although this is just a subset of the labels, there are still infrequent codes. For example, only 45 codes from the 157 appear in at least 1% of the EHRs. This fact makes the task even more challenging, as, for around 28% of the labels, there are only a few samples from where the model can learn. Even though the number of labels is the same, the distinct label sets (i.e., label combinations that are unique) are larger in the Swedish dataset than in the Spanish (1,288 and 558, respectively) due to the higher number of records. The ratio between the distinct label sets and the number of records

²http://dsv.su.se/healthbank
is similar, 6.97 for Spanish and 6.91 for Swedish, meaning that about the same number of EHRs lead to the same number of unique label sets.

The most significant differences come when evaluating the length of the EHRs, as the Spanish EHRs are significantly longer. While the Spanish records convey 984 words on average, the Swedish only have 74 words. The standard deviation is also more prominent in proportion, with 491 for the Spanish and 77 for the Swedish (note that the standard deviation is higher than the mean). Although the records from both datasets are Discharge Summaries, it seems that not all the Swedish records are complete summaries, but instead a summary or even one-sentence synopsis of the patient’s outcome.

3 Methodological Approach

Focusing the attention on the methodology, in Amin et al. (2019) the authors demonstrate the effectiveness of transfer learning with pre-trained language representation model BERT without attention for the multi-label classification of German non-technical summaries (NTSs) of animal experiments. In e-Health 2020 the authors of López-Garcia et al. (2020) tackled the task as a multi-label classification problem using BERT model Devlin et al. (2019) for the automatic clinical coding of medical cases in Spanish. NLU results crucial to this task and Transformers-based Language Models (LM) are, doubtlessly, the key strength of most recent approaches such as multi-label biomedical text classification Gu et al. (2020). All this and the inherent challenges related to our work (e.g. the ability to distinguish concepts leveraging semantically related diseases) motivated us towards BERT-based approaches. Another fact in favour to this choice rests on the ability to the transfer learning between the two languages and, if possible, get benefits from one Language Model to the other. That is, the resources from one language can boost the LM of the other one, while the system remains decoupled from the data.

In order to tackle the multi-label text classification task, we applied a model with a Transformer-based architecture. The problem to solve is the mapping between the input of the EHRs (the raw text, \( X \)) and a subset of ICDs from the entire label set, \( C \), where \(|C|\) is the number of codes. The Deep Learning model is trained for the downstream task with pairs of input and output (i.e., EHR texts and ICD codes). The Transformer-based neural network model is trained with instances comprising pairs of input (EHR text) and output (ICD codes). The transfer learning approach of sharing the LM of the other one, while the system boosts the LM of the other one, alleviates the training process for each language since just the task-dependent module (i.e. ICD multi-

From the input text, \( X_j \), fed to the Language Model part of the model, a hidden document representation is obtained. The importance of this rests in that our multi-label classifier is built on top of a BERT model (see Section 3.1). The LM is the core of the Transformer-based NLP models. The principal contribution of this work is the use of the hidden representation to compute attention weights that are label-specific for each input token. After computing the attention, the final output (label predictions) is computed with a fully connected layer that is fed with another document representation got from the label-specific attention layers. To support the reproducible research, we release the code of the per-label attention mechanism with this article.

3.1 Baseline: BERT to Boost LM

The Language Models based on Transformers, specifically BERT models Devlin et al. (2019), have been acknowledged due to their ability to generate contextual representations. In this work, we have to differentiate between very similar diagnoses (all from the gastrointestinal service), which motivated the chosen BERT model as the LM part of our multi-label text classification system to generate the representation of the EHRs. A BERT model is also suitable because of its built-in self-attention function, which can connect different locations of a single input sequence to one another. We also turned to BERT because it has been shown to expand Recurrent Neural Networks’ ability to model dependencies to long-distance patterns Hochreiter and Schmidhuber (1997).

In an attempt to encompass Spanish and Swedish, EHRs were represented with shared LMs. The transfer learning approach of sharing the LM poses two advantages. On the one hand, it alleviates the training process for each language since just the task-dependent module (i.e. ICD multi-
label classification) has to be trained. On the other hand, this bypasses the lack of in-domain data for languages other than English. Indeed, the multi-lingual LM, with English, leverages other languages such as Spanish and Swedish in a synergistic effect since cross-language regularities are captured by Pires et al. (2019).

The LM part is the core of the BERT models, but coupling different heads on top of the LM is what concedes the ability to tackle numerous downstream tasks, as multi-label classification. Since there are many parameters to describe both the LM and the head for the downstream task, training a BERT model is challenging. The LM module contains the broad majority of the parameters that must be inferred during the training stage. The ICD multi-label classification head built for this study, for example, accounts for less than 1% of the total model parameters (even though using the smallest variant of BERT, which has 110M parameters). With this in mind, we opted to train the multi-label heads from scratch while fine-tuning the LMs instead of training the LMs from scratch.

Because of memory and computational limitations, we used the BERTbase as the baseline BERT model (our GPUs are limited to 8GB of DRAM memory). The BERTbase model comprises 12 Transformers blocks, 12 self-attention heads, and an internal embedding layer size (d) of 768, totaling 110M parameters. The pre-trained BERTbase Multilingual model was used. The downstream tasks’ attention and output layers are connected to the output of LM, the hidden document representation, \( \mathbf{H} \), of the EHR.

### 3.2 Contribution: Per-ICD Attention Head

Having opted for the multilingual BERT to cope with the LM, next we proposed to improve the task-dependant head. The aim was to leverage ICD-dependant attention mechanisms in an attempt to enhance the model with added NLU capability when it comes to distinguishing ICDs within the same hospital-service (Digestive in our case).

Our multi-label classification head incorporates a per-label (per-ICD) attention mechanism. The model can classify the EHRs with respect to the ICD labels that are present through the text while also calculating the importance that each input token (word) has in relation to each of the ICDs.

Here, \( N \) is the number of tokens of the EHR (length) and \( d \) is the BERT hidden layer dimension (i.e., the representation of documents, being \( d = 768 \) for BERTbase models). Then, rather than perform the pool operation (across the document length, \( N \)), as in the original BERT Devlin et al. (2019) for classification, our head uses a per-ICD attention mechanism. The per-ICD attention mechanism allows the classifier to discover the correct relationships between the input tokens and each label.

For each ICD label, \( C_i \), the attention vector \( \alpha_{C_i} \in \mathbb{R}^{C_i \times N} \) is computed from the learnable vector parameter \( \mathbf{u}_{C_i} \in \mathbb{R}^d \), following (1), where \( C \) is the full set of ICD labels.

\[
\alpha_{C_i} = \text{Softmax}(\mathbf{H}^T \mathbf{u}_{C_i}) \tag{1}
\]

The attention scores must be computed as a probability distribution, representing the importance between each token and ICD label pair, and to that end, the model leverages the Softmax function. The matrix multiplication between \( \alpha \) and \( \mathbf{H} \) is calculated to get an ICD representation for each class from the attention weights. In the end, the maximum through the labels’ dimension is taken, obtaining the document representation on the final layer (\( \mathbf{v} \in \mathbb{R}^d \)), which combines the per-ICD attention representation.

The final layer of the head for multi-label classification is a regular one that allows getting the probabilities for each ICD label. It is a linear layer that takes the document representation (\( \mathbf{v} \)) as input, which takes into account the attention weights for each input token and label pair. After that, a Sigmoid function is applied to get the actual probabilities of each ICD, as in (2).

\[
\hat{y}_i = \sigma(\mathbf{W}_i^i \mathbf{v}_i + b_i) \tag{2}
\]

The probability of each ICD class (\( C_i \in C \)) being on the given input text is \( \hat{y}_i \). The parameters of the final layer are the weights matrix \( (\mathbf{W}) \) and bias \( (\mathbf{b}) \). Regarding the training of the model, it is carried out by minimising the loss function, precisely, the Binary Cross-Entropy (BCE) loss, as in (3). On this equation, the \( \hat{y} \) is the output of the previous final layer, and \( \mathbf{y} \) is the vector that encloses the ICD codes present on the EHR (i.e., the appearance or lack of ICD codes). Figure 1 shows an architectural outline of the system.

\[
\text{BCE}(\hat{y}, \mathbf{y}) = -W[\mathbf{y} \log(\hat{y}) + (1 - \mathbf{y}) \log(1 - \hat{y})] \tag{3}
\]
4 Experimental Framework

We propose the following experimental setup to evaluate our BERT model’s performance with per-ICD attention compared to the benchmark (standard BERT model) on the multi-label ICD classification downstream task. The experimental setup comprises the two minority languages (in terms of in-domain clinical data available), Spanish and Swedish, and a gastrointestinal label set of 157 labels. Each experiment is carried out twice, with the same experimental and training parameters, one with the regular multi-label classification head (as the baseline) and the other with our head with per-ICD attention. We show the results from the experimental results in Table 1 and Figures 2 and 3, for Spanish and Swedish, respectively.

The model with our per-ICD attention head obtains better results in both languages. It is important to note that the results improve considerably even in this context with a considerably large label set (157 labels). This finding is consistent with the following hypothesis: many terms can be important when dealing with a wide number of ICD codes at once and long EHRs, but probably only a few of them are relevant for each ICD code individually.

Multi-label ICD classification is often assessed by means of the Area Under the ROC Curve (AUC) micro averaging the metric for all the ICDs involved (denoted as AUCm in Table 1). For Spanish, the per-ICD model surpasses the base BERT model by 9.16 points, also improves slightly for the Swedish, with an improvement of around 1 point. In Figures 2 and 3 we show the confusion matrices for each experiment. Each confusion matrix is the average of the matrices of each ICD class, and we have computed two versions, i.e. one with arithmetic averaging (aka samples average) and the other with weighted averaging. In both, the darker the colour, the higher the metric, always in the range [0 – 100]. The weighted averaged matrices are computed considering the support (relative frequency) of each ICD class. Note that the TPR (True Positive Rate) and FNR (False Negative Rate) shown in Table 1 are also the arithmetic average of each corresponding model, but the CM show also the FPR (False Positive Rate) and TNR (True Negative Rate), while the weighted average of each metric. Regarding the per-class performance, there is a positive association with the support; the more frequent the label, the better are the results.

If we analyse the matrices, it can be observed that the source of improvement of the per-ICD model can be broken down; while the True Negatives stay close (as with a large label set, the majority of classes are negative), the True Positives improves considerably, with an increment of almost 100%. In the same way, the False Negatives decrease by around 20%. Although the Swedish results are in general weaker, this behaviour is appreciated similarly for both languages. Therefore, given the results, it seems that our per-ICD attention head is able to improve the Precision of the regular BERT models for ICD multi-label classification with large label sets. Nevertheless, the per-ICD model outperforms regular BERT in terms of performance, but also in interpretability capabilities, as it has the ability to export the attention weights, allowing its visualisation.

5 Discussion

Within the clinical text mining field, the main weakness tends to be the availability of corpora due to the natural patient’s confidentiality policy Cohen and Demner-Fushman (2014). As a result, for the research to make progress, the so important comparability might get compromised. By contrast, through this work the authors are glad to make available their own implementation of the per-ICD attention approach as a secondary contribution of

3To get the source code of the implementation, simply e-mail the first author.
Another aspect related with the corpus is the complexity and length of the input EHR. The average length of the input of the works mentioned Névéol et al. (2018b); Cappellato et al. (2019) are variable from a few words in the case of Italian, Hungarian and French to 350 words for the documents written in Spanish Miranda-Escalada et al. (2020). By contrast, in our paper we deal with documents in Spanish and Swedish with an average length of 800 (exceeding the aforementioned ones) and 70 respectively.

According to these results, the per-label attention mechanism improves Precision. While more performance is still necessary for a fully automated system, the results suggest that it is suitable for multi-label classification of EHRs according to the ICD standard, specifically applying it as a clinical DSS, as the per-ICD attention can aid the expert in the EHR codification process.

6 Conclusions

We have dealt with the codification of EHRs of the gastrointestinal service for Swedish and Spanish hospitals. We have developed a BERT model for multi-label classification incorporating a per-label attention mechanism.

The results obtained have revealed that the proposed model outperforms the regular BERT. We have proved this fact for two languages with minority resources in clinical NLP, showing that solutions of language independent nature work. Moreover our proposal generates an interpretable output that helps to know the relevance of the tokens with respect to each ICD assigned to the EHR. To sum up, the per-label attention mechanism differentiates semantically ICDs that are related and aids to explain the core of each label. Future work may include testing BERT models trained for the specific languages, as the BETO model Cañete et al. (2020) for Spanish.

Abstract

In this paper we address the problem of fine-tuned text generation with a limited computational budget. For that, we use a well-performing text generative adversarial network (GAN) architecture - Diversity-Promoting GAN (DPGAN), and attempted a drop-in replacement of the LSTM layer with a self-attention-based Transformer layer in order to leverage their efficiency. The resulting Self-Attention DPGAN (SADPGAN) was evaluated for performance, quality and diversity of generated text and stability. Computational experiments suggested that a transformer architecture is unable to drop-in replace the LSTM layer, under-performing during the pre-training phase and undergoing a complete mode collapse during the GAN tuning phase. Our results suggest that the transformer architecture need to be adapted before it can be used as a replacement for RNNs in text-generating GANs.

1 Introduction

Since the introduction of the Transformer in late 2017 by Vaswani et al. (2017), pure self-attention architectures have become ubiquitous in the natural language processing community.

Initially introduced by Bahdanau et al. (2015), the self-attention mechanism proved to be particularly useful in the context of neural machine translation to augment existing recurrent neural networks (RNNs). Recurrent neural networks (RNNs), introduced by Rumelhart et al. (1986) and expanded by Hochreiter and Schmidhuber (1997); Cho et al. (2014), were the state of the art in learning and generating sequential models, notably for texts. With the addition of the attention mechanism, in the context of machine translation, they could focus better on the words and word combinations corresponding to the same concepts in different languages and focus on learning equivalences between them as opposed to trying to infer them directly from the whole excerpts of parallel texts used for learning.

Following the initial introduction of the attention mechanism to augment the RNNs, architectures combining the two became de-facto state of the art. Stacking RNN layers, adding pass-through mechanisms and separating the architecture into encoder and decoder with an attention layer in the middle became a standard, powering among others Google's Neural Machine Translation system (Wu et al., 2016; Johnson et al., 2017). Despite impressive performance, those architectures had a fundamental limitation to their ability to scale. The RNN training and evaluation are sequential by their nature, which means that architectures relying on the RNNs could hardly benefit from the arrival of massively parallel computing.

The innovation of the Transformer was to show that it was possible to learn sequence-to-sequence mapping while dispensing entirely with RNN layers, using only self-attention mechanisms ("Attention is all you need") - Vaswani et al. (2017)). By stacking several layers of self-attention networks to form an encoder and a decoder, as well as introducing multi-head architectures, where each layer of self-attention network could be trained in parallel, the Transformer and architectures derived from it scaled up easily and could be trained in parallel at a scale that was previously unreachable.

That scalability enabled a continuous ramp-up of performance through parameter and training dataset size increase (Brown et al., 2020), which eventually hurt itself against the limitations of reasonable demands on computational power in deployments. In turn, this led to an extensive research into making Transformer-based architectures more efficient, focusing at first on specific instances (Jiao et al., 2020; Sanh et al., 2019) and more recently on more general approaches (eg. Li et al. (2020);
Mandava et al. (2020); Fedus et al. (2021); Ren et al. (2021)). Combined with the existence of specialized, energy-efficient hardware that is highly compatible with the Transformer architectures, this makes Transformer-based architectures an attractive architecture to get the best value of limited computational budget.

The text-generating capabilities of the Transformer also gave rise to a new generation of models specialized in text generation. Rather than mapping texts between languages, they focused on mapping a prompt to a text that would follow it. Google’s BERT model (Devlin et al., 2019) isolated and scaled up the Transformer encoder stack in order to perform masked training - predicting masked words in a text - referred to as autoencoding models (Rumelhart et al., 1986; Hinton et al., 2006; Erhan et al., 2010). On the other side of the spectrum, OpenAI’s generative pre-training (GPT) family of models (Radford et al., 2018, 2019; Brown et al., 2020), focused on approximating the decoder stack and using the tokens from the prompt in order to initialize the hidden state of the self-attention modules stack - referred to as autoregressive models (by similarity with statistical autoregressive methods (Yule, 1926; Wold, 1938; Slutzky, 1937; Box and Jenkins, 1970), see Bowman et al. (2016) for machine learning applications).

Despite their impressive performance, when it comes to the text generation, both types of models are essentially autoregressive and are trained by max likelihood methods with regards to the training datasets. This poses several challenges. First, the autoregressive models learn the next token as a continuation of real texts they encounter in training, yet during the generation phase they continue from the text they themselves have generated. This means that during the generation phase they can rapidly go off the deeper end into an uncharted territory, they don’t have a statistical model, and start generating degenerate output - a problem referred to as exposure bias (Holtzman et al., 2020). So far, solutions to this problem, such as scheduled sampling (Bengio et al., 2015), are far from perfect and result in less diverse sampling and mode collapse (Huszar, 2015). On top of that, the autoregressive nature of the model means that even in the territory where it has learned an appropriate token distribution, it will still be learning potentially undesirable biases (Hutchinson et al., 2020), with no means to correct them other than to curate the entire dataset used to train the model (reviewed in depth by Bender et al., 2021).

Trying to learn the explicit statistical structure of natural language is, however, not the only way to train generative models. Adversarial Generative Networks (GANs) are a different training mode, where a generative model learns to generate outputs that are indistinguishable from the ones in the training dataset through a competition with a critic model, trained in tandem with it. Introduced by (Goodfellow et al., 2014), they are more robust to output degeneration, given that they always train in the generative mode, and require less computational resources than traditional autoregressive models. Besides, a number of different pre-trained critics can be used to eliminate undesired biases or on the contrary, introduce desired ones, such as specifying an artistic style of an image (Gatys et al., 2015).

The adversarial learning approach has been highly successful for training image generation models, allowing high-quality image generation (Brock et al., 2019), day-to-night or summer-to-winter image translation (Isola et al., 2017), or sketch-to-image translation (Lu et al., 2018). GANs application to text generation, however, remained relatively limited. A major reason for that is that the sampling step leading to discrete and sequential token organization, needed for text generation, is problematic for gradient estimation, which is essential for training GANs. As such, most existing text-generating GANs rely on a max-likelihood autoregressive pre-training with the actual adversarial training phase being short and using a small learning rate, similar to a fine-tuning. Unfortunately such an approach failed to address the shortcomings of the purely autoregressive models they acquire during the pre-training phase.

However, recently de Masson d’Autume et al. (2019) was able to demonstrate that it was possible to train a text-generating GAN architecture from scratch, thus avoiding entirely the problems encountered by autoregressive max-likelihood methods. A curious property of the Scratch-GAN he developed, is that while it seems to solve problems that plagues both RNNs and pure self-attention autoregressive models learning the explicit text token distribution, the authors still opted for RNN blocks, foregoing the advantages of Transformer architectures in NLP and self-attention in image-generating GANs (Zhang et al., 2019).
Given the massive advantages of the Transformer presents when it comes to training as well as with regards to the amount of research performed to make them more efficient, as well as better capabilities of Transformers compared to GANs, we wanted to know if it was possible to perform a drop-in replacement of RNNs with Transformers. Such a Transformer-based GAN could provide two main benefits: the ability of produce higher quality samples at a reduced computational cost compared to traditional RNN-based GANs, and a more scalable language GAN.

In order to approach this question, we chose to perform an experimental evaluation, based on a classical text-generating GAN - Diversity Promoting GAN (DPGAN), developed by Xu et al. (2018). We chose DPGAN due to its straight-forwards architecture and training mode, similarity of its rewards structure to the state of the art text-generating GANs de Masson d’Autume et al. (2019) and the presence of the maximum likelihood pre-training, that we were expecting to be particularly favorable to the Transformer layers. We refer to the DPGAN with RNN layers replaced by a transformer as Self-attention DPGAN (SADPGAN).

2 Related Work
The power of the Transformer architecture in the language modelling tasks and its potential to further improve existing GAN architectures did not escape the attention of the machine learning community. So far, self-attention architectures in GANs focused on image generation tasks. Perhaps the two best known examples are TransGAN (Jiang et al., 2021) and Self-Attention GAN (SAGAN) (Zhang et al., 2019). More recent advances, such as the introduction of Generative Adversarial Transformers by Hudson and Zitnick (2021) have build on the Transformer architecture even further, enabling long-range correlation to improve over the existing state of art, showing a potential for it in the GAN setting. However, a common point between all of them is that they focus on the generation of images, rather than texts, and use only a single encoding layer for self attention or attempt to modify self-attention mechanism to better suite the image generation, diverging from the Transformer architecture.

The approach to text generation by combining the Transformer and GANs that comes closest to ours is the SALSA-Text, developed by Gagnon-Marchand et al. (2019). SALSA-Text is a text-generating GAN build around a Transformer, discarding the original layer normalization and replacing it with the spectral layer normalization. In addition to that, SALSA-Text uses a modified Transformer architecture, with less layers and a different structure, as well as a specific training regimen, meaning it is more of a GAN built around a Transformer rather than a GAN where an RNN layer has been replaced with a pure self-attention based layer.

Here, we examine the Transformer applicability as a general-purpose element that can be drop-in in architectures requiring a latent space encoding and thus directly replace RNNs structures as LSTMs and Gated Recurrent Units (GRUs).

3 Contribution and Outline
Our contribution consisted in assessing the potential of Transformers as a drop-in replacement of LSTMs in text-generating GANs. Through three different experiment involving SADPGAN, we showed that Transformers, despite achieving remarkable results in several NLP tasks, fail to adapt to the adversarial learning and adversarial fine-tuning context (Jeddi et al., 2020), causing SADPGAN to consistently come short of the DPGAN performance and to exhibit severe mode collapse. This results suggest that as of now, the Transformer can’t be directly used as a replacement for LSTM without further architectural and training mode changes.

4 Methodology
Our work is built upon an existing PyTorch implementation of DPGAN by Liu et al. (2020b).

We used an iterative approach, first implementing a layer using exclusively Transformer encoders, then adding the decoder stack with masking and finally adding teacher forcing during training. For each of these steps we compared the training results to the original implementation.

Since our goal was to investigate the possibility of replacing LSTM layers in text-generating GANs by dropping in Transformer layers, and not to achieve new state of the art for text-generating GANs, we kept our models relatively small: embedding and hidden dimension of 32, Transformer encoder/decoder with two layers, each with 4 attention heads of size 64.

The training loop for both GANs consisted in
120 iterations of MLE pre-training for the generator followed by another 120 epochs of adversarial training between the discriminator and generator. To assess the performance of both architectures, we used two negative log likelihood metrics, $NLL_{gen}$ and $NLL_{div}$, which measure the quality and respectively diversity of the generated text and (self)BLEU scores when using real data. For the NLL metrics lower values correspond to better results while for BLEU higher scores are desirable. The code developed for this project is available from https://github.com/TheBlueHawk/RANLP21-70, specifically the RANLP-2021 release. For the ease of use, it was packaged integrated into the code from Liu et al. (2020b).

5 Results and Discussion

5.1 Experiment #1

Following the example set by Jiang et al. (2021) in image GANs, we first tried to drop-in a Transformer encoder block, ensuring that it would properly fit the rest of the GAN architecture. For this preliminary experiment we trained both SADPGAN and DPGAN on a synthetic dataset with a vocabulary of 5000 words.

As shown in figure 1, for SADPGAN we didn’t observe any improvement during MLE training. This can be explained by the choice of architecture: using only Transformer encoders without combining them with up-sampling layers for image generation or using bidirectional attention heads as in Devlin et al. (2019), doesn’t allow the model to correctly learn how to produce realistic samples.

5.2 Experiment #2

Following the results of the first experiment, we modified the Transformer block by adding a Transformer decoder after the Transformer encoder. Contrary to an encoder-only architecture, the addition of the decoder requires a second input, the output vector (also known as target), which is fed to the first masked multi-head attention layer of the decoder. To leave a maximum freedom to the decoder when generating sentences, we decided to feed it with an empty vector. For this second experiment we trained both model on real data, specifically the Lin et al. (2014) annotation dataset using a pre-trained Word2Vec embedding. Word samples were obtained in parallel using multinomial sampling.

The set of modifications permitted SADPGAN to improve the quality of the generated text during the MLE pre-training iterations but the learning curve flattened out rather quickly and performed worse than the original implementation, with also a decrease of output diversity. During the adversarial training we observed a severe mode collapse: the original DPGAN produced very similar sentences while SADPGAN eventually produced exclusively empty sentences. See table 1 for some samples randomly drawn at the end of pre-training and adversarial training.

The reason for this particular behaviour lies in the role of the target vector, which act as a ground truth in a teacher forcing scenario. This means that parallel sampling cannot be performed without forcing the use of the empty sentence as a reference.

5.3 Experiment #3

To address the problems of experiment #2 we used two modifications: a new target vector and autoregressive sampling. As a target vector we used the input sentence to the encoder but shifted right by one position: this allowed a correct implementation of teacher forcing during the training phase. During the evaluation phase or when sampling, we don’t want the teacher to influence the output of

Figure 3: $NLL_{div}$ and $NLL_{gen}$ losses of SADPGAN and DPGAN during the third experiment.

The results of pre-training show a greater improvement of the quality of samples but at the cost of severe lack of diversity, resulting in common words repeated in sequence. Again, the adversarial training further exacerbate the issues resulting in total mode collapse. BLEU and self-BLEU scores for different n-grams at the end of pre-training and adversarial training are reported in table 2 for both DPGAN and SADPGAN.

6 Conclusion

Following our results, we have observed that a Transformer architecture cannot be used as a simple drop-in replacement for RNNs in the context of text-generating GANs, at least not in its unmodified form.

This result is not entirely surprising. Despite a great performance of the Transformer and its derivatives in different NLP tasks, Transformer-based architectures are all but simple to train, as reviewed in Liu et al. (2020a).

Another problem with Transformer architectures is their tendency to overfit the distribution of the text they are learning and fail to generate novel text in case insufficiently diverse and varied training datasets are used. In the case of the DPGAN, the small size of the training dataset and the relatively small size of batches likely place us directly into the overfitting territory. Upon the transition into the adversarial training, this overfitting is likely mutually amplified, leading to more and more degenerate text outputs.
A more fundamental problem is that in DPGAN, we are still faced with the transition from the max-likelihood training regime to a generative regime. Which means that even with improved datasets, the generator is likely to wander off into the uncharted territory as it tries to generate a new token based on the tokens it has already generated rather than tokens sampled from the training dataset. While this problem is present as well with the RNNs, it seems that the output quality decay occurs faster with the Transformer-based architecture.

Despite the existing wealth of text-generating GANs, none, except for SALSA-text (Gagnon-Marchand et al., 2019) are Transformer-based, but persistently use RNNs, notably LSTM layers, including in the most recent, state-of-the-art ones, such as (de Masson d’Autume et al., 2019). In case of SALSA-text, a modified architecture and a different regularization methods are used, both in two specific setups. It seems that part of this trend in using RNNs rather than a Transformer-based architecture is rooted in the existence of fundamental differences in the way the Transformer learns compared to the RNNs, that make it particularly vulnerable to the hazards of adversarial training regiments.

As a result, we expect that developing text GAN architectures using self-attention based architectures instead of RNNs ones would require designing new GAN architecture from scratch to ensure a initialization and evaluation/reward structure that would be compatible with the the Transformer layer. A pure self-attention layer capable to be a drop-in replacement for RNNs is still to be developed. Given the similarity between the adversarial phase occurring in the majority of current text-generating GANs and the adversarial fine-tuning mechanism (reviewed by eg. Jeddi et al. (2020)), we expect that text-generating model fine-tuning to avoid undesirable patterns and adversarial prompts (such as exemplified in Bender et al. (2021)) would not be straightforwards and rely on the development of more robust and stable self-attention architectures.

7 Future Work

While this paper presents a negative result, we did not evaluate a number of approaches that could stabilize the training of pure self-attention architectures. Such approaches could prove to be key to the development of self-attention architectures that can be used as drop-in RNN layers replacements.

An interesting avenue is to build upon the achievements of Gagnon-Marchand et al. (2019), and start with a reduced Transformer architecture, combined with a spectral normalization. Building up on this idea, Noise Stability Regularization proposed by Hua et al. (2021), suggested that noise regularization methods were capable to significantly improve the stability pre-trained pure self-attention generative networks fine-tuning, which could indicate an overall improvement in stability that would be visible in generative adversarial training. The regularization approach has been as well highlighted by several other publications, such as Nguyen and Salazar (2019) and would be the first line of research to be investigated.

Another angle of attack would be to increase the amount of tokens used for initialization of the Transformer on the generator side as well as to perform the initialization on multiple levels. This approach have been shown to perform well in Shin et al. (2020). Similarly, existing Transformer architectures are known to require learning rate schedulers for training, something that seems to be entirely absent from almost all existing text-generating GAN architectures. It is possible that

a learning rate scheduler needs to be incorporated into a Transformer layer for it to be able to become generally applicable. The importance of the learning rate scheduler for Transformers has been extensively documented in the past, notably by Popel and Bojar (2018) and could also be key in stabilizing the training of Transformer-based architectures.

Overall, in the absence of proof that pure self-attention architectures are inherently unstable in the adversarial training context, there is a number of potential approaches to make them work in the context of GANs and leverage their advantages that are to be explored.

Acknowledgments

We would like to thank the Armasuisse - Swiss Cyber Defence Campus for the Distinguished Post Doctoral Fellowship supporting AK, and for providing the computational infrastructure for experiments, as well as Drs Rachid Guerraoui (EPFL) and Ljiljana Dolamic (CYD/Armasuisse), for oversight and general advice on this project, and finally Fabien Salvi (EPFL) for the technical support regarding the computational infrastructure organization.

Abstract

We propose a novel framework for predicting the factuality of reporting of news media outlets by studying the user attention cycles in their YouTube channels. In particular, we design a rich set of features derived from the temporal evolution of the number of views, likes, dislikes, and comments for a video, which we then aggregate to the channel level. We develop and release a dataset for the task, containing observations of user attention on YouTube channels for 489 news media. Our experiments demonstrate both complementarity and sizable improvements over state-of-the-art textual representations.

1 Introduction

Disinformation in the news and in social media is perceived as having a major impact on society, e.g., during the 2016 US Presidential election (Grinberg et al., 2019) and the Brexit referendum (Gorrell et al., 2018). During the COVID-19 pandemic outbreak, the moral panic (McLuhan, 1964) around online disinformation grew to a whole new level as the first global infodemic.¹ Nowadays, fighting disinformation online grew to a whole new level as the first global infodemic.¹ Nowadays, fighting disinformation online has been recognized as one of the most important issues societies around the world are facing today.

In this paper, we highlight an aspect of disinformation that is often neglected. Rather than examining the truth-value of individual piece of information, we investigate the general quality of the attention regimes in different news outlets, by analyzing news media’s YouTube channels.

YouTube is the largest and the most popular platform for video sharing with over two billion users and it is also the second most widely used news source in USA, after Facebook.² While the platform has been scrutinized for the way in which it may amplify marginal and sometimes radical contents (Munn, 2019; Ribeiro et al., 2020), the connection between attention dynamics and disinformation levels is still largely unexplored.

Here, we do not focus on specific videos, but rather on entire YouTube channels of news media and their attention dynamics. In particular, we are interested in differentiating the “attention cycles” (Downs, 1972; Leskovec et al., 2009) of YouTube channels, that is to assess the rapidity and the steepness with which their videos rise and fall in the consideration of their audiences. While some outlets encourage extensive and diverse discussions, other tend to concentrate everyone’s attention on the latest hot-button, thus distracting the public opinion instead of nourishing it (Venturini, 2019).

Our contributions are the following:

- We propose to model the factuality of news media based on the user attention cycles in their respective YouTube channels.
- We release a specialized dataset for the task.³
- We show experimentally that considering attention cycles yields considerable performance gains on top of text representations for predicting the factuality of news media.

The paper is organized as follows: Section 2 presents related work. Section 3 describes our dataset. Section 4 discusses our methodology. Section 5 presents the experiments and results. Section 6 offers analysis and discussion. Section 7 concludes and points to directions for future work.

2 Related Work

Significant efforts have been dedicated in the last years to automating the detection of disinformation (which is commonly referred to as fake news), which we look at more closely in this section. At the end, we mention previous attempts to use data from YouTube for media classification tasks.

Analysis of the Content Many approaches have been proposed to analyze both the style and the content of fake news. Using natural language processing techniques, Horne and Adali (2017) pointed out how fake news can be characterized by stylistic features such as the overuse of proper nouns, punctuation, capital letters, negation terms, and repetitions in the text (Rubin et al., 2016). Fake news has also been associated with intensity of sentiment and emotions, compared to mainstream news (Gianchanou et al., 2019). Here, we also use textual representations, but (i) we focus mainly on analyzing the user attention cycles in YouTube channels, and (ii) we aim at categorizing entire news media outlets rather than individual pieces of news.

Analysis of the Response Many researchers used the user reactions in social media platforms to identify disinformation, e.g., the content and the number of replies to a piece of news, or the propagation of the content in the network. For instance, Zhao et al. (2015) classified disputed claims based on their comments and reactions, assuming that, if a claim is not true, at least some replies would question its factuality. Indeed, later studies (Ruchansky et al., 2017; Nguyen et al., 2020) have shown that user response features are quite important. Here, we also focus on inspecting the user response and its potential link to disinformation, but we use user attention cycles in YouTube.

Analysis of Entire News Media Outlets Looking at a news media outlet as a source of low-quality content is another way to approach the problem. In these methods, features modelling the overall trustworthiness of the source are used, such as (i) Does the news media outlet use verified accounts on established platforms, such as Wikipedia and Twitter? (ii) If it does, do these accounts have a proper description, location, website references, etc? (iii) How does the URL of the media’s website look like? (iv) Does the medium express political bias or sentiment? Baly et al. (2018) and Baly et al. (2020) used features motivated by these questions to achieve better results in combination with content features and user profiles in social media. In our work, we also aim at classifying entire news media outlets, but we do so using user attention cycles in YouTube along with text.

Using Temporal Attention Data for Disinformation Detection We focus on the analysis of temporal patterns associated with news outlets of different type and quality. Previous studies (Ruchansky et al., 2017; Nguyen et al., 2020) have suggested that a combination of temporal, content-based, and user-based features is promising for disinformation detection. As the dynamics of the viral spread is often associated with successful junk news, we look at studies focusing on modelling virality, such as (Hoang et al., 2011) for tweets. Similar features are well-suited for our task, as described in Section 4.1.2, but (i) we model the user behavior differently, and (ii) we focus on data collected from the YouTube channels of the target news media.

Using YouTube Data for Classification The YouTube platform contains information that is still underexplored for the purposes of disinformation detection. Dinkov et al. (2019) looked into detecting the left-centre-right political bias of YouTube channels. Baly et al. (2020) included features from the news source’s YouTube channel, derived from both sound and user profiles. The above work uses raw statistics about the number of views, likes, dislikes, and comments per video. We, instead, use much richer temporality features in combination with the textual representation of the videos.

3 Data

We started from a corpus of news media outlets, whose reliability has been evaluated by Media Bias/Fact Check (MBFC). Lead by a team of independent journalists and researchers, MBFC has analyzed close to 4,000 news outlets over the past six years. For each news outlet, they provide a detailed analysis summarized by a ‘factuality’ score chosen among: Very High, High, Mostly Factual, Mixed, Low, and Very Low.
Factuality | Channels | Videos |
<table>
<thead>
<tr>

<td>37,148</td>
</tr>
</tbody>
</table>

Table 1: Statistics about the dataset, showing the distribution of the channels and of the videos for each level of factuality of reporting.

We searched the YouTube channels of news outlets in the MBFC corpus and we monitored all the videos they published from February’2020 to August’2020. Using the YouTube Data API,\(^5\) we collected the number of views, likes, dislikes and comments collected during the first seven days after the publication of each video. We also stored its title and its description.

We observed that the percentage of media channels labelled with the Very High and the Very Low categories was 3.1% and 1%, respectively. We thus merged Very High with Mostly Factual with Mixed; and Very Low with Low, ending up with a 3-way labelling: High, Mixed, and Low.

Finally, for the sake of data balancing, we excluded the channels with fewer than 20 videos, and we capped the most prolific channels at the newest 100 videos. The final distribution of channels and their corresponding videos for each level of factuality is shown in Table 1.

4 Method

Our system is composed of two main components focusing on (i) data preparation, and on (ii) sequential classification, respectively. Below, we describe the representation we use for video-level and also for channel-level classification.

4.1 Representation

The data preparation component transforms the YouTube source data and produces representations (or features) for our model. We generate representations both for the textual content of the videos and for the user attention data, for which we introduce a number of novel features, presented in Section 4.1.2.

4.1.1 Textual Features

We gathered the title and the description of each video. We extracted Sentence BERT embeddings (768 features) for each title and description. These embeddings are derived from a modification of the pretrained BERT model, which yields semantically meaningful sentence embeddings of size 768, which are trained to be readily comparable using cosine similarity (Reimers and Gurevych, 2019).

4.1.2 Attention Features

We hypothesize that the attention received over time by the videos in a YouTube channel can be used to predict the quality of its contribution to the online public debate, as captured (albeit imprecisely) by the factuality score assigned by MBFC. We generate a set of features that model the user attention cycles by looking at the temporal variation of the number of user actions (Views, Likes, Dislikes, and Comments) in the first week after a video has been published. We aim to model the following:

- How are user actions distributed hourly/daily?
- How much are the user actions concentrated in peak hours?
- At what moment in time does the peak hour for each user action type occur?
- How steep is the time series in terms of the distribution of hourly user actions?

We define \( UA_{d_i} \) as the total number of user actions that occurred by the end of day \( i \). In our case, \( i \) ranges in \( \{1, 2, \ldots, 7\} \). Similarly, \( UA_{h_j} \) is the number of user actions occurring by the end of hour \( j \) after the publication of the video. We generate a set of attention features for each user action, which we group into the following categories:

1. User actions daily percentage \((D_{d_i})\), or the fraction of user actions out of the total that occurred on day \( i \), where \( 1 \leq i \leq 7 \), and \( UA_{d_0} = 0 \) (7 features per user action):

\[
D_{d_i} = \frac{UA_{d_i} - UA_{d_{i-1}}}{UA_{d_7}}
\]

2. User actions daily cumulative percentage \((DC_{d_i})\), or the fraction of user actions out of the total by the end of day \( i \), where \( 1 \leq i \leq 7 \) (7 features per user action):

\[
DC_{d_i} = \frac{UA_{d_i}}{UA_{d_7}}
\]

\(^5\)http://developers.google.com/youtube/v3/docs/videos
3. User actions daily increase ($DI_d_i$), or the proportion of increase in the number of user actions on day $i$ compared to day $i - 1$, where $2 \leq i \leq 7$ (6 features per user action):

$$DI_d_i = \frac{UA_d_i - UA_{d_i-1}}{UA_{d_i-1}}$$

4. User actions hourly increase ($HI_{h_j}$), or the proportion of increase in the number of user actions during hour $j$ compared to those during hour $j - 1$, where $2 \leq j \leq 168$ (167 features per user action):

$$HI_{h_j} = \frac{UA_{h_j} - UA_{h_{j-1}}}{UA_{h_{j-1}}}$$

5. User actions average hourly increase per day ($AHI_{d_i}$), or the average hourly increase in the number of user actions on day $i$, where $1 \leq i \leq 7$ (7 features per user action):

$$AHI_{d_i} = \frac{\sum_{j=(i-1)*24+1}^{i*24} HI_{h_j}}{24}$$

6. User actions majority interval length ($MI_T$), or the number of hours containing the majority of the user actions

$$MI_T = \min_{1 \leq i, j \leq 168} \left\{ j - i \left| \frac{UA_{h_j} - UA_{h_i}}{UA_{h_{168}}} \geq T \right. \right\}$$

where $T$ (one of $\{0.5, 0.7, 0.9\}$) is the majority share (3 features per user action).

7. User actions peak delay interval ($PDI$), or the number of hours leading to the hour with the highest concentration of user actions (1 feature per user action):

$$PDI = \arg\max_{\{i|2 \leq i \leq 168\}} UA_{h_i} - UA_{h_{i-1}}$$

8. User actions alive interval length ($AI$), or the hour up to which user actions were recorded (1 feature per user action):

$$AI = \min_{1 \leq p \leq 167} (p|UA_{h_i} - UA_{h_{i-1}} = 0, \forall i \in \{p+1, \ldots, 168\})$$

9. User actions peak share ($PS$), or the number of user actions during the peak hour divided by the total (1 feature per user action):

$$PS = \max_{2 \leq i \leq 168} \left\{ \frac{UA_{h_i} - UA_{h_{i-1}}}{UA_{h_{168}}} \right\}$$

Figure 1: First day breakdown into periods

Most of the attention received by the videos in our corpus is concentrated in the first day after a video has been published, and thus we monitor the attention during this period more closely. Besides daily and hourly, we look at six additional periods during the first day, as depicted on Figure 1. We extract the following features: (i) Percentage of User Actions per Period, (ii) User Actions per Period Increase, and (iii) User Actions Average Hourly Increase for a Period. This yields 18 additional features and a total of 218 features per user action.

To model the opinion of the users regarding the videos, we also use features derived by ratios of different user action types:

- **Positive Reactions**: the ratio between the number of likes and the number of views;
- **Negative Reactions**: the ratio between the number of dislikes and the number of views;
- **Engagement**: the ratio between the number of comments and the number of views;
- **Controversiality**: the ratio between the number of likes and the sum of the number of likes and dislikes.

For each of these ratios, we calculate a set of features that show how the numbers change daily, similarly to the User Actions Daily Percentages (7 features per ratio) and the User Actions Daily Cumulative Percentages (6 features per ratio) features. We further generate ratio features for the more granular first day periods (6 features per ratio), which yields a total of 19 ratio-driven features. Overall, we have 952 attention features per video.

### 4.2 Models

Our architecture contains two consecutive classifications: (i) for YouTube videos, and (ii) for YouTube channels. As we want to make use of the features derived from the YouTube videos, we labelled each video with the factuality score of the channel that published it, using distant supervision.
Thus, the video classification learns to predict the factuality labels that are projected from the corresponding channels. Naturally, not all videos published by a low-factuality channel necessarily contain disinformation. Yet, this is not a problem since we do not aim at classifying correctly individual videos, but at detecting factuality-related patterns, which would then be used at the channel level: our channel classifier uses the predictions of the video-level classifier to predict the factuality of channels.

4.2.1 Video Modelling
For each video, we have 768 features from the sentence-level BERT representation. We calculated these features once for the title and once for the description of the video, obtaining a total of 1,536 textual features.

We further have 952 attention-driven features per video. To validate the relevance of these features with respect to our classification task, we apply a set of feature selection methods over the training split of our dataset, namely ANOVA, Pearson correlation, and Spearman correlation. According to these methods, the ratio features turn out to be the most relevant ones. We selected the best 100 features from each method or 124 attention video-level features, which we used in our classification experiments. Combined with the 1,536 textual features, this yielded a total of 1,660 features per video.

4.2.2 Channel Modelling
For the second classifier, at the channel level, we generate the following groups of features:

1. YouTube statistics (total of 13 features):
   - Popularity (7 features): number of subscribers, average number of hourly, daily, and weekly views and comments;
   - Activity (5 features): number of videos, average number of videos published hourly, daily, and weekly, and average number of videos per channel subscriber;
   - Attention concentration (1 feature): Gini index measuring the concentration of video views within a channel.

2. Averaged videos features (1,660) features): average values of the features for the videos published by the channel. For each video feature, we have a corresponding aggregated channel feature.

3. Aggregated video-level classifier predictions features (9 features): for each channel, we aggregate the predictions of the video-level classifier for the videos in that channel. We use three types of aggregations:
   - maximum probability across the videos for each factuality label;
   - average probability across the videos for each factuality label;
   - factuality distributions percents: for each factuality, this is the percent of videos predicted to have that factuality.

5 Experiments and Evaluation
We train two subsequent classifiers for factuality prediction: for videos and for channels. We conduct experiments with different models and we compare them to a majority-class baseline. We evaluate the models in terms of accuracy, balanced accuracy, and mean absolute error (MAE). MAE is a more relevant measure in our case as it takes into account the ordering of the labels: confusing high factuality with mixed factuality is a smaller error than confusing it with low factuality.

While our ultimate goal is to classify channels, we start with video classification, then we aggregate the predictions, and we use them to make predictions at the channel level.

We divide the dataset into training, development, and test split at the channel level. Then, for the video-level experiments, we use for training/development/testing the videos for the respective channels. Note that this guarantees that all videos for a given channel go into the same split.

5.1 Video-Level Classification
Below, we report results using Gradient Boosted Decision Trees (GBDT). We also experimented with logistic regression, ordinal logistic regression, and SVM with various kernels, but they performed worse. We trained separate models (a) using the textual representation, and (b) using the user attention cycles. Table 2 shows the evaluation results.

</tbody>
</table>

Note that our datasets are not well-balanced and have very few examples of low-factuality videos and channels. To mitigate this, we apply oversampling using SMOTE (Chawla et al., 2002), which generates additional synthetic examples. Moreover, it is important that the video classifier generates predictions for the low-factuality and the mixed-factuality classes; otherwise, the predictions for these classes could be lost when aggregating for the channel classification. Thus, we also report balanced accuracy, as it is important when choosing which video experiments to select for aggregation.

5.2 Channel-Level Classification

We experimented with several approaches for channel classification:
- using aggregated video-level features to obtain channel-level representation;
- using the posterior probabilities of video-level classifiers;
- using the previous two together;
- ensemble of different channel-level classifiers.

For the ensemble aggregation, we experimented with three methods for choosing the most likely class for a given channel:
- after averaging the predictions from the various models (mean);
- after getting the maximum probability prediction from the various models (max);
- after getting the minimum probability prediction from the various models (min) – tells us which class is least likely to be wrong.

The results are shown in Table 3. All experiments use GBDT, except for experiment 8, which uses ordinal logistic regression.

6 Discussion

Below, we analyze the results and we perform an ablation study.

6.1 Result Analysis

We can see in Table 3 that all models improve over the majority class baseline by a sizable margin. We further see that using average information on user attention cycles (line 4) performs better than using textual features (lines 1–3). Moreover, combining the two yields the best result (line 8). The other two sets of user attention features: channel statistics and aggregated video-classifier predictions, do not contribute to the combined user attentions model (compare line 4 to line 6).

The relative improvements over the majority class baseline in terms of accuracy are generally smaller than those for MAE, which can be explained by class imbalance. To improve accuracy, the models need to learn to assign mixed and low factuality labels properly (as the majority class is high factuality). Most of the trained models undervalue the unrepresented classes. If some of the balancing techniques are applied, the models recognize better the low and the mixed examples, but at the cost of false positives for these classes from the high-factuality examples, which decreases the overall accuracy. In contrast, MAE rewards models that can improve the small classes even given the risk of introducing some errors for the majority class.

6.2 Ablation Study

As our focus is on attention cycles, we performed an ablation study for these features against the combined user attention channel model. The results are shown in Table 4. We can see that ratio features such as controversiality and positive reactions alone yield the best accuracy and MAE. Using the predictions of the video-level classifier as features yields the best balanced accuracy. This confirms the importance of having accurate low- and mixed-factuality predictions for the video classifier prior to the aggregation. Finally, the overall best results, when considering all measures, are achieved when combining all features.

7 Conclusion and Future Work

We proposed a novel framework for predicting the factuality of reporting of news outlets by studying the user attention cycles in their respective YouTube channels. We further designed a rich set of features derived from the temporal evolution of the number of views, likes, dislikes, and comments for a video, which we then aggregated at the channel level. Our experiments demonstrated both complementarity and sizable improvements over state-of-the-art textual representations.

We further developed and released a dataset containing observations about user attention on YouTube channels for 489 news media. We hope that this will enable future research on using data from video sharing platforms.

In future work, we plan to improve the class imbalance of the dataset by extending it with more examples. We further want to integrate additional features based on the comments for the videos and other information sources such as Twitter and Wikipedia. Finally, we plan to study the utility of user attention cycles for other related tasks such as political ideology detection for news media.

Ethics and Broader Impact

Data Collection Our dataset was collected from YouTube, using their public API.

User Privacy Our dataset contains aggregated attention statistics without any user data.

Biases Any biases found in the dataset are unintentional, and we do not intend to do harm to any group or individual.

Intended Use and Misuse Potential Our dataset and the proposed model can enable the development of systems for automatic detection of reliable/unreliable YouTube channels, which could support media literacy, as well as analysis and decision making for the public good. However, they could also be misused by malicious actors.

Environmental Impact Finally, we would also like to warn that the use of large-scale Transformers requires a lot of computations and the use of GPUs/TPUs for training, which contributes to global warming (Strubell et al., 2019).

Acknowledgments

This research is part of the Tanbih mega-project, developed at the Qatar Computing Research Institute, HBKU, which aims to limit the impact of “fake news”, propaganda, and media bias by making users aware of what they are reading, thus promoting media literacy and critical thinking.

This research is also partially supported by Project UNITe BG05M2OP001-1.001-0004 funded by the OP “Science and Education for Smart Growth” and co-funded by the EU through the ESI Funds.

Deep CNN–LSTM hybrid neural networks have proven to improve the accuracy of Optical Character Recognition (OCR) models for different languages. In this paper we examine to what extent these networks improve the OCR accuracy rates on Swedish historical newspapers. By experimenting with the open source OCR engine Calamari, we are able to show that mixed deep CNN–LSTM hybrid models outperform previous models on the task of character recognition of Swedish historical newspapers spanning 1818–1848. We achieved an average character accuracy rate (CAR) of 97.43% which is a new state–of–the–art result on 19th century Swedish newspaper text. Our data, code and models are released under CC BY licence.

2 Related Work

Mainly due to the introduction of recurrent neural networks (RNNs) in particular with the Long Short–Term Memory (LSTM) architecture (Breuel, 2017) great progress has been made in the field of OCR in recent years. Today most of modern OCR systems leverage deep learning algorithms for training models and to improve performance. For instance some state-of-the-art OCR systems use shallow LSTM neural networks, consisting of one or two hidden layers (Breuel, 2008). LSTM models became a standard in 2013 (Breuel et al., 2013) and LSTM-based networks have proven to be one of the most effective approaches for complex natural language processing (NLP) tasks (Hochreiter and Schmidhuber, 1997; Alom et al., 2019). Likewise Convolutional Neural Networks (CNNs) have shown outstanding results for image data processing tasks (Krizhevsky et al., 2017) including

1https://pdf.abbyy.com

2Data, code and models are released under CC BY licence:
https://github.com/mskelb/EXJOBB
feature extraction (Lecun and Bengio, 1995). Hybrids of these two network structures are used in a high diversity of fields and have achieved state-of-the-art results in many cases (Wick et al., 2018).

Breuel (2017) presented a groundbreaking deep hybrid CNN–LSTM implementation for text recognition, that outperformed previously state of the art methods based on shallow LSTMs. Reul et al. (2017) show that transfer learning drastically improves character accuracy rates on early printed books, compared to when training models from scratch. A year later this have become the default approach for training models. In their continued research Reul et al. (2018) utilize a combination of cross-fold training and confidence voting and succeed to significantly reduce character error rates on early printed books, compared to training a single model on a single fold. Along the same lines, in our work we also train an ensemble of models on a cross-fold of the same GT data and then combine the models through voting.

Drobac and Lindén (2020) and Wick et al. (2018) approach the complex task of OCR for historical prints by utilizing these types of deep CNN–LSTM hybrid networks. To improve OCR results for historical Finnish and Swedish newspapers and journals Drobac and Lindén (2020) train mixed-language models and after post-processing of the OCR output achieve 1.7% CER for the Finnish, and 2.7% CER for the Swedish test set from 1771 to 1874. Unlike Drobac and Lindén (2020) we do not apply any post-processing method but rather focusing on increasing the accuracy of the Swedish character model.

In Wick et al. (2018) error–rates are successfully reduced to a factor of up to 55% for digitised historical texts from the ICDAR 2017 dataset, achieving an average CER of 1.5%. To further improve these results, confidence voting was applied, resulting in CER below 0.5%. Moreover, Wick et al. (2018) show these types of deep neural networks significantly outperform shallow networks in terms of both recognition capabilities and speed.

3 Calamari Deep CNN–LSTM Hybrid Networks

Calamari is a high–performance Tensorflow–based package for line based recognition using state of the art Deep Neural Networks (DNNs) (Wick et al., 2020). The advantage of Calamari is that the software supports customized deep network architectures composed by Convolutional Neural Networks (CNNs) and Long Short–Term Memory (LSTM) layers, trained by the Connectionist Temporal Classification (CTC) algorithm described in Graves et al. (2006). It uses the Tensorflow 3 framework for deep neural network computations, and consequently supports training and recognition on the graphics processing unit (GPU), which is proven to significantly reduce the overall computation time (Wick et al., 2020).

Calamari also provides additional features that might improve accuracy rates, such as pre–training, early stopping, cross–fold training, data argumentation, and confidence voting of different predictions. However, while data augmentation has been shown to improve accuracy for small data sets, it impairs the accuracy for larger data sets according to Wick et al. (2020). Moreover, Calamari with its deep network architecture has proven to significantly outperforms the shallow one–dimensional LSTM based neural network approach, such as the one used by OCRopus (Breuel, 2008) in terms of both recognition capabilities and speed (Drobac and Lindén, 2020; Wick et al., 2018).

The default neural network structure consists of two consecutive CNN blocks containing a convolution and a max–pooling layer, both connected with a ReLU–activation function. Each of the two convolution layers has a kernel size of 3 x 3, the first one consists of 40 filters, and the second one of 60 filters. The pooling layer has a kernel size and stride of 2 x 2. This is followed by a bidirectional LSTM layer, and finally an output layer with a drop–out rate of 0.5 in order to prevent overfitting. Given the predictions of the output–layer and the GT labels, the CTC–loss is computed.

4 Data and Preprocessing

The reference data we experimented with forms part of the KubHist data (Adesam et al., 2019). It is a large collection of approximately 300 thousand Swedish historical newspaper editions, spread over roughly 200 years. The collection has been digitised and OCRed by the National Library of Sweden.

Part of the KubHist, more specifically a reference data of 400 pages spanning between 1818 and 2018, was processed through an enhanced OCR–process (Dannélls et al., 2019) by combin-
ing two OCR engines: Abbyy FineReader, and the open source system Tesseract. This two–OCR engine system was originally developed in cooperation with the Norwegian software company Zissor in 2017 and is based on the principle of evaluating and comparing the OCR results from multiple engines. The approach has been proven to improve the character recognition accuracy for some newspapers (Dannélls et al., 2020). Many errors however remain. The reference data comes with a ground truth (GT) data available in plain text files. It was first segmented down to paragraph level, and further manually transcribed through double–keying.

This reference material has been previously used to evaluate the two–OCR engine system, focusing on the time period 1818–2018. The evaluation results show that accuracy varies from 56.65% to 98.41%, on character level, depending on the newspaper edition. These results further constitute the very baseline of this project.

4.1 Challenges

The challenge of the KubHist corpus lies in the amount of OCR errors that are currently very high in some parts of the collection. Especially texts from the early 19th century where it is estimated that most of the text (roughly 75%) is printed in Blackletter. The Blackletter typeface is generally challenging for OCR systems to recognize due to the many font variations, low distinctiveness of characters, and in many cases, lack of training data of acceptable quality (Holley, 2009; Furrer and Volk, 2011). Large part of the OCR errors is a result of the low accuracy of the pre–trained language models that were trained on a limited amount of Swedish data and were used in the OCR process.

4.2 Data Preprocessing

To test the performance of our mixed deep CNN–LSTM hybrid models, part of the avail-

able reference material has been used for training, validation and testing respectively. This dataset we experimented with contains two pages from each newspaper edition during the time period 1818–1848. In all 30 newspaper editions, one from each year, and 60 newspaper pages that have been further pre–processed through image binarization and de–skewing using the ocropus-nbin script provided by OCRopus. For the binarization procedure adaptive thresholding has been applied. All newspaper pages have been further re–segmented into text line images using the ocropus-gpageseg script, also provided by OCRopus, comprising a total of 8 413 lines, 67 441 words and 423 414 characters. To maintain the data as clean as possible incorrectly segmented text lines as well as non textual content such as vertical and horizontal lines etc. have been manually removed.

5 Experiments and Results

Our strategy for dividing the dataset into training and test sets has been to randomly selecting lines from each newspaper page. 80% has been allocated for training and 20% for testing. This way of randomizing generates a good diverse training data and hence a good representation of the data that is important for constructing a model able to generalize well (Drobac and Lindén, 2020). In total, 6 742 lines containing 53 963 words and 338 701 characters have served as training set, 1 671 lines containing 13 478 words and 84 713 characters as test set. For training of a single model (single voter) the final training set has been further split into training and validation subsets, again with a split ratio of 80:20. In total the generated training subset comprises 5 400 lines and the validation set 1 349 lines. More details can be found in Table 1.

Table 1: Details of the training, validation and test sets. B:A is the distribution of Blackletter and Antiqua.
Once the line images have been prepared we use them together with their ground truth to train models with Calamari. During training early stopping has been applied in order to avoid overfitting and improve generalization. If performance on the held out validation dataset after each epoch has not improved after 5 epochs or if validation loss has begun increasing training was stopped. One approach for reducing overfitting is to add more examples to the training data. However, since segmenting newspaper pages into image lines and linking them to their corresponding GT lines has turned out to be relatively time consuming. Adding more data in order to investigate whether results can be improved has not been done.

To improve performance and find the optimal neural network structure for our data a series of experiments have been performed using different network configurations. These include testing out different combinations and dimensions of the CNN and LSTM layers and in this way expanding the network. These experiments are described in the following sections. In all our experiments both single models are trained as well as using a combination of cross-fold training and subsequent confidence voting. Training was performed using a 5–fold over the same training data resulting in 5 models with different characteristics. These 5 models are then used to recognize the held out test lines. For each test line a total of 5 output sequences are generated, 1 from each model. These 5 output sequences later serve as the input for the voting process in order to determine the final output by using confidence scores.

After experimenting with different network configurations both by training single models and by combining cross-fold training and confidence voting we found that the best results were achieved using the following neural network, seen in Equation 1.

\[
\begin{align*}
\text{cnn} &= 80 : 3 \times 3, \text{pool} = 2 \times 2, \\
\text{cnn} &= 100: 3 \times 3, \text{pool} = 2 \times 2, \\
\text{lstm} &= 200, \text{dropout} = 0.5, \\
\text{lstm} &= 200, \text{dropout} = 0.5.
\end{align*}
\]

(1)

The optimized neural network consists of two consecutive CNN blocks containing a convolution layer followed by a max–pooling layer. Both connected with a ReLU–activation function. Each of the two convolution layers have a kernel size of 3 x 3. The first one consists of 80 filters and the second one of 100 filters. The pooling layer has a kernel size and stride of 2 x 2. The two CNN blocks are followed by two LSTM layers containing a total of 400 nodes divided over two layers with 200 nodes each.

5.1 Experimental Setup

We ran four experiments using the following model combinations:

- **M1**: single model trained using Drobac and Lindén (2020) neural network in Equation 3.
- **M2**: single model trained using Calamari’s default neural network in Equation 2.
- **M3**: single model trained using the optimized neural network in Equation 1.
- **M4**: 5 best models trained using cross-fold training with the same optimized neural network in combination with subsequent confidence voting.

**Experiment I** In this initial experiment we train a single model using Calamari’s default neural network as specified in Equation 2

\[
\begin{align*}
\text{cnn} &= 40 : 3 \times 3, \text{pool} = 2 \times 2, \\
\text{cnn} &= 60: 3 \times 3, \text{pool} = 2 \times 2, \\
\text{lstm} &= 200, \text{dropout} = 0.5.
\end{align*}
\]

(2)

**Experiment II** We further train a single model following the same network architecture as in Drobac and Lindén (2020) and in Equation 3. Similar to the default Calamari network this network contains two consecutive CNN blocks containing a convolution and a max–pooling layer. Both are connected with a ReLU–activation function as can be seen in Equation 4.2. Each of the two convolution layers has a kernel size of 3 x 3. The first one consists of 128 filters and the second one of 128 filters. The pooling layer has a kernel size and stride of 2 x 2. In addition, the LSTM layers contain a total of 1 200 nodes divided over two layers with 600 nodes each. Here we want to investigate how performance changes using a deeper network.

\[
\begin{align*}
\text{cnn} &= 128 : 3 \times 3, \text{pool} = 2 \times 2, \\
\text{cnn} &= 128: 3 \times 3, \text{pool} = 2 \times 2, \\
\text{lstm} &= 600, \text{dropout} = 0.5. \\
\text{lstm} &= 600, \text{dropout} = 0.5.
\end{align*}
\]

(3)

**Experiment III** In this experiment we want to find the optimal neural network for our data. In
Table 2: CAR results for the four different models. Respective model combinations: M1–Drobac, M2–Calamari, M3–Single model trained with the optimized network, M4–5 best models trained with the optimized network.

Reul et al. (2018) it was shown that a combination of cross-fold training and confidence voting led to significantly lower character error rates compared to training a single model. Therefore to test the models’ ability of predicting never seen before data we have followed the same approach in our continued experiments. However, in order to investigate how much this combination can improve performance models have been trained both by (1) single training resulting in a single voter and (2) by cross-fold training resulting in 5 models.

Experiment IV This experiment investigates the transferability of models and their ability to generalize on previously unseen data. In this case unseen data is a collection consisting of journals and newspaper published in Finland between 1771 and 1874. Two relatively small datasets of text line images and their corresponding GT have been randomly sampled from the Swedish test dataset in Drobac and Lindén (2020). The first set contains 50 lines printed in Fraktur and the second 50 lines printed in Antiqua. Models have been tested on each separate test set using confidence voting. What has been interesting to see here is how mixed models behave on a specific font type.

5.2 Evaluation Metrics

Calamari uses the Character Error Rate (CER) metric defined as the “edit distance (ed) of two sequences $s_1$ and $s_2$ normalized by the maximum length” (Wick et al., 2020) as stated in Equation 4. Edit distance corresponds to the Levenshtein distance and the sequences to the text lines and the corresponding GT lines. There are two common ways of measuring OCR errors or accuracy. One of which is at the character level (CER or CAR) and the other one at the word level (WER or WAR) (Holley, 2009).

$$CER = \frac{ed(s_1, s_2)}{\max(\|s_1\|, \|s_2\|)}$$ (4)

While CER is used for measuring performance of our models CAR has previously been used in the evaluation process of the two–OCR engines in Dannélls et al. (2020). In order to give a fair comparison of results a conversion has been made between CER and CAR. Moreover, when testing an ensemble of 5 models on the held out test lines we use the confidence based voting to combine them.

5.3 Results

Table 2 summarises the performance in average CAR (%) and CER (%) of the different combinations of the trained models tested on different datasets. Models in (1)–(4) have been evaluated using our test data. Models in (5) have been evaluated using 50 lines of Fraktur and in (6) 50 lines of Antiqua has been used originating from the Swedish test set in Drobac and Lindén (2020).

As Table 2 shows the test results trained with a single model (M2) reveals a significant improvement in CAR. An average 96.06% CAR was achieved corresponding to 3.94% CER. This can be compared to our baseline with an average CAR of 82.37% in Dannélls et al. (2020) for the specific time period.

The test results of M1 shows slightly lower CAR of 95.55% corresponding to 4.45% CER compared to using Calamari’s default network.

The best CAR was achieved when voting with 5 models (M4 in Table 2) originating from 5-fold training using the neural network in Equation 1. We achieved CAR of 97.43% corresponding to CER of 2.57% after evaluation on the test set.

Training a single model (M3 in Table 2) with the same neural network and then evaluating on the test set resulted in a slightly lower CAR of 96.44%
Table 3: CAR for each newspaper edition spanning between 1818–1848. The second column show previously obtained results from the evaluation of the two OCR–engine system in Dannéls et al. (2020), which constitutes the baseline for this project. Third column show results obtained after cross-fold training and voting using the neural network architecture in Equation 1. The forth column show the different in percentage units between the baseline and our results.

</table>

Average 82.37% 97.43% +15.06
corresponding to a CER of 3.56%. Compared to using voting this is nearly a 1% drop in CAR corresponding to approximately 827 more errors in the output. In total the best CAR of 97.43% is an improvement of 15.06% in comparison to the baseline. The results for each individual newspaper edition can be found in Table 3. In total CAR has improved for each individual newspaper edition.

All results were achieved through voting by the 5 models trained using the optimized neural network in Equation 1. Evaluation of the results on the test dataset containing 50 lines of Fraktur showed 96.84% CAR corresponding to 3.16% CER, displayed at row (5) in Table 2. On the test set containing Antiqua a slightly lower CAR of 96.44% was achieved corresponding to 3.56% CER.

5.4 Error Analysis

Table 4 show confusion matrices over the 10 most common character errors made by the single model (left) and after voting using an ensemble of 5 models (right). All models were trained using the optimized neural network in Equation 1. The most common confusions are in both cases as expected similar characters, such as “¨a” and “a”, “¨o” and “o” and the confusion between long–s “ſ” and “f”. Most notable when using voting the number of confusions of “¨o” and “o” dropped from 95 to 52 occurrences and the deletion of a space dropped from 53 to below 10 occurrences. In summary, all confusions were reduced using voting. However, the confusions between “¨a” and “a”, and “¨o” and “o” still constitute the most frequent confusions.

6 Conclusion and Future Work

In this paper we have investigated how deep CNN–LSTM hybrid neural networks can be utilized in order to improve current OCR results for 19th century Swedish newspaper text. Mixed deep CNN–LSTM hybrid models have been successfully trained in Calamari for the task of character recognition of Swedish historical newspaper texts spanning 1818–1848. Initial testing with the Calamari default network revealed a significant improvement in accuracy compared to our baseline (avg. 82.37% CAR) resulting in a CAR of 96.06%. This test alone showed the advantage of training individual mixed models over pre–trained models from commercial systems such as ABBYY FineReader. Highest CAR of 97.43% was achieved through voting with 5 best models using the optimized network. Thus, the combination of cross-fold training and confidence based voting significantly improve accuracy rates compared to training a single model using the same neural network. Furthermore, our best results show a significant improvement over the baseline results for the specific time period.

A promising future direction is to incorporate active learning (Reul et al., 2018). Active learning is based on the principle of maximal disagreement. An ensemble of voters (or models) are first trained on a set of training lines with their corresponding GT. Then, the voters are given unseen text lines and make predictions. Those lines where voters disagree the most on is then added to the training data for subsequent training enabling a maximal learning effect.
Acknowledgments

This work has been funded by the Swedish Research Council as part of the project Evaluation and refinement of an enhanced OCR-process for mass digitisation (2019–2020; dnr IN18-0940:1).

It is also supported by Språkbanken Text and Swe-Clarin, a Swedish consortium in Common Language Resources and Technology Infrastructure (CLARIN) Swedish CLARIN (dnr 821-2013-2003). The authors would like to thank the RANLP anonymous reviewers for their valuable comments.

Abstract

In this work, we provide an extensive part-of-speech analysis of the discourse of social media users with depression. Research in psychology revealed that depressed users tend to be self-focused, more preoccupied with themselves and ruminate more about their lives and emotions. Our work aims to make use of large-scale datasets and computational methods for a quantitative exploration of discourse. We use the publicly available depression dataset from the Early Risk Prediction on the Internet Workshop (eRisk) 2018 and extract part-of-speech features and several indices based on them. Our results reveal statistically significant differences between the depressed and non-depressed individuals confirming findings from the existing psychology literature. Our work provides insights regarding the way in which depressed individuals are expressing themselves on social media platforms, allowing for better-informed computational models to help monitor and prevent mental illnesses.

1 Introduction

Mental health disorders are a common problem in our world. Currently, mental health issues are on the rise: there is a 13% increase in the past decade according to World Health Organization (WHO)1, with depression being at the forefront. Many mental illnesses remain undiagnosed due to social stigma, leading people to live 1 in 5 years of disability in their lifetime.

With the rise of social media websites, interdisciplinary researchers in natural language processing, psychology and network analysis have turned their attention to automatically detect and monitor mental health manifestations through users’ individual activity on social media platforms (e.g. Facebook, Twitter, Reddit). The research is primarily focused on analyzing users’ texts from posts and comments and determining, through computational linguistics models, the risk for various mental conditions - self-harm, depression, addictions etc.

Research is fulfilled through curated datasets (Yates et al., 2017; Losada and Crestani, 2016; Amir et al., 2019) with texts from primarily Reddit and Twitter. At the forefront of incentivising interdisciplinary research on monitoring mental health on social media are workshops such as the Early risk prediction on the Internet (eRisk) Workshop2 and the Workshop on Computational Linguistics and Clinical Psychology (CLPsych)3.

CLPsych and eRisk are two significant initiatives focusing on the interdisciplinary research area between computational linguistics and psychology. The eRisk Workshop, from the Conference and Labs of the Evaluation Forum (CLEF), focuses on the technologies that can be used for early risk detection of different pathologies or safety threats (Losada et al.). In five years of existence, the workshop addressed multiple mental health problems: pathological gambling, depression, self-harm and anorexia.

The CLPsych Workshop was co-located with several international conferences on natural languages processing, the last edition was co-located with the Annual Conference of the North American Chapter of the Association for Computational Linguistics (NAACL). Throughout the seven editions of this workshop, it hosted shared tasks on depression, post-traumatic stress disorder (PTSD) (Coppersmith et al., 2015b), labeling crisis posts from the peer-support forum ReachOut4 (Milne et al., 2016), predicting current and future psychological health from childhood essays (Lynn et al., 2018), the degree of suicide risk (no risk, low, moderate, no risk, low, moderate,
or severe risk) (Zirikly et al., 2019) and suicide risk prediction from real data donated through OurDataHelps5 (Goharian et al., 2021).

In the present study, we perform a part-of-speech analysis and contribute to the understanding of the differences in social media discourse between depressed and non-depressed individuals. We focus on the differences in part-of-speech use and ground them in the existing literature from psychology researchers. We aim to answer the following two research questions:

RQ1: Are there significant differences in part-of-speech use between individuals with self-reported depression diagnosis and control?

RQ2: Can these part-of-speech features be used alone to differentiate individuals with depression from controls?

2 Related Work

Detecting the manifestations of mental health disorders from social media is an interdisciplinary research problem for researchers from psychology, natural language processing and network analysis. The two main approaches used to detect cues of depression from online users are: extracting linguistic features for a quantitative analysis or using automated models for classification.

The differences in language between depressed and non-depressed individuals focus on greater use of negative words, the personal pronoun "I" (Rude et al., 2004), more words with negative polarity, frequent dichotomous expressions (e.g. always, never) (Fekete, 2002), cues of rumination (reflected in greater use of past tense verbs) (Smirnova et al., 2018) in texts from depressed individuals.

Most linguistic features are extracted using the Linguistic inquiry and word count (LIWC) lexicon (Pennebaker et al., 2001). LIWC provide a list of dictionary words for more than seventy categories: part-of-speech (e.g. personal pronouns, first-person personal pronouns, nouns, present/future/past verbs, adjectives), psychological processes (e.g. social, affective, cognitive processes), personal concerns (e.g. work, money, religion, death), etc. It is used to detect cues of depression (Loveys et al., 2018; Nalabandian and Ireland, 2019; Eichstaedt et al., 2018), neuroticism (Resnik et al., 2013), to explore the language of suicide poets (Stirman and Pennebaker, 2001), etc.

Other approaches to mental illnesses detection from text rely on character and word n-grams (Coppersmith et al., 2015a; Pedersen, 2015) or topic modelling techniques (Preotiuc-Pietro et al., 2015; Bucur and Dinu, 2020).

Recent studies analyzing the online discourse of social media users with depression have focused on other particularities of language, such as offensive language. Birnbaum et al. (2020) found that depressed individuals use more swear words in their Facebook messages compared to controls. Bucur et al. (2021b) apply offensive language identification techniques and show that users with depression diagnosis use more offensive language in their Reddit posts, individuals manifesting signs of depression in their posts having a more profane language and fewer insults targeted towards other individuals or groups.

Computational models used to detect the cues of depression from social media texts rely on traditional machine learning classifiers (e.g. SVM, Naïve Bayes) (De Choudhury et al., 2013; Al-darwish and Ahmad, 2017; Tadesse et al., 2019), CNNs (Orabi et al., 2018; Yates et al., 2017), RNNs (Orabi et al., 2018) or transformer models (Martínez-Castañó et al., 2020; Uban and Rosso, 2020; Bucur et al., 2021a).

In the multimodal framework (involving text, voice and visual cues), the use of syntactic features (e.g. pronouns, adverbs usage) seems to improve the performance in depression detection, further emphasizing the relationship between linguistic features and depression (Morales et al., 2018).

Recently, researchers began exploring the interpretability and explainability of the decisions made by automatic classifiers for mental illnesses detection from social media to further understand the manifestations of different mental disorders in written language (Uban et al., 2021b,a).

3 Data

In our experiments, we use the dataset from the eRisk workshop containing posts written in English from the social media platform Reddit.

The eRisk 2018 dataset (Losada and Crestani, 2016) was created for the early detection of depression task. It contains two classes of users, depression and control. Users from the depression class were annotated by their mention of diagnosis in their posts (e.g. "I was diagnosed with depression"), but expressions such as "I have de-
pression”, “I am depressed” were not taken into account. The authors removed the mentions of diagnosis from the dataset. Users from the control group are random individuals who do not have any mention of diagnosis in their post, including those active in the depression subreddit\cite{Caragea2016}. The training dataset provided by the organizers contains 135 depressed users and 752 controls, while the test dataset contains 79 depressed users and 741 controls. We use both train and test splits in our exploration, consisting of a total of approximately 90,000 submissions from users with a depression diagnosis and over 985,000 in the control group.

4 Methods

Part-of-Speech Analysis For each post in our dataset, we use the spaCy\footnote{https://www.reddit.com/r/depression/} part-of-speech tagger to extract the corresponding tags and also morphological features (e.g. person and number for pronouns) for each word. We extract the universal POS tags\footnote{https://spacy.io/} and the ones from The Penn Treebank tagset\cite{Taylor2003}. We use the latter to explore the differences in the verb tenses. We assign the tenses according to their tags: VBD and VBN corresponding to past tense, VBG, VBZ and VBP corresponding to present tense, and MD tag before a VB corresponds to the future tense\cite{Caragea2016}. From the morphological features provided by the spaCy tagger, we extract the person and the number for all the pronouns. After this analysis, we use the following features in our exploration:

**Universal Part-of-Speech:** ADJ, ADV, NOUN, PROPN, VERB, ADP, CCONJ, DET, PART, SCONJ, AUX, PRON

**Verb tenses:** Past, present, future

**Person of pronouns:** First, second and third-person

**Pronoun number:** Singular and plural, only for the first-person

For each of these features, we compute their frequency for each post in the dataset. For the universal POS, the frequency is computed as the number of occurrences of a specific tag normalized by the total number of tags in a post. For verb tenses, the frequency of each tense is calculated as a percentage of the total number of verb occurrences. For the three kinds of personal pronouns, each frequency is computed as a percentage of the number of all personal pronouns. The frequency of singular and plural first-person pronouns is computed as a percentage of all first-person pronouns.

To further explore the part-of-speech usage in the social media dataset, we also use some special measurements\cite{Havigerova2019}:

**Pronominalisation Index (PI):** reflecting the usage of pronouns, instead of another part-of-speech (e.g. nouns). It is computed as the number of pronouns divided by the number of nouns\cite{Litvinova2016}.

**Formality Metric**\cite{Mairesse2007}: \( F_{\text{NOUN-ADJ-PREP-ART-PRON-VERB-ADV-INJ}} \)

Moreover, we test the discriminatory power of both POS tags frequency usage in users’ texts and the specific computed indices. For this, we employ a Random Forest classifier on the train set of the eRisk 2018 dataset on the aforementioned features. To interpret the trained model and to estimate the importance of each feature, we employ SHapley Additive exPlanations (SHAP)\cite{Lundberg2017} to measure each feature’s contribution to the classifier decision. SHAP offers a game-theoretic approach to quantify feature importance, aligned with human intuition.

**Classification** We opted for a simple Random Forest model, trained with 50 estimators and a max depth of 15, to avoid overfitting, with balanced class weights, since the dataset is heavily imbalanced. On the test set for the eRisk 2018 dataset, we obtain a weighted F\(_1\)-score of 78.37% (with balanced class weights) and a macro F\(_1\)-score of 51.93%. While the classification task is difficult, we are interested in exploring the feature importances of the model, which shed light on the model behaviour and provide us with insights regarding which POS tag is most discriminatory.

We further present our findings and provide interpretations and discussions based on recent findings in psychology.

5 Results and Discussion

Addressing our **RQ1**, we compute the Welch t-test for all our features and demonstrate that there are statistically significant differences (p-value <0.001) in part-of-speech usage between depressed and non-depressed individuals. In this
section, we present these differences and their interpretation from the psychology research.

Figure 1: Frequency of content part-of-speech

Content Part-of-speech  In Figure 1, we present the usage of content words for the two classes from the eRisk 2018 dataset. Individuals diagnosed with depression tend to use fewer common and proper nouns in comparison with control users. They also use more verbs and adverbs in their posts. The discourse is focused around actions, but with fewer entities (e.g. nouns), showing a defective linguistic structure with less interest in the environment (e.g. people, objects) (De Choudhury et al., 2016).

To further understand these differences, we pay a closer look at the frequencies of nouns and verbs in the social media discourse. We compute the keyness score (Kilgarriff, 2009; Gabrielatos, 2018) for verbs and nouns separately. In the keyness analysis, we compare the frequencies of nouns and verbs from the posts written by individuals with depression diagnosis (target corpus) in comparison to the posts from control users (reference corpus). In Figure 2, we present the top 20 verbs and nouns from each corpus, ordered by their log-likelihood ratio \( (G^2) \) (Dunning, 1993).

Rumination is a cognitive process focusing on past and present negative content and resulting in emotional distress (Sansone and Sansone, 2012). It is present in several mental health disorders (e.g. depression, anxiety, obsessive-compulsive disorder, post-traumatic stress disorder). In depression, rumination is defined as behaviors and thoughts that focus one’s attention on one’s depressive symptoms and on the implications of these symptoms (Nolen-Hoeksema, 1991). The rumination, as a response to depression, focuses the person’s attention on their emotional state and inhibits the actions necessary to distract them from their mood. In Figure 3, when comparing the usage of the three verb tenses (present, past and future) between the two groups, we expected that signs of rumination would be present in our analysis of verb tenses, with texts from depressed users being shifted into the past (Smirnova et al., 2018), but this result is not found in this sample of individuals.

Regarding the usage of future tense, depressed people have a lower frequency of verbs portraying future actions. This result may be a consequence of
anhedonia, people suffering from depression reporting lower anticipatory pleasure, and thus talking online less about their future plans. Anhedonia, defined as markedly diminished interest or pleasure in all, or almost all activities most of the day, nearly every day (Association et al., 2013), is a common symptom of depression.

The higher frequency of cognitive verbs (e.g. *feel*, *think*, *know*) in the texts written by depressed individuals indicates the cognitive impairments and judgement issues specific to depression. People with depression have cognitive deficits and biases in the processing of emotional information and they are unable to adaptively regulate their emotions (De Choudhury and De, 2014). Individuals with or without depression may not differ in their initial response to an adverse event. Still, they differ in their ability to recover once they have experienced the negative emotion. Depressed individuals are not able to repair their mood. Instead, they remain in a negative state of mind, which is related to increased negative thoughts, selective attention to negative stimuli and greater accessibility of negative recollections (Joormann, 2010). In comparison, the individuals from the control group use more action verbs (e.g. *vote*, *lead*, *show*, *begin*, *create*). In addition, depressed individuals are more passive; they have a lower level of general activity, consistent with symptoms of depressive disorder (Hopko et al., 2003).

Being an online social media platform similar to forums, Reddit is organized in subreddits with specific topics. It also has several communities dedicated to mental health problems. Compared to other social media platforms that require real-name authentication (e.g. Facebook), Reddit affords users anonymity or pseudo-anonymity. Complete anonymity is almost impossible, users providing bits of information with every interaction on the platform (e.g. comments, posts). Reddit allows users to create *throwaway* accounts to engage temporary without revealing their identity (Kilgo et al., 2018). These types of accounts are used to discuss sensitive information or stigmatizing problems. De Choudhury and De (2014) study the mental health discourse on Reddit and show that its communities allow a high degree of information exchange related to mental health. Users use Reddit to self-disclose the challenges faced in their daily lives or in personal relationships. They also seek emotional support or specific information about mental illnesses diagnosis and treatment. Their study demonstrates that Reddit fills the gap between social media platforms like Twitter and Facebook and online health forums regarding mental health discourse.

Examining the frequencies of nouns in the eRisk 2018 dataset, we show in Figure 2 that the users with self-reported depression diagnosis use their Reddit account to disclose and discuss their mental health problems (e.g. *depression*, *anxiety*, *therapist*) or their personal relationships (e.g. *friend*, *boyfriend*, *relationship*, *mom*, *dad*). The process of seeking online support is also shown in the frequency of verbs: *feel*, *talk*, *diagnose*, *help*.

Even if the dataset contains control users active in the depression subreddit, the majority of control users seem to post on other themed subreddits (e.g. politics). Bucur and Dinu (2020) perform a topic modelling analysis and show that texts from control users are found in topics related to their hobbies, as opposed to depressed people, who are more focused on their feelings and life events. Our results are in line with this study, the users from the control group use more politics-related words (e.g. *trump*, *government*, *president*, *news*, *vote*).

![Figure 4: Frequency of functional part-of-speech](image)

**Functional part-of-speech** In Figure 4, we present the frequencies of functional part-of-speech for depressed and control users. Depressed individuals generally use fewer functional words in their texts in comparison with control users, with the exception of pronouns. Neurons involved in content words processing are equally distributed over both hemispheres, while function words are processed mainly in the left hemisphere (Pulvermüller et al., 1995). Lower preposition usage may be an outcome of deficient activation of the left hemi-
sphere regions, responsible for producing more abstract lexical units (Litvinova et al., 2016). Function words are highly social, the capacity to use function words requires social skills (Pennebaker, 2017).

The Figure 5 shows the differences in personal pronouns used by the two groups. The high frequency of first-person singular pronouns indicates a higher self-preoccupation in depressed individuals, as opposed to the first-person plural pronouns, which shows collective attention. Second and third-person pronouns indicate social interactivity and contain references to other people or things in the environment (De Choudhury et al., 2016).

Depressed users use more first-person singular pronouns. The frequencies of first-person plural pronouns are inversely proportional to the first-person singular pronouns frequencies. This result is in line with the self-focused attention tendency (SFA) in depressed individuals. SFA is a cognitive bias linked to depression; the high frequency of first-person singular pronouns in speech or written text is considered a linguistic marker of SFA (Brockmeyer et al., 2015). Individuals with depression have deficits in other-focused social cognitions, they are impaired in Theory of Mind reasoning and empathy. Theory of Mind enables people to make inferences on the behaviour of others and their own (Premack and Woodruff, 1978). Erle et al. (2019) show that individuals exhibiting high levels of depressive symptoms were impaired on tasks involving overcoming their egocentrism.

The usage of fewer first-person plural pronouns in texts from users diagnosed with depression may be a sign of a lesser sense of belonging. The information-processing biases of depressed individuals make it hard for them to perceive cues of acceptance and belonging in social interactions, and to view ambiguous social interactions as being negative (Steger and Kashdan, 2009).
providing information about the context in order to avoid ambiguity (Heylighen and Dewaele, 2002).

Addressing our RQ2, we show in Figure 7 the Shapley values for a random sample of 1500 posts from the eRisk 2018 test set. A higher Shapley value corresponds with a higher importance in the final model decision based on the feature value. We used all computed POS features and indices in our model, but show only the top 20 for clarity. It is evident that from the summary plot, the absence of proper nouns is the most discriminatory factor in the decision to classify a person as depressive. Moreover, the use of pronouns (also evident in the Pronominalisation Index) is highly correlated with positive model output. The high usage of first-person singular pronouns and low usage of first-person plural pronouns confirms both our findings in the exploratory analysis and psychology literature.

6 Conclusion

In this work, we provide an extensive analysis of part-of-speech usage in social media texts from depressed and non-depressed users. Our findings are confirmed by studies in psychology and show that individuals diagnosed with depression use more pronouns (especially first-person singular pronouns) and verbs, and fewer common and proper nouns. Their social media discourse revolves around their life experiences and sentiments, as opposed to control users who are not interested in discussing their problems online.

Moreover, we also provided insights into the discriminatory power of POS frequencies by employing SHAP, a game-theoretic approach for model interpretation. Through this, we showed that depressive users can be characterized most easily, primarily through their usage of pronouns and proper nouns.

InFoBERT: Zero-Shot Approach to Natural Language Understanding
Using Contextualized Word Embedding

Pavel Burnyshev  Anfrey Bout  Valentin Malykh  Irina Piontkovskaya
Huawei Noah’s Ark lab, Moscow Russia
lastname.firstname@huawei.com

Abstract

Natural language understanding is an important task in modern dialogue systems. It becomes more important with the rapid extension of the dialogue systems’ functionality. In this work, we present an approach to zero-shot transfer learning for the tasks of intent classification and slot-filling based on pre-trained language models. We use deep contextualized models feeding them with utterances and natural language descriptions of user intents to get text embeddings. These embeddings then used by a small neural network to produce predictions for intent and slot probabilities. This architecture achieves new state-of-the-art results in two zero-shot scenarios. One is a single language new skill adaptation and another one is a cross-lingual adaptation.

1 Introduction

Dialogue systems become more and more popular in everyday life. A dialogue system has two main language understanding tasks which are of key importance for any skill: user intent recognition and information extraction from user input. The former task traditionally is interpreted as a classification problem, since the possible intents list assumed to be given. The latter task is formulated as slot filling, i.e. extraction of a text span considered to be a slot value. With dialogue systems becoming more popular their functionality is also growing in terms of both skills available to use and languages their functionality is accessible in. The rapid growth entails lack of usage data for the new skills and new languages and causes the lists of intents and slots to be dynamic thus make classical approaches inapplicable. We consider these newly emerged scenarios and demonstrate that our approach is well suited for both. In the first scenario, there are several known domains and a few unknown domains. The second scenario contains skills with training data for one language (English) and only test data for two other languages (Spanish & Thai).

In this paper, we present a new architecture which is based on pre-trained language models, like BERT (Devlin et al., 2019), and uses a small “head” (i.e. a neural network using the embeddings from the language models as input) evaluated in two scenarios: zero-shot single language natural language understanding on Schema-Guided Dialog dataset (Rastogi et al., 2019) and zero-shot cross-lingual natural language understanding on Multi-lingual Task-oriented Dialog dataset (Schuster et al., 2019). For the Schema-Guided Dialog dataset, there is a baseline described alongside the dataset which is evaluated in the zero-shot transfer learning setup. It is using deep contextualized embedding model (BERT) to embed the utterances and natural language descriptions for the slots and intents. Another approach was presented in (Ruan et al., 2020), where the authors present a system based on the baseline with an addition of hand-crafted context features. Our model is also close to this baseline with some important differences (described in section devoted to our approach) allowing it to outperform both previously presented approaches. For the Multi-language Task-oriented Dialog dataset there are also published baselines in zero-shot cross-lingual transfer setup described alongside the dataset. The authors train a whole machine translation system to make embeddings of utterances and use them for prediction in both tasks. Another approach proposed in (Liu et al., 2019b), where the authors use combination of recurrent neural network and latent variable model. Also an approach was presented in (Liu et al., 2020). The authors use BERT model to embed utterances and use special context gate for prediction in both tasks. We also use a pre-trained language-model to embed natural language descriptions of slots and intents and to achieve state of the art results in the
zero-shot scenario.

Formal contribution of this paper is four-fold: we present a new model architecture for (1) zero-shot intent classification and (2) zero-shot slot filling which with usage of appropriate embedding model achieves a new state of the art results on (3) cross-skill and cross-domain transfer and on (4) cross-language transfer.

2 Related Work

There are several baseline systems for MTD which we describe here, while baseline systems for SGD are described alongside our model in the specific section below. One baseline system (Multi. CoVe) presented in (Schuster et al., 2019) is based on deep contextualized embedding model CoVe (McCann et al., 2017). This system is using bidirectional LSTM (Hochreiter and Schmidhuber, 1997) over CoVe embeddings with CRF for slot prediction and an attention mechanism for intent recognition. This system has a variant with usage of an autoencoder for produced embedding refinement (Multi. CoVe w/ auto). (Liu et al., 2020) are using the same design as Multi. CoVe with other embedding models, namely multilingual BERT and XLM (Lample and Conneau, 2019), this approach is called Transformer-MLT. In this work is also presented adaptation of RCSLS model (Joulin et al., 2018) used as an embedding one, which aligns word embeddings with help of retrieval loss (RCSLS-MLT).

The authors of (Liu et al., 2019b) are using slightly different approach. Their system is using cross-lingually aligned word embeddings, they are fed into bidirectional LSTM, which output is used by attention mechanism for intent recognition and by a latent variable model for joint slot and intent prediction. In the work (Schuster et al., 2019) also presented another baseline called Translate Train. This system is using direct alignment of word tokens to fed this alignment into CRF for prediction.

There are models which use contextualized representations for natural language understanding in different setups. An approach to slot filling called Zero-Shot Adaptive Transfer described in (Lee and Jha, 2019). A model takes an utterance and natural language description of a slot and produces BIO-encoding of the utterance, i.e. points to the span, containing the value. To contextualize the word representations authors use bidirectional recurrent neural network. Another approach is presented in (Xu et al., 2020), where the authors use multilingual BERT as embedding model and predict jointly slots and intents with additional refinement task of data source prediction.

Deep contextualized embeddings, especially BERT, have been used for intent classification and slot filling tasks in other setups, e.g. (Chen et al., 2019; Chao and Lane, 2019; Zhang et al., 2019; He et al., 2020), where authors consider classic setup with shared slots and intents for train and test. There were also other works focused on zero-shot modeling (Bapna et al., 2017; Xia et al., 2018; Shah et al., 2019), domain adaptation and transfer learning techniques (Rastogi et al., 2017) in recent years. Deep learning based approaches have achieved state of the art performance on dialogue state tracking tasks. Popular approaches on small-scale datasets estimate the dialogue state as a distribution over all possible slot-values (Henderson et al., 2014; Wen et al., 2017) or individually score all slot-value combinations (Mrkšić et al., 2017; Zhong et al., 2018). Such approaches are not practical for deployment in virtual assistants operating over real-world services having a very large and dynamic set of possible values. Addressing these concerns, approaches utilizing a dynamic vocabulary of slot values have been proposed (Rastogi et al., 2018; Goel et al., 2019; Wu et al., 2019).

3 Task Description and Datasets

We consider two independent scenarios in this work, although they share an important feature: zero-shot transfer learning. The first scenario is a cross-skill and cross-domain transfer which is evaluated on Schema-Guided Dialog (SGD) dataset. It is formulated as follows: in each domain, there are one or more skills. Each skill has its intents and slots described. Also a skill could share an intent and/or a slot with another skill, but in general case, they are not sharing anything. To complicate things, in the dataset there is a domain (Alarm) which is presented only in the development set, but not in the train set.

The second scenario is a cross-lingual transfer and is evaluated on Multi-language Task-oriented Dialog dataset (MTD) dataset. Each skill presented in the dataset is described (to a reasonable extent) identically in all three languages. So a system could be trained on one language and evaluated on the other two languages.
Schema-Guided Dialog

Schema-Guided Dialog dataset is described in (Rastogi et al., 2019). This dataset contains task-oriented dialogues in different domains. Each skill has a so-called schema, which contains one-sentence descriptions of slots and intents used in this skill. Each dialogue has slots and intents marked up. It is important to mention that domain could be represented by more than one skill, e.g. a person could rent a car using two different services. The skill in one domain could be split into train and dev sets. Another important feature of this dataset is that it contains multi-domain conversations. The general statistics for this dataset is presented in Tab. 1. Additional statistics on the cross-domain dialogues distribution is presented in Tab. 2.

Multi-turn Task-oriented Dialog

Multi-turn Task-oriented Dialog dataset is described in (Schuster et al., 2019). This dataset consists of dialogues in three different languages, specifically English, Spanish, and Thai. The dialogues share semantics for intents and slots across the languages, which makes it possible to formulate a zero-shot cross-lingual task, i.e. a model could be trained on one language and evaluated on another language without any additional training. The semantics, in this case, is represented by one-sentence description for slots and intents. This dataset contains only one skill per domain and no multi-domain dialogues. The general statistics for this dataset is presented in Tab. 3. For this dataset, there is published train/validation/test split, which we follow in our experiments.

## Table 3: Summary statistics of the Multi-turn Task-oriented Dialog dataset. Note that the slot type `datetime` is shared across all three domains and therefore the total number of slot types is only 11. Train/Dev/Test values are separated with slash.

### 4 Instruction Following BERT

We think of the natural language descriptions of intents and slots as instructions for a model to follow in order to achieve a result, which is either intent classification or slot filling. We base our approach on BERT-like models, especially their contextualization ability, and we show that these models could solve both parts with a small help of an additional simple module. We add to the pre-trained language-models a recurrence module for intent classification task and a feed-forward module for slot filling. We call our approach Instruction Following BERT (**InFoBERT**).

#### 4.1 BERT Model

To better present our work we start with brief description of the Bidirectional Encoder Representations from Transformers (BERT) model described in (Devlin et al., 2019). The modules in it are interconnected, so the model has access to the whole sequence at once. BERT model has a specific training procedure, which consists of two tasks: next sentence prediction and masked language modeling, that requires the model to use specific tokens, like [SEP] which separates different sentences in the text sequence, [CLS] which requires a model to make a decision (binary in the original setup), or [MASK] which hides a particular token from model input, so model is required use a context to perform a prediction of a masked token. The usage of these special tokens in training procedure is illustrated in Fig. 1. We have experimented with BERT and several derivative models, namely RoBERTa (Liu et al., 2019a) and ToD-BERT (Wu et al., 2019) for SGD dataset and
multilingual BERT, XLM (Lample and Conneau, 2019), XLM-RoBERTa (Conneau et al., 2020), and Language-Agnostic BERT Sentence Embedding (Feng et al., 2020) for MTD one.

Figure 1: BERT training setup. The figure adopted from (Devlin et al., 2019).

4.2 Intent Classification

For each skill, there is a known list of possible intents, and each intent is accompanied with a natural language description. To represent rejection in the classification we add special intent “NONE”, for which we use a separate description. This design is close to previous art for SGD. Although (Rastogi et al., 2019) system ignores a dialog history entirely, and (Ruan et al., 2020) system uses only hand-crafted history-based features. While our approach takes into account whole dialogue history using a recurrent neural network which is fed by a sequence of [CLS] token embeddings from all the utterances (including system ones). We denote [CLS] token embedding for \( i \)-th utterance as \( u_{i}^{\text{CLS}} \), and \( \hat{u}_{i}^{\text{CLS}} \) RNN output vector for this input. More formally:

\[
\{ \hat{u}_{i}^{\text{CLS}} \}_{i=1}^{n} = \text{RNN} \left( \{ u_{i}^{\text{CLS}}, c_{i-1} \}_{i=1}^{n} \right),
\]

where \( c_{i} \) is a state of the recurrent module on \( i \)-th step, and \( n \) is a number of utterances in a dialogue.

We denote \( I_{j}^{\text{CLS}} \) [CLS] token embedding from \( j \)-th intent description. To obtain the logits for possible intents, we compute dot-product between utterance vector representation and intent vector representation and normalize obtained scores using softmax (SM) function. More formally:

\[
P_{i}^{\text{intent}} = \text{SM} \left( \{ u_{i}^{\text{CLS}} \}^{T} \cdot I_{j}^{\text{CLS}} \mid j = 0..m \} \right),
\]

where \( m \) is a number of the intents in a skill, and \( I_{0} \) is reserved for “NONE” intent. The output logits are fed into conditional random field to incorporate further intent usage statistics.

To make the model more robust we use a Gaussian noise in form of \( d_{emb} \) normal distributions with zero mean and zero covariance adding it to all the embedding outputs of a language model. \( d_{emb} \) is an output language model embedding size.

4.3 Slot Filling

Generally, a slot has no list of possible values available, we call such slot the non-categorical one. In a case where the list of possible values is available, the slot is called categorical. MTD dataset contains only non-categorical slots, while SGD dataset contains both types. In this work we concentrate only on the non-categorical slots since they are more general and presented in both datasets we consider. The task is to extract a value from an utterance represented as a sequence of tokens, so the extracted value will be a span.

We denote \( s_{k}^{\text{CLS}} \) an embedding of [CLS] token for \( k \)-th slot description. Then to compute probability distributions for an utterance tokens (\( u_{il} \mid l = 1..L \)) to be a start (\( P_{i}^{k,\text{start}} \)) or an end (\( P_{i}^{k,\text{end}} \)) of a span we compute:

\[
P_{i}^{k,\text{start}} = \text{SM} \left( \{ u_{il}^{\text{CLS}} \} \cdot W_{\text{start}} \cdot s_{k}^{\text{CLS}} \mid l = 1..L \} \right),
\]

\[
P_{i}^{k,\text{end}} = \text{SM} \left( \{ u_{il}^{\text{CLS}} \} \cdot W_{\text{end}} \cdot s_{k}^{\text{CLS}} \mid l = 1..L \} \right),
\]

where \( L \) is an utterance length, \( W_{\text{start}} \) and \( W_{\text{end}} \) are trainable matrices. It is important to mention, that these matrices are the only additional weights we use to perform the task.

To train the model for non-categorical slots extraction we use classic cross-entropy loss, summing it over all possible slots and utterances.

To make the model more robust we add slot-value dropout. This technique is related to one described in (Xu and Sarikaya, 2014), but in our work we are replacing the whole value span with [MASK] tokens thus requiring the model to rely on the value context.

Our setup is close to previous art for SGD. Our approach differs on the one hand from (Ruan et al., 2020) with usage of additional matrices for start and end token prediction, and on the other hand from (Rastogi et al., 2019) with usage of only one matrix for each prediction, while the baseline is using two matrices. Both these approaches do not use slot-value dropout.

5 Experiments

We conduct experiments on two datasets, described in the section devoted to the datasets. For both SGD and MTD datasets we measure quality for tasks of intent classification and non-categorical slots extraction in the zero-shot scenario. To measure the intent classification quality, we use accuracy metric, due to a model has a dynamic list of intents to choose from. To measure the slot extraction quality we use F1 metric, which allows us to measure both
the precision and recall of a slot detection.

In our experiments we use LSTM as a unit of the recurrent module in the intent classification task. We use one layer with hidden size equal to the output embedding size of a underlying language model throughout all the setups.

In our experiments on the SGD dataset we measure quality only for intents and slots not present in the original training set. To conduct the experiments on the SGD dataset we use BERT (Devlin et al., 2019) as an embedding model, specifically BERT-base variant for both tasks (InFoBERT-B); and RoBERTa (Liu et al., 2019a) model, specifically RoBERTa-large for intent classification and RoBERTa-base for slot filling (InFoBERT-R). We also use ToD-BERT (Wu et al., 2020) model denoting it InFoBERT-T. For the slot filling task the slot-value dropout probability of 0.35 was used. Since there were no explicitly presented metrics we measure in the original SGD paper, we reproduce their results using publicly available code\(^1\). The results are presented in Tab. 4. As one could see from the table InFoBERT-T outperforms both the baselines in the combined domain intent recognition task. Unfortunately, (Ruan et al., 2020) did not presented results for single domain task, but basing on our experiments we expect the results for their model would be close to presented ones.

In our experiments on the MTD dataset we use English data as training set and Spanish & Thai data as a validation and test sets. For the MTD dataset we use multilingual BERT (Devlin et al., 2019) as an embedding model (InFoBERT-M), XLM (Lample and Conneau, 2019) model (InFoBERT-X), XLM-RoBERTa (Conneau et al., 2020) model (InFoBERT-XR), and Language-Agnostic BERT Sentence Embedding (Feng et al., 2020) model (InFoBERT-L). The noise standard deviation was set to 0.1 for InFoBERT-M model and to 0.01 for InFoBERT-X one. For the slot filling task the slot-value dropout was used with two probabilities 0.2 and 0.35. The results are presented in Tab. 5. In the table there are results named “Translate Train”. This is a special setup considered as a strong baseline. In this setup English data is translated to target language and used to train a model. These results and the results for Multi. CoVe [w/ auto] marked with * are adopted from (Schuster et al., 2019). The results of RCSLS-MLT and Transformer-MLT marked with † are adopted from (Liu et al., 2020).

As one could see from Tab. 5 InFoBERT-L variant of our model significantly outperforms all the baselines for Spanish language data, although for Thai language InFoBERT-XR is better than other baselines in intent prediction, with exception of Translate Train. For Thai slot tagging task InFoBERT-X variant is the best outperforming the Translate Train (and all the baselines).

5.1 Thai Language Performance Analysis

The analysis of Tab. 5 shows that all the models with exception of InFoBERT-X variant of our model show significantly lower results on Thai slot filling task. The models we present and Transformer-MLT baseline could be split into two groups: the one using BERT tokenization model and the one using an external engine. We found out that all the models, including multilingual BERT, XLM-RoBERTa, Language-Agnostic BERT Sentence Embedding model, are using the same tokenization engine originally presented in BERT code\(^2\). Even XLM model by default is using this engine - this fact could explain low results for Transformer-MLT baseline. We found out that this
default engine is broken against Thai text, thus it corrupts input text during tokenization. But XLM model could be set to use external tokenization which handles the text correctly. This allows it to significantly improve the results on Thai language data.

It is interesting that the intent recognition results though being affected by this fault are still could achieve high performance. We suppose this fact is related to classification task structure where the whole utterance is regarded, allowing a model to overcome tokenization issues.

6 Conclusion

In this work we presented a model architecture which allows us to use different embedding models as a building block. This architecture is demonstrated to be effective in two zero-shot transfer tasks, namely cross-domain and cross-lingual. Our model using an appropriate embedding model (ToD-BERT for cross-domain task and several multi-lingual models for cross-lingual one) shows state of the art performance on the intent recognition and slot filling tasks.

It is interesting to mention that in our experiments we found that the best results for Spanish and Thai languages in the cross-lingual transfer task are not achievable at the same time. We suppose that this fact could be explained by the errors in the tokenization model used for most of the multi-lingual models. Thus usage of Language-Agnostic BERT Sentence Embedding model as an embedding one allows our system to outperform all the other systems on Spanish language data, but broken tokenization in this model does not allow to show any improvement for Thai language.

As future work authors consider the study of other BERT descendant models, which are plenty nowadays. Another direction of the work is research in low resource scenario, when some data is available for a model to tune onto. In closing, we hope that this work will facilitate the research in the direction of transfer learning in dialogue systems.

Abstract

This paper presents an active learning approach that aims to reduce the human effort required during the annotation of natural language corpora composed of entities and semantic relations. Our approach assists human annotators by intelligently selecting the most informative sentences to annotate and then pre-annotating them with a few highly accurate entities and semantic relations. We define an uncertainty-based query strategy with a weighted density factor, using similarity metrics based on sentence embeddings. As a case study, we evaluate our approach via simulation in a biomedical corpus and estimate the potential reduction in total annotation time. Experimental results suggest that the query strategy reduces by between 35% and 40% the number of sentences that must be manually annotated to develop systems able to reach a target $F_1$ score, while the pre-annotation strategy produces an additional 24% reduction in the total annotation time. Overall, our preliminary experiments suggest that as much as 60% of the annotation time could be saved while producing corpora that have the same usefulness for training machine learning algorithms. An open-source computational tool that implements the aforementioned strategies is presented and published online for the research community.

1 Introduction

Machine learning, and specifically supervised learning, is one of the most effective tools for automating complex cognitive tasks, such as recognising objects in images or understanding natural language text. One of the main bottlenecks of supervised learning is the need for high-quality datasets of labelled samples on which statistical models can be trained. These datasets are usually built by human experts in a lengthy and costly manual process. Active learning (Cohn, 2010) is an alternative paradigm to conventional supervised learning that has been proposed to reduce the costs involved in manual annotation.

The key idea underlying active learning is that a learning algorithm can perform better with less training examples if it is allowed to actively select which examples to learn from (Settles, 2009). In the supervised learning context, this paradigm changes the role of the human expert. In conventional supervised learning contexts, the human expert guides the learning process by providing a large dataset of labelled examples. However, in active learning the active role is shifted to the algorithm and the human expert becomes an oracle, participating in a labelling-training-query loop. In the active paradigm, a model is incrementally built by training on a partial collection of samples and then selecting one or more unlabelled samples to query the human oracle for labels and increase the training set. This approach introduces the new problem of how to best select the query samples so as to maximise the model’s performance while minimising the effort of the human participant.

The simplest active learning scenario consists of the classification of independent elements $x_i$ drawn from a pool of unlabelled samples. Examples range from image classification (Gal et al., 2017) to sentiment mining (Kranjc et al., 2015), in which the minimal level of sampling (e.g., an image or text document) corresponds to the minimal level of decision. i.e, a single label is assigned to each $x_i$. More complex scenarios arise when the decision level is more fine-grained than the sampling level. In the domain of text mining, an interesting scenario is the...
The task of entity and relation extraction from natural language text (Zhang et al., 2012). In this scenario the sampling level is a sentence, but the minimal level of decision involves each token or pair of tokens in the sentence, and furthermore, these decisions are in general not independent within the same sentence. In this case, it is not trivial to estimate how informative an unlabelled sample will be, since each sample has several sources of uncertainty.

This research focuses on the tasks of entity and relation extraction, proposing an active learning strategy to reduce the overall time of annotation for human experts, by actively selecting the most informative sentences to annotate. We also consider the problem of providing some instances of entities and relations pre-annotated to further reduce the annotation time for the human, while minimising the number of erroneous suggestions. In contrast with the usual formulation, we focus on the problem of obtaining the corpus per-se, and the task of training the underlying machine learning models is considered as means to an end rather than as the primary objective.

The contributions of this research can be summarised as follows:

- **We present an active learning strategy for the problem of entity and relation extraction from natural language text that greatly reduces the annotation time for human experts by actively selecting the most informative sentences and providing pre-annotated suggestions when possible.**

- **We propose an informativeness measure for entity and relation extraction that factors in the uncertainty of annotations in a sentence counter-balanced by its similarity to the labelled set.**

- **We evaluate our proposal in an experimental corpus in the biomedical domain, and study the impact of the query strategy and the benefit of providing pre-annotated suggestions, in terms of reducing the overall time of annotation.**

- **As a tangible result, we provide the source code for a prototype annotation tool that implements the aforementioned strategies and is compatible with the BRAT annotation tool, available online under an open-source license (https://github.com/knowledge-learning/assisted-annotation).**

The remaining sections of this paper are organised as follows. Section 2 reviews the most relevant research related with active learning in general and specifically for entity and relation extraction. Section 3 presents the formal definition for our active learning approach. Section 4 describes a computational prototype tool that implements this strategy. Section 5 evaluates our proposal in the context of a corpus of entities and relations in the biomedical domain. Section 6 presents a discussion of the most relevant insights that our research provides. Finally, Section 7 presents the main conclusions of our research.

2 Related Works

This section reviews some of the most relevant research related with active learning in general, and specifically focused on entity detection and relation extraction. One of the most important design decisions in active learning is how to intelligently select the novel unlabelled samples in the most efficient way. The underlying assumption is that we want to train a model to the highest possible performance (measured in precision, $F_1$, etc.) while minimising the human cost (measured in time, number of samples manually labelled, or any other suitable metric). This requirement is often framed as the selection of the most informative unlabelled samples, and formalised in terms of a query strategy (Settles, 2009). The most common query strategies for general-purpose active learning can be grouped into the following categories:

(i) **Uncertainty sampling**: The most informative samples are considered those with the highest degree of uncertainty, given some measure of uncertainty for each sample (Lewis and Catlett, 1994).

(ii) **Query by committee**: The most informative samples are considered those with the highest disagreement among a committee of either different models or different hypotheses from the same underlying model (Seung et al., 1992).

(iii) **Expected model change**: The most informative samples are considered those that produce the highest change in the model’s hypothesis...
if they were included in the training set (Settles et al., 2008).

(iv) Variance and error reduction: The most informative samples are those which produce the highest reduction in the model’s generalisation error or, as a proxy, its variance (Roy and McCallum, 2001).

Expected model change (iii) and variance/error reduction (iv) strategies are heavily dependent on the specific learning model used. In contrast, uncertainty sampling (i) and query by committee (ii) are applicable in general with a high degree of model agnosticism. Furthermore, relevant subsets of both strategies can be formalised under a single framework if we define the uncertainty as a measure of the entropy of the model’s predicted output. In this framework, query-by-committee can be implemented via weighted voting, thereby assigning empirical probabilities to the possible outputs.

Weighted density is a complimentary strategy in which the most informative samples are weighted by how representative they are of the input space, for example, by measuring their similarity to the remaining samples (Settles and Craven, 2008). This approach attempts to counter-balance a noticeable tendency to select outliers as the most informative samples—a problem associated with other query strategies—since outliers are often the samples that create the highest amount of uncertainty, disagreement or hypothesis change.

Recent advances in natural language processing have produced an increased interest in active learning to alleviate the requirement for large annotated corpora (Olsson, 2009; Tchoua et al., 2019). Settles and Craven (2008) compare several strategies for active learning in sequence labelling scenarios, concluding that query strategies based on measures of sequence entropy combined with weighted sampling outperform other variants. Meduri et al. (2020) propose a comprehensive benchmark to evaluate different active learning strategies for entity matching. In the task of named entity recognition, CRF models have been used to select query samples (Claveau and Kijak, 2017; Lin et al., 2019). The task of relation extraction also benefits from active learning approaches, both in general-purpose settings (Fu and Grishman, 2013) and in domain-specific settings (Zhang et al., 2012). However, despite the growing body of research, it is still a challenge to apply active learning in joint entity recognition and relation extraction, especially in scenarios with low resources (Gao et al., 2019).

3 Active Learning Strategy for Entity-Relation Annotation

This section presents our active learning strategy for human-in-the-loop annotation of corpora based on entity recognition and relation extraction. A high-level overview of the process is illustrated in Figure 1.

Our active learning strategy is designed for an arbitrary corpora of independent natural language sentences, each of which must be annotated by a human expert at token level. We consider a pre-defined set \( E \) of entity labels, each of which can span one or more tokens, continuous or discontinuous. Additionally, there is a predefined set \( R \) of binary relation types between entities, where the possible relations between each pair of entities can depend on the entity type, i.e., not all relation types are defined for all entity labels. There is no sub-token annotation, and not all tokens need to be annotated. This abstract annotation schema can represent a broad range of different tasks, from domain-specific relation extraction (e.g., gene-protein interaction) to general-purpose semantic representation (e.g., AMR parsing).

The active learning strategy proposed in this research works iteratively in batches of \( K \) sentences (e.g., \( K = 10 \)). At any point there will be a labelled pool \( L \) with \( |L| = n \times K \) sentences that have been manually annotated by a human annotator, and a large unlabelled pool \( U \) of raw sentences. Initially, the human annotator selects \( K \) representative sentences and performs a full manual annotation (step 0). Afterwards, two machine learning models are iteratively trained on the manually labelled sentences (step 1) and a metric of informativeness, \( I(s) \), is computed for each sentence \( s \in U \) (step 2). The top \( K \) sentences in terms of \( I(\cdot) \) are selected (step 3) and the model produces a prediction of entity and relation labels for each one (step 4). Each prediction has an associated metric of uncertainty, \( H(\cdot) \), estimated by the models. Based on this uncertainty and pre-defined thresholds \( u_e \) and \( u_r \) for entities and relations respectively, all the entities \( e_i \) (relations \( r_j \)) with an estimated uncertainty \( H(e_i) > u_e \) (\( H(r_j) > u_r \)) are discarded. Finally the selected and partially annotated sentences are presented to the human annotator, who must correct the incorrect annotations.

223
and add the missing ones (step 5). The corrected sentences are incorporated to the labelled pool for the next iteration (step 6).

The following components for the active learning strategy need to be specified: a machine learning model $M_E$ that predicts entity labels; a machine learning model $M_R$ that predicts relations; and, suitable definitions for $I(\cdot)$ and $H(\cdot)$ based on these machine learning models. We will not define specific machine learning models at this point, since different models can be suitable for different corpora. For our strategy to work, the machine learning models $M_E$ and $M_R$ are only required to provide a probability distribution over the possible labels rather than a single prediction. This is a soft restriction that many machine learning models comply with.

To measure the informativeness $I(s_i)$ of each sentence $s_i \in U$, we define a metric based on uncertainty sampling with weighted density, inspired by Settles and Craven (2008).

First, given the set of $n$ entity annotations $E_i \in E^n = \{ e^i_1, \ldots, e^i_n \}$ and $m$ relation annotations $R_i \in R^m = \{ r^i_1, \ldots, r^i_m \}$ predicted for a sentence $s_i$, we define the uncertainty of each entity $e^i_k$ (or relation $r^i_k$) as the entropy of the probability distribution for all possible labels for that entity or relation. Formally:

\[
H(e^i_k) = -\sum_{l_j \in E} P(e^i_k = l_j | s_i; \theta) \log_2 P(e^i_k = l_j | s_i; \theta)
\]

\[
H(r^i_k) = -\sum_{l_j \in R} P(r^i_k = l_j | s_i; \theta) \log_2 P(r^i_k = l_j | s_i; \theta)
\]

Where $\theta$ represents the parameters of the machine learning model used to estimate these probabilities.

We can define the mean uncertainty associated to the predicted entities and relations, respectively, as follows:

\[
\bar{H}(E_i) = \frac{1}{n} \sum_{e^i_k \in E_i} H(e^i_k)
\]

\[
\bar{H}(R_i) = \frac{1}{m} \sum_{r^i_k \in R_i} H(r^i_k)
\]

Second, we define an information density metric $ID(s_i)$ to estimate how representative each sentence $s_i$ is with respect to the input space. In a similar formulation to Settles and Craven (2008), $ID(s_i)$ is defined as the average similarity of the sentence $s_i$ to the cluster of $K$ labeled sentences:

\[
ID(s_i) = \frac{1}{K} \sum_{s_j \in L_i^*} \text{sim}(s_i, s_j)
\]

Where $L_i^*$ is the subset of $K$ labeled sentences that maximize the similarity metric with respect to $s_i$. Any sensible similarity metric can be used. In this research we propose the use of Doc2Vec embeddings (Le and Mikolov, 2014) pre-trained on the unlabeled set $U$ to estimate sentence similarity.
Finally, the overall informativeness of an unlabeled sentence \(s_i\) is estimated based on the uncertainty measures \(\hat{H}(\cdot)\) of each component, weighted by the information density of the sentence:

\[
I(s_i) = \left[ \hat{H}(E_i) + \hat{H}(R_i) \right] \times ID(s_i)^\beta
\]

Where \(\beta\) is a scaling factor to balance exploitation versus exploration, i.e., decreasing the uncertainty of the model versus selecting more varied sentences to reduce model bias.

If we consider the annotation of a sentence as a stochastic process, where each entity or relation annotation is a random event, then \(\hat{H}(\cdot)\) is a finite approximation of the entropy rate of the annotation process. This provides an intuitive interpretation for the informativeness measure \(I(\cdot)\) in the domain of information theory. The most informative sentences are those whose entropy rate is maximum (weighted by density). Maximum entropy rate has been successfully applied to feature selection in other machine learning scenarios (Einicke et al., 2017).

4 Computational Prototype

The strategy presented in Section 3 is implemented as a web application that can be integrated with the BRAT annotation tool (Stenetorp et al., 2012). This application is independent of BRAT and relies only on the file system to iteratively select batches of sentences and apply suggestions. The web interface is simple to use, allowing the user to ask for a new batch, and decide whether to accept, modify or discard the annotation suggestions (see Figure 2). This tool is compatible with any entity and relation annotation schema that can be represented in BRAT Standof ANN format (Yepes et al., 2013).

As explained in Section 3, two different machine learning models \(M_E\) and \(M_R\) must be implemented to evaluate the informativeness metric \(I(\cdot)\). These models must provide probability estimates for each label, and should be efficient enough to be trained in the same time it takes a human annotator to annotate a single batch, such that the new batch is always ready. For the previous reasons, we selected two simple machine learning models based on standard formulations for the problems of entity recognition and relation extraction respectively.

For entity model \(M_E\), we select a conditional random field (CRF) classification model with syntactic and semantic features extracted with the spacy library. The extracted features include coarse and fine-grained part-of-speech tagging, lemmatization, a standard NER labeling, as well as indicator variables for several syntactic patterns (e.g., numbers, dates, punctuation, emails, URLs, etc.). By this means, the entity recognition problem is framed as a sequence tagging problem using the BILOUV encoding and Viterbi decoding. Special hand-crafted rules are designed to account for multi-word entities with discontinuous word spans. The uncertainty of each entity \(H(e_k)\) is estimated by the normalized marginal probabilities of the CRF model on the token sequence, averaging the probabilities of the tokens that correspond to the same entity. Despite its simplicity, this model achieves an \(F_1\) score of 0.78 in the entity extraction subtask of the eHealth-KD Challenge 2020, which is competitive with state-of-the-art techniques in past benchmarks (Piad-Morffis et al., 2019b).

In the case of the relation model \(M_R\), this subtask is more complex and simple baselines perform significantly worse than state-of-the-art models. However, since complex models cannot be trained in the required time, we decided to maintain a simple baseline. The problem of extracting all relations in a sentence is modeled as a set of independent classification problems between all pairs of entities in the sentence. Each pair is represented by the same characteristics used in the entity recognition subtask, applied to both entities under analysis, plus a bag-of-words encoding of the tokens that appear in the smallest dependency subtree that contains both entities. The uncertainty \(H(r_{ij})\) of each pair is computed from the marginal probabilities provided by a logistic regression model trained on each pair representation. For the information density metric \(ID(\cdot)\) an implementation of Doc2Vec from the gensim library is used.

5 Experiments and Results

To validate the effectiveness of the active learning strategy proposed in this research we selected a recent manually annotated corpus of Spanish sentences in the biomedical domain, i.e., the eHealth-KD 2020 corpus (Piad-Morffis et al., 2020). This selection was motivated by the relative complexity of the annotation schema proposed in this corpus, which contains different entity and relation types, multi-word tokens, overlapping annotations and other characteristics that make it a challenging annotation process even for human experts (Piad-Morffis et al., 2019a). The corpus contains a total
Figure 2: Screenshot of the web application prototype for semi-automatic corpus annotations integrated with the BRAT annotation tool. The right panel shows an illustrative selection of annotated sentences in the schema of the eHealth-KD 2020 corpus (Piad-Morffis et al., 2020), see Section 5.

of 1300 sentences in Spanish, manually annotated with a general-purpose entity-relation schema. Of these, a set of 1000 sentences is used as the unlabeled pool \(U\), and the remaining 300 are used for testing the final performance of all machine learning models trained in the experiment. The corpus has been split following the authors’ recommendations. Figure 2 shows an illustrative example of the annotation schema applied to 3 exemplary English sentences, in the context of the prototype application developed in this research.

We simulated the assisted annotation process to evaluate the effect to annotating the corpus using active learning strategies versus annotating the corpus in the original order without suggestions (baseline). As the process of annotating a corpus is expensive, it was simulated using the gold annotations in the training collection. The improvement can be estimated by comparing how many sentences need annotating to reach a specific performance of the machine learning algorithms (measured in terms of \(F_1\) in the testing collection).

To study the relative impact of the different components of our query strategy, we evaluated three different variants. They consisted of using the full query strategy proposed in Section 3 with \(\beta = 1\), as well as considering only entity uncertainty \(\hat{H}(E_i)\) and relation uncertainty \(\hat{H}(R_i)\) respectively. Figure 3 shows how the \(F_1\) metric improved with each batch of sentences, for the first 500 sentences. The target \(F_1\) is the final score obtained by training the models \(M_E\) and \(M_R\) on the full 1000 sentences of the corpus. In general, the curves that correspond to the active learning strategy (i.e., assisted variants) approach the target \(F_1\) significantly faster than the unassisted baseline.

To illustrate the degree of time-reduction achieved, Figure 4 shows the minimum number of sentences that must be annotated to reach different relative target \(F_1\) scores. For example, after annotating the first 400 sentences it is possible to achieve a 95% of the ultimate \(F_1\) score when using all the corpus. However, to reach the target score, the first 880 out of a 1000 sentences must be annotated if the corpus is annotated in the original order (baseline). By contrast, using our active learning strategy only between 530 to 580 sentences must be annotated to reach the same target \(F_1\), thereby saving between a 35% and a 40% of human annotation time.

Another interesting finding is to estimate the extent to which the suggested annotations further reduce the total annotation time. A human annotator using the tool will need to accept some of the suggested annotations, correct the ones that are wrong and annotate the ones that are missing. Each of these actions has a different cost in time. For quantifying the improvement in overall time that the suggestions produce, we assigned a relative cost (in terms of abstract time units) to each of the following types of annotations:

**Missing annotations:** annotations that the model did not suggest and the human annotator must produce, have a cost of 1 time unit.

**Spurious annotations:** annotations that the model suggested and are wrong, which must be eliminated by the human annotator, have a cost of 2 time units.

**Correct annotations:** since the human annotator must at least recognise the annotation is correct, the cost is 0.25 time units.
Partial annotations: annotations that are partially correct either because the spans are partially covering or the label is wrong, have a cost of 0.5 time units.

This cost structure assumes that the problem of correcting wrong annotations is more complex than simply producing the correct annotations, while acknowledging that even agreeing with correct annotations has a non-zero cost. For an active learning strategy to be helpful it must provide enough correct annotations to outweigh the cost of correcting the wrong annotations; hence, it should prioritise precision over recall.

Figure 5 shows the relative effect (in terms of reducing the overall annotation time) of enabling annotation suggestions for different combinations of the entity and relation thresholds \( u_e \) and \( u_r \). It can be observed that on average, the entity suggestions produce a positive effect (green colour) across a wide range of thresholds, while the relation suggestions tend to produce a negative effect as more suggestions are allowed. This is a direct consequence of the \( M_R \) relation model’s performance, which achieves at most an \( F_1 \) score of 0.27, while the entity model \( M_E \) achieves up to a 0.78 score. The optimal time reduction is achieved for an entity threshold \( u_e = 2.4 \) and a relation threshold \( u_r = 0 \), producing an estimated 24% reduction in the total annotation time. Interestingly, these parameters result in an overall performance for the machine learning model of \( F_1 = 0.54 \), with a precision of 0.78 and a recall of 0.41. As expected, given the asymmetrical cost structure, it is preferable to prioritise precision rather than recall for the annotation suggestions.

An overall reduction in annotation time for this experimental simulation can be estimated by combining the improvements provided by annotation suggestions and the sentence ordering. Assuming both effects are independent, the best case scenario for this corpus suggests the following. Using the active learning approach a human annotator would have needed to annotate only 530 sentences out of 1000, each of them with an estimate time cost of 76% compared to the full annotation. This results in an overall reduction of as much as 60% of the total annotation time, producing a smaller corpus on which machine learning models can still be trained, delivering the same performance as those trained on the original corpus.

6 Discussion and Future Work

The machine learning model used for entity recognition \( M_E \) achieves a result comparable with the state-of-the-art in this corpus while being simple enough to be trained during annotation. Not only does the model produce a significant reduction in the number of sentences that need to be annotated but it also is capable of pre-annotating entities that are often correct, even when factoring in the significantly higher cost of correcting the wrong suggestions. By contrast, the relation extraction model \( M_R \) performed significantly worse than current state-of-the-art in this corpus. However, even if the pre-annotated relations suggested by this model are on average not beneficial, it is interesting to note that using only the uncertainty of relations \( H(R_i) \) as a query strategy still produces a significant time reduction (see Figure 4, assisted (relations)). Un-
Unfortunately, all good performing models for this problem are composed of complex deep learning architectures that cannot be trained sufficiently fast enough to be used during the annotation process in a commodity hardware.

Indeed, using simple models is necessary in active learning scenarios where algorithms must be trained interactively, but even without considering this issue, there are additional factors to consider related to model complexity. We argue that an interesting trade-off exists between the capacity of a model and its usefulness for active learning. Very simple models (underfit) will have a high uncertainty in all samples, while very complex models (overfit) will overestimate their certainty. In both cases, the informativeness \( I(\cdot) \) for all sentences will be very similar, and there is no sensible way to choose the most informative ones. This suggests that there may be an optimal middle ground where the model learns enough to provide useful suggestions while still maintaining a healthy level of uncertainty. The fact that even weak baselines (like the relation model \( M_R \)) are still a useful source of information when actively selecting unlabelled sentences is one surprising conclusion of our research. This seems to suggest that even in very complex scenarios where state-of-the-art models are impossible to train interactively, using weaker surrogate models can still provide a significant benefit for human-in-the-loop learning.

Regarding the generalisation of our approach, the fact that the corpus is in the Spanish language is irrelevant for our experimental results since the machine learning models used are language-agnostic and no language-specific heuristics were applied. Hence, these results should generalise to other languages and annotation schemas albeit with different baseline \( F_1 \) scores according to the complexity of the underlying learning problem. Nevertheless, we are interested in evaluating our approach using languages other than English since the creation of linguistic resources is one of the main difficulties of NLP research, especially for other languages. An ongoing research priority is to validate this strategy on other corpora with different annotation schemas.

In future work, we will explore how to explicitly control the complexity of a model during the active learning process by controlling the model’s capacity. Two strategies that can be analysed are the use of ensemble methods and deep learning architectures with early stopping. In both cases, the intuitive idea is to iteratively refine a machine learning model up to the point where a sufficiently good performance is achieved but before the model overfits on the small labelled set of sentences, such that uncertainty measures are still relevant. Another interesting scenario in which to apply this approach is when many annotators exist for the same text. In this case, the models can learn contradictory hypotheses due to differences between annotators. Interestingly, in the case of active learning, this is a positive phenomena, since inter-annotator disagreement is a meaningful proxy for annotation difficulty. Active learning models trained on a pool of sentences with multiple, possibly contradictory annotations, will naturally tend to select sentences that are more likely to cause disagreement between annotators. In this context, it can be interesting to explore query-by-ensemble methods where each model in the ensemble is trained on a different annotator’s pool to maximise model variance.

7 Conclusions

In this article, we present an approach for reducing the time involved in manually annotating a corpus of natural language sentences that contains entities and relations. This approach uses active learning with uncertainty sampling and weighted density, and provides an estimated reduction of 60% of total annotation time in a simulated experiment with a real corpus. This improvement is derived from two independent factors: intelligently sorting which...
sentences to annotate and providing pre-annotated suggestions with a high-degree of certainty. The proposed strategies have been implemented into a computational tool that is applicable to a broad range of corpus annotation schemas and is available for the research community.

Abstract

The style transfer task (here style is used in a broad “authorial” sense with many aspects including register, sentence structure, and vocabulary choice) takes text input and rewrites it in a specified target style preserving the meaning, but altering the style of the source text to match that of the target. Much of the existing research on this task depends on the use of parallel datasets. In this work we employ recent results in unsupervised cross-lingual language modeling (XLM) and machine translation to effect style transfer while treating the input data as unaligned. First, we show that adding “content embeddings” to the XLM which capture human-specified groupings of subject matter can improve performance over the baseline model. Evaluation of style transfer has often relied on metrics designed for machine translation which have received criticism of their suitability for this task. As a second contribution, we propose the use of a suite of classical stylometrics as a useful complement for evaluation. We select a few such measures and include these in the analysis of our results.

1 Introduction

In this paper we consider the problem of unsupervised holistic textual style transfer – both the accomplishment of the task, as well as its evaluation. The “style” of text is roughly the way in which a text communicates its content. It might be thought of as the “voice” characteristic of a given author, an emergent quality that encompasses a wide range of (more or less measurable) characteristics such as register, sentence structure, and vocabulary choice. Holistic style transfer takes a given text – written a priori in one “style” – and then rewrites it (preserving its content) in another style. Holistic style transfer is distinct from more narrow style modification techniques which manipulate specific characteristics of prose such as formality, simplicity, or sentiment.

To illustrate our idea of holistic style consider the following pair of translations of the opening lines of The Aeneid of Virgil.

Arms and the man I sing, the first who came, Compelled by fate, an exile out of Troy...(Humphries et al., 1987)

I sing of arms and the man who of old from the coasts of Troy came, an exile of fate, to Italy and the shore of Lavinium...(Mackail, 1885)

As another example compare verses from two different “versions” of a fixed verse from the Book of Genesis, the first from the King James Version

And a river went out of Eden to water the garden; and from thence it was parted, and became into four heads.

and the second, the same verse, but in the New International Version:

A river watering the garden flowed from Eden; from there it was separated into four headwaters.

In both example pairs we can see that the content in the passages is the same, but the (holistic) style differs noticeably.

The examples above are effectively examples of a human-executed style transfer. The potential applications of a machine holistic style transfer are numerous. For example, various periodicals often try to have a single “voice” and an unsupervised
style transfer of the kind studied here would enable a staff writer to produce the content required of an article which was then “stylized” per the requirements of the venue. Thus, a style transfer platform could be a high-powered editorial assistant. Such a platform could also assist aspiring writers. All that said, one should not be blind to the more nefarious potential of successful style transfer machinery which could be useful for spoofing an audience to productive, or unproductive writerly ends (Nature, 2020).

One machine learning approach to holistic style transfer is to adopt and adapt the frameworks of translation models, treating each style as a language. Along these lines, much of the existing research on this task depends on the use of parallel datasets, a schema that follows early work in machine translation, but parallel datasets in this domain are in fact rare. This motivates our approach wherein we continue to be inspired by machine translation work and employ recent results in unsupervised cross-lingual language modeling (XLM) to effect holistic style transfer while treating the input data as unaligned, an important next step in advancing this area in light of the scarcity of parallel datasets. Additionally, we show that modifications to this framework which take advantage of the differences between the style transfer and machine translation tasks can improve model performance. Specifically, we add “content embeddings” to the XLM which capture human-specified groupings of subject matter and observe improvement over the baseline model for a range of metrics.

That brings us to the paired challenges resident in evaluating a style transfer technique. This task is complicated by the emergent nature of style. The analogy of style transfer to translation and concomitant efforts to use techniques from machine translation for the style transfer task have inspired the importation of evaluation metrics from machine translation to the style transfer setting, (Xu et al., 2012; Jhamtani et al., 2017; Carlson et al., 2018), although not without criticism (Tikhonov et al., 2019; Xu et al., 2016). As the evaluation of a style transfer task should a priori measure the similarities of source and target texts to their “native environments”, it seems natural to bring to bear some of the techniques from the field of stylometry, a discipline focused on the quantitative analysis of textual style. Stylometry (or stylometrics) was born of a nineteenth century effort to settle – quantitatively – scholarly dispute around the temporal ordering of Plato’s Dialogues (Lutoslawski, 1897)). For this task, over 500 individual and measurable textual characteristics were identified. Since that time stylometrics have been used (most famously) to address questions of disputed authorship (see e.g., Mosteller and Wallace (1964); Boyd and Pennebaker (2015)). If we imagine a system which perfectly performs style transfer as we have defined it, then the output of the system – in terms of its individual characteristics – should be stylistically indistinguishable from text written by the author whose style is targeted. It thus seems natural to use a range of stylometric measures used in the past to distinguish between authors’ styles as an evaluation for the performance of such a system. This line of reasoning motivates a second contribution of this work wherein we introduce the idea of using stylometric measures for evaluation. We evaluate our systems using several stylometric measures in addition to the more commonly previously used metrics and show that the stylometric approach is a useful domain specific complement to translation-based metrics for the evaluation of the complex, subtle, and important task of style transfer.

2 Related Work

Style transfer has some long roots. It is possible to frame the early work on text simplification (e.g., Specia (2010)) or paraphrasing Xu et al. (2012) as a form of style transfer. Style transfer research makes use of a range of datasets for training and evaluation. Examples include the corpus of Shakespearean plays and their “translations” into contemporary English (Xu et al., 2012) for paraphrasing and a corpus of Wikipedia pages and their simplified versions (Zhu et al., 2010) which is used for the general task of text simplification.

The more stylistic features that are incorporated into building a model, the closer it gets to the kind of holistic effort we have described above. To that end, we highlight Ficler and Goldberg (2017) wherein a supervised style transfer model is developed which focuses on the modification of prose with respect to six aspects of style, including register, sentiment, focalisation, and prolixity. A broader approach for supervised holistic style transfer is addressed in Carlson et al. (2018); Xu et al. (2012). They make use of a model that depends on a corpus of versions of the Bible, a priori aligned through the canonical and shared structuring of
Book, Chapter, and verse, to learn the differences between examples written in different styles.

Unsupervised methods pose new challenges for style transfer. Previous related work uses unsupervised training for generating text in a particular style. This includes the generation of stylized text (Hu et al., 2017) and modification of the sentiment or formality of prose (Shen et al., 2017; Li et al., 2018; Gong et al., 2019; Li et al., 2019). There have also been advances in the use of unsupervised approaches for machine translation. Many of these rely on the idea of back-translation (Artetxe et al., 2017; Lample et al., 2018) to automatically generate a synthetic parallel from unaligned data. Lample and Conneau (2019) uses this concept along with a novel cross-lingual language model objective for pre-training to achieve impressive performance on the unsupervised translation task.

3 Experiments

3.1 Data

Our work makes use of eight cleaned and aligned public domain versions of the Bible introduced in Carlson et al. (2018) and made available on Github. (That paper mentions the availability of thirty-four versions, but twenty-six of them have copyright restrictions that restrict their distribution.) These represent eight different English writing styles. The texts are divided hierarchically (and canonically), into version, book, chapter and verse, so that the verses from different versions are parallel. For our unsupervised work we do not take advantage of the alignment during training, but the alignment does enable an objective evaluation of our output.

Our major methodological advance is the introduction of another coarse level of hierarchy which we call content, which we use to modify the language model. We see this kind of coarse labeling as an approach which is broadly generalizable to situations in which fine-scaled parallel alignment does not exist. In the case of the Bible, we use nine “divisions” of the Bible which are classical groupings of thematically similar texts.1 See Table 1 for the divisions used. We do not use the exact data splits detailed in Carlson et al. (2018), but instead split the data as required by the formulation of our models. We use some books of the YLT (Young’s Literal Translation) and BBE (Bible in Basic English) versions for validation and testing as style transfer between these versions was identified as the “hardest” task in Carlson et al. (2018). The validation set contains the BBE and YLT versions of 1 Kings, Zephaniah, Mark, and Colossians. The testing set contains the BBE and YLT versions of Judges, 1 Samuel, Philippians, and Hebrews. The remaining books from BBE and YLT and all books from the other six (publicly available) Bible versions make up the training data.

The parallel texts allow for automatic and objective evaluation of translations. While the models we describe can be generalized to other non-parallel datasets, in those cases objective evaluation would be more difficult.

Table 1: Our partition of Bible books into divisions.

3.2 Baseline System

Lample and Conneau (2019) introduced a method for cross-lingual language model pretraining from non-parallel data2. Their model, XLM, feeds token, position, and language embeddings to a Transformer model (Vaswani et al., 2017) which tries to predict masked words. This task, Masked Language Modeling (MLM), was introduced by Devlin et al. (2018) and unsupervised translation was

---

1There is no authoritative partition into divisions, but there are many similar varieties. Our choice among these options is somewhat arbitrary, but has historical and disciplinary support. An example of Old Testament divisions which match ours can be found at [http://www.scriptureman.com/ot.gif](http://www.scriptureman.com/ot.gif) and our New Testament at [http://jpatton.bellevue.edu/inspired-table2.jpg](http://jpatton.bellevue.edu/inspired-table2.jpg)

2Code found at: [https://github.com/facebookresearch/XLM](https://github.com/facebookresearch/XLM)
demonstrated as an application of these pretrained language models. We use the XLM as our baseline.

In our experiment, we treat each version of the Bible in the data as a language. So the embeddings fed to the Transformer for MLM training are position and token embeddings as before, and version embeddings replacing the language embeddings of the original system. Our transformer architecture has embeddings of length 512, 6 layers, 8 attention heads and a 0.1 dropout rate.

We train the language model from scratch until the perplexity of the validation data for the BBE→YLT version has stopped improving. We then use this pretrained language model to initialize Transformers for both the encoder and decoder of our machine translation/style transfer model and train on the task of unsupervised translation until the BLEU score of the validation data for the BBE→YLT task has stopped improving. This design is based on that used by Lample and Conneau (2019) in the original paper. We call these models “XLM”.

3.3 Model with Content Embeddings

Using Bible divisions as a grouping of content similarity, we modify the XLM embedding structure accordingly and include a content embedding in addition to the token, position, and language (style) embeddings. In a different context other considerations or structural organization may suggest a different articulation of content. This additional embedding is treated similarly to the three embeddings in the baseline system. The input of each token passed to the Transformer is the combination of four embeddings instead of three. Just as in the XLM, these embeddings are updated during the training process. Our intuition is that for some datasets, the model may have difficulty distinguishing whether differences in language arise because of differences in the style of writing, or differences in the content. By providing training data where both style and content are designated, we anticipate that the model will be better able to reproduce the differences which are style-specific. Similar intuition has led to other approaches which allow a model to learn style and content separately (Fu et al., 2017; Zhang et al., 2018).

In this new formulation, we provide all four embeddings to the Transformer and then train towards the MLM objective as before. We call this model “XLM + Content” (see Figure 1). We use the same parameter settings as in the “XLM” model and as before, we stop training of the language model when the perplexity of BBE→YLT evaluation task has stopped improving. Once again this transformer which was pretrained on the MLM task is used to initialize the encoder and decoder of a machine translation/style transfer model. This transfer model continues training until the BLEU score of the evaluation data BBE→YLT has stopped improving. Note that the alignment (parallel nature of the texts) makes possible the BLEU scoring.

![Figure 1: “XLM + Content” model training on the MLM objective. Based on Figure 1 of Lample and Conneau (2019). The choice of types for content embeddings are human-assigned before training as seen in Table 1.](image)

4 Results

4.1 Evaluation Metrics

The existence of parallel texts allows us to evaluate our results using the standard translation quality measures BLEU (Papineni et al., 2002) and PINC (Chen and Dolan, 2011), which reward similarity to the target and dissimilarity to the source respectively. PINC was created from a desire to “measure lexical dissimilarity with the source sentence” and its creators say “In essence, it is the inverse of BLEU” (Chen and Dolan, 2011). The results of these evaluations can be seen in Table 2.

We find that our model with content embeddings has a higher (better) PINC score for all four test books, indicating that it has more aggressively made changes than the baseline system. “XLM + Content” also attains a sizeably Higher BLEU score on Philippians and Hebrews. The BLEU score for the other two test books are similar between the two systems.
Table 2: The BLEU (PINC) scores of the unmodified source and the output of each model for each test book. All scores are when translating from Bible version YLT to Bible version BBE.

4.1.1 Stylometry-Inspired Evaluation

This combination of BLEU and PINC scores for evaluating style transfer in text has been used in other work (Xu et al., 2012; Jhamtani et al., 2017; Carlson et al., 2018), but not without criticism (Tikhonov et al., 2019; Xu et al., 2016). Arguably, style transfer – especially for the situation in which there is no parallel (aligned) text – cries out for new kinds of measures. As mentioned in the Introduction, we believe that classical stylometric measures provide a natural source of appropriate options. Some approaches to stylometry are structural, while others focus on word usage frequency. For example, function word-based approaches have proved to be a useful (partial) fingerprint for authorial style in some cases (see e.g., (Mosteller and Wallace, 1964; Binongo, 2003)).

Thus inspired we augment the use of BLEU and PINC through several stylometrically inspired metrics. The first is the identification of frequent idiosyncratic words, words that seem simultaneously characteristic of one style but absent or rare in another. This form of bespoke evaluation checks to see if 17 frequent words with known translations have been correctly translated in the YLT→BBE test task. All the words occur frequently and exclusively in YLT. Examples include unto, hath, flee, doth and the full list can be seen in Table 3. These words occur 2,522 times in YLT source lines in the test set. In this test, a YLT→BBE translation is counted as correct if the BBE version does not include the idiosyncratic word from the YLT line. Accuracy scores in this evaluation increase with the complexity of the model: 99.3% (“XLM”) and 99.8% (“XLM + Content”).

In addition to this test of frequent idiosyncratic words, we analyze the entire test set of source, reference, and model outputs with a few other simple stylometrics: number of multi-syllable words, average number of syllables per word, average number of letters per word, and number of complex words (Dale and Chall, 1948). The results can be seen in Table 4. On all 4 of these evaluation metrics we find that the model modified to include separate content embeddings (XLM+Content) is closer to the target BBE than is the unmodified XLM model. This analysis provides further evidence that the content embeddings are enabling the model to produce better results.

4.2 Example Outputs

Table 5 shows two test data example inputs and their targets alongside the corresponding outputs of our systems. In the first example, note that both outputs correctly remove the use of quotation marks as is consistent with the BBE target and modernize the archaic Thou and dost. The “XLM + Content” also correctly changes the word testify to witness. In the second example, the “XLM + Content” model correctly changes age-during to eternal.

5 Conclusion and Future Work

The task of holistic textual style transfer requires a system to take text in a native (source) style as input and then rewrite the text, retaining the meaning while changing the style consistent with a specified target. In many potential applications this task will need to be performed in contexts where there is no parallel data which captures the styles of interest available for training. Examples range from the journalistic (writing articles in a given editorial style) to the literary (writing the style or voice of a given author). Contexts such as these have large corpora of source and target examples, but presumably – no source/target pairings.

In this work we demonstrated that a modern unsupervised machine translation technique could be applied to unsupervised holistic textual style transfer in the context of different styles (well known and publicly available versions) of the Bible. We

</table>

show that by adding an additional “content embedding layer” to encode the type of content in text, holistic style transfer is improved. The parallel nature of Bible versions enables us to objectively measure the effect of our innovation of content embedding – improvement is witnessed in terms PINC and BLEU scores that are greater when using content embedding than when not. Specifically, this improves upon the work of Carlson et al. (2018) and makes use of their publicly accessible data. We further introduce new measures of style transfer quality (a simple test of frequent idiosyncratic words as well as source/target comparisons of some basic stylometric measures – number of multi-syllable words, syllables per word, letters per word, number of complex words) as novel evaluations of style transfer, supplementing the traditional – and by some accounts, somewhat flawed – use of the PINC and BLEU metrics in this context. These new measures are a contribution in their own right to the space of evaluation frameworks for style transfer and also support our claim that content embedding improves style transfer.

The broader range of possible stylometric evaluation measures suggests that at least with respect to evaluation, a requirement of perfect evaluation and parallel texts might be relaxed.

While the Bible may seem to be particularly suited to the partition into content classes we employ, we believe this technique can be directly applied to many other textual sources as well. Similar to Bible versions, many translations exist of other classical works such as the epics written by Homer or Dante. In many of these translations alignment does not exist line by line so traditional supervised methods are not applicable. They are however “softly aligned” by book or chapter making content embeddings a natural choice. A model trained on these could then produce Homer’s Iliad in the style of a translator who only produced a version of the Odyssey. Similarly, many translations of classic non-English novels exist and this system could be used to create a new translation targeting the style of a particular translator.

Demand for English-to-English style transfer also exists commercially. Examples here include poetry parodies (Zaranka, 1981), continuations of stories from famous authors (James, 2011), or modernized retellings of stories (Rivers, 2012; McKinley, 2011). In these cases the content of the text either exists publicly or is written by the author. The style however is intentionally changed, either to match the works of another writer, or to remove the idiosyncrasies of the original style. Unsuper-
vised style transfer models could be used to help produce these works.

In addition to these potential applications, our results reinforce the idea that consideration of content and style independently can improve the results of style transfer models. In cases where our technique cannot be directly applied, this provides additional evidence to researchers that finding a way to separate the two may improve results.

In conclusion, this work highlights the utility of the Bible as a dataset for holistic style transfer, demonstrates that unsupervised machine translation methods for holistic style transfer are possible and can be objectively evaluated, provides further evidence — and an actionable methodology — for the idea that learning content independent of style can be beneficial, and proposes the use of classical stylometric measures for evaluation of style transfer systems.

Abstract

This study describes the development of a Portuguese Community-Question Answering benchmark in the domain of Diabetes Mellitus using a Recognizing Question Entailment (RQE) approach. Given a premise question, RQE aims to retrieve semantically similar, already answered, archived questions. We build a new Portuguese benchmark corpus with 785 pairs between premise questions and archived answered questions marked with relevance judgments by medical experts. Based on the benchmark corpus, we leveraged and evaluated several RQE approaches ranging from traditional information retrieval methods to novel large pre-trained language models and ensemble techniques using learn-to-rank approaches. Our experimental results show that a supervised transformer-based method trained with multiple languages and for multiple tasks (MUSE) outperforms the alternatives. Our results also show that ensembles of methods (stacking) as well as a traditional (light) information retrieval method (BM25) can produce competitive results. Finally, among the tested strategies, those that exploit only the question (not the answer), provide the best effectiveness-efficiency trade-off. Code is publicly available\(^1\).

1 Introduction

Question answering (QA) aims to automatically retrieve precise, rather than merely relevant, answers to a given question. The field has faced exponential progress along the years with new corpora (Rajpurkar et al., 2016; Ahmad et al., 2019) as well as computational models which approach the task from different perspectives. One of these is known as Recognizing Question Entailment (RQE).

Given a premise question (aka query), a RQE approach aims to retrieve semantically similar archived questions which have been already answered (Ben Abacha and Demner-Fushman, 2019). The task became relevant thanks to popular Community QA forums, such as Yahoo Answers, Quora and Stack Overflow, where an RQE approach is used to automatically search a large body of material looking up for archived question-answer pairs entailing a user posed question.

Besides popular forums, a domain in which RQE approaches are highly beneficial and have been extensively studied is the medical one. Russell-Rose and Chamberlain (2017) showed that, when using traditional information retrieval search engines to query medical information, healthcare professionals spend on average 60 minutes to formulate a search strategy, 3 minutes to analyse the relevance of a retrieved document, and 4 hours of total search time. Ben Abacha and Demner-Fushman (2019) suggest that healthcare consumers may also benefit from QA systems through which they can ask for desired information in natural language instead of having to perform complex search strategies. In fact, a study reveals that, in 2013, 59% of U.S. adults searched for health information online and 35% used healthcare search engines to figure out what medical condition they or someone else had\(^2\).

To advance the state-of-the-art in RQE approaches for medical-specific applications, some benchmarks have been proposed. Targeting Frequently Asked Question (FAQ) by healthcare consumers, Abacha and Demner-Fushman (2016) introduced a collection of 8,890 pairs of questions labelled as having or not the same meaning. In the TREC 2017 LiveQA track, a medical question answering task was proposed addressing the automatic answering of consumer health questions received by the U.S. National Library of Medicine (Abacha et al., 2017). Under the shared-task, a

\(^1\)https://github.com/Dia-Bete/RANLP2021

\(^2\)https://www.pewresearch.org/internet/2013/01/15/health-online-2013/
total of 738 question-answer pairs were publicly released. Finally, Ben Abacha and Demner-Fushman (2019) released MedQuad, a dataset with 47,457 medical question-answer pairs of 37 question types extracted from 12 websites of the National Institutes of Health of United States.

Although the RQE task has been extensively studied, as is the case with other NLP subfields, studies and approaches largely focus on the English language. In this study, we go in a different direction, facing the challenge of developing an NLP approach for a low resource language. Specifically, our study focuses on the Portuguese language and investigates the development of a Community Question Answering system in the particular domain of Diabetes Mellitus using RQE. This allows investigating new challenges in terms of multi-lingual NLP problems.

From an application domain (Health) perspective, world-wide, the number of people with diabetes increased from 108 million in 1980 to 422 million in 2014\(^3\). It is expected that the disease will reach 629 million in 2045. These numbers are partially explained by the rapidly increase of the disease in low- and middle-income countries, such as Brazil, where around 12 million people have this health condition. Aiming to cope with this disease and to have a better quality of life, a significant number of Portuguese speakers with this condition engages in dedicated public forums. In order to improve the access to information about this health condition for these speakers, this study aims to leverage RQE approaches to build BeteQA, a Portuguese community question-answering system to provide prompt and accurate answers to questions about Diabetes Mellitus posed by social forum users.

To meet our goal, similar to Abacha and Demner-Fushman (2016); Abacha et al. (2017) and Ben Abacha and Demner-Fushman (2019), we first built a Portuguese benchmark with 785 pairs between premise questions and archived answered questions annotated as perfect match, relevant and irrelevant, following Nakov et al. (2016, 2017). Based on our benchmark corpus, we leveraged and evaluated several RQE approaches ranging from traditional information retrieval (IR) methods (BM25 and TF-IDF cosine similarity) to novel large pre-trained language models such as BERT (Devlin et al., 2019).

For the latter methods, we evaluated them according to both zero-shot and fine-tuned learning setups. We also used ensemble models (stacking) based on a learn-to-rank model to combine the outputs of the previous methods with other traditional linguistic features.

Experimental results show that a supervised transformer-based method trained in multiple languages and for multiple tasks (MUSE) outperforms the alternatives in a zero-shot setting. Moreover, results show that the ensemble method (stacking) as well as a traditional (light) IR method (BM25) have the potential to provide competitive results. Finally, among the tested strategies, those that exploit only the question (not the answer), provide the best effectiveness-efficiency trade-off. Our failure case analysis also reveals that most failures occur for longer sentences containing a smaller number of relevant candidates and harder separability.

The remainder of this paper is organized as follows: Section 2 describes how the benchmark was built. Section 3 explains the RQE models leveraged to rank similar questions about Diabetes. Section 4 describes the experimental methods while Section 5 discusses the experiment results and a failure analysis. Section 6 presents related work and Section 7 concludes our study.

### 2 Data

**Collection** To build a Portuguese RQE benchmark in the domain of Diabetes Mellitus, we first manually extracted Portuguese questions about this health condition from specialized Websites and Social Media forums. In particular, most questions were extracted from the FAQ section in the website of the Brazilian Association about Diabetes\(^4\) as well as in forums about this health condition, such as DIABETES - DIABÉTICOS\(^5\), a Facebook community about Diabetes with around 85 thousand Portuguese speaking users.

**Preprocessing and Anonymization** To keep users’ privacy, the extracted questions from forums were manually de-identified by first removing emojis, fixing orthographic mistakes and paraphrasing non-fluent syntactic structures which could point to idiosyncratic wordings by users. Then any identifier, such as name, phone or address, was removed from the questions. Moreover, quasi-identifiers,
such as age and relative mentions, were modified. Users’ age were modified by randomly choosing a number in the interval of \([\text{age} - 5; \text{age} + 5]\), whereas mentions to relatives were randomly changed by the reference to a relative with similar age, such as parent ↔ uncle, parent in law; sibling ↔ cousin, partner; soon ↔ nephew. We collected a total of 1474 questions.

**Answers**

4 Medical students were recruited to review the question-answer pairs extracted from FAQ sections of websites as well as to formulate answers to the de-identified questions from public online forums. During the evaluation process, each question was answered by a single medical student. In case of doubts, the respective question would be discussed among the students together with a medical specialist. To organize the process, the students kept a standardized database of answers to the collected questions. Each answer in this database was classified according to 10 topics: 1) General information about Diabetes; 2) Diagnosis; 3) Chronic complications; 4) Acute complications; 5) Treatment; 6) Treatment control; 7) Comorbidities; 8) Signs and symptoms; 9) Motivation; and 10) Highly frequent, though unrelated to diabetes.

Answers were elaborated pursuant to Article 37 of Chapter V of the Brazilian Code of Medical Ethics, which prohibits treatment prescription without actual patient examination. Hence, the answers were constructed with the aim of informing the user about diabetes and related issues, without offering any diagnosis or treatment. In cases where the user requested some type of intervention, answers were prepared in order to guide them to seek a public healthcare unit, both to obtain an accurate diagnosis and to have adequate therapeutic plans designed by healthcare professionals.

**RQE benchmark**

To finally build the benchmark, we randomly selected 200 questions (roughly 15%) as premises, whereas the remaining 1274 (together with their answers) were indexed by a BM25 model (Jones et al., 2000). For each premise question, we retrieved the 5 most similar candidate questions, together with their answers, using BM25. Finally, following (Nakov et al., 2016, 2017), given 1000 triples (premise question, candidate question, candidate answer), a medical student was recruited to annotate whether the candidate question was a perfect match, relevant or irrelevant to the premise one. The candidate question was considered a perfect match when it conveyed exactly the same semantic meaning as the premise question. When both candidate and premise questions shared the same topic, but were not semantically identical, the candidate was labeled as relevant. Otherwise, the candidate question was labeled as irrelevant to the premise question.

Once the annotation was concluded, premise questions with only irrelevant candidate questions were ruled out, resulting in a corpus with 157 premise questions, each one aligned with 5 annotated question-answer pairs.

**3 Models**

Drawing on our collected Portuguese benchmark about Diabetes, we evaluated several approaches to rank question-answer pairs to their premise questions. Such approaches range from traditional bag-of-words information retrieval techniques to novel methods based on continuous vector representations and Learn-to-rank ensembles.

**3.1 Token-Based Approaches**

**BM25** is a fast information retrieval technique (Jones et al., 2000) which, in the context of RQE, calculates the relevance of archived question-answer pairs to a given premise question using a family of scoring functions based on bag-of-words.

**Cosine Similarity over TF-IDF** ranks the similarity of archived documents, such as questions or question-answer pairs, to the premise question by computing the cosine similarity between their TF-IDF vector representations (Salton and McGill, 1986). TF-IDF is a bag-of-words technique, standing for *term frequency–inverse document frequency*. As the name implies, a TF-IDF vector representation of a document is computed by counting the frequency of its tokens as well as their specificity, defined by an inverse function of the number of documents in which each of its tokens occurs.

**3.2 Embedding-Based Approaches**

Currently, sparse bag-of-words vector representations have given place to dense vectors computed by neural networks and popularly known as (word, sentence or document) *embeddings* (Mikolov et al., 2013). We leveraged some of these representations as RQE approaches.
3.2.1 Skip-Gram Wang2Vec
We used the Brazilian Portuguese word embeddings of 300 dimensions computed by a skip-gram Wang2Vec architecture described in Hartmann et al. (2017). To obtain the embedding representations of a multi-word document such as a question, we first looked up for the word-embeddings of each of its tokens and then averaged them. Absent tokens in the skip-gram Wang2Vec vocabulary were represented by the embedding of the OOV (out-of-vocabulary) token. During ranking, we used cosine similarity to measure the semantic distance between a premise question and its candidates.

Limitation Skip-Gram Wang2Vec provides context-free representations of words, i.e. the approach does not distinguish the meaning of a particular occurrence of a word taking its surrounding context into account. For instance, the word *bank* would be represented by the same vector representation in the expressions “financial bank” and “river bank”.

3.2.2 BERT-Based Approaches
More recently, several studies have proposed large neural language models which compute context-sensitive word embeddings representations (Howard and Ruder, 2018; Peters et al., 2018; Devlin et al., 2019). These language models take the local word context into account to generate its meaning representation. One of the first and most popular approaches of this kind is the “Bidirectional Encoder Representations from Transformers” (BERT) (Devlin et al., 2019), which encodes the meaning of a word into a vector taking its surrounding words (before and after) into account. BERT is pretrained in an unsupervised fashion using objective functions like word-denoising (i.e., predicting a masked word in a text) and next sentence prediction. In our study, we leveraged some of its multilingual and Brazilian Portuguese variations to the RQE task in the Diabetes Mellitus domain.

**BioBERTpt** is another variation of BERT which was pre-trained with Brazilian Portuguese Clinical texts (Schneider et al., 2020) for the task of named entity recognition in the target domain.

3.2.3 MUSE
Differently from BERT that trains large language models in an unsupervised fashion style, other studies have sought to learn a semantic vector space among words and documents by training a neural network in a supervised context with multiple downstream tasks. A state-of-the-art approach in this genre is the “Multilingual Universal Sentence Encoder” (MUSE) (Yang et al., 2020). MUSE embeds texts in 16 languages, which are later fed into classification heads for the target task. In particular, the approach is trained for 3 types of tasks: semantic retrieval, bitext retrieval and question answering retrieval. The study also showed that the model can learn cross-lingual vector representations, i.e. it is possible to measure the semantic similarity between two texts of different languages. Despite this cross-lingual resource, we only used the model to embed Portuguese texts about Diabetes Mellitus. In particular, we used the MUSE approach based on the Transformer architecture (Vaswani et al., 2017).

Different from BERT approaches, we followed Yang et al. (2020) and measured the similarity between the vector representations of premise questions and their question-answer candidate pairs using dot product instead of the cosine similarity.

3.3 Learn-to-rank Ensemble (Stacking)
We sought to investigate whether ensembling (i.e., stacking) the semantic similarity measures computed by the previous RQE approaches could boost the results for ranking candidate question-answer pairs to their corresponding premise questions. To fulfill this goal, we trained a Coordinate Ascent...
learn-to-rank approach (Metzler and Croft, 2007). Besides feeding the learn-to-rank approach with semantic features, we also wanted to analyse whether features which assess the quality of the questions can help the RQE task. Relying on Dalip et al. (2012), we used three types of textual quality assessment features as explained next.

3.3.1 Features

Our learn-to-rank approach uses four types of features, one based on the semantic measures computed by the previously described approaches and 3 other which assess the quality of texts based on its length, style and readability. The quality assessment features were computed for both premise questions and their corresponding question-answer candidate pairs.

Semantic Features the semantic similarities computed by our token-based, skip-gram wang2vec, BERT-based, MUSE approaches are used as semantic features by our learn-to-rank ensemble approach.

Length Features we compute several quality assessment features based on length such as the size of a text based on the number of phrases, words and characters.

Style Features we count the total number of phrases higher/lower than the average phrase length in the text; the size of the largest and shorted phrases; the number of articles; prepositions; auxiliary and total number of verbs; coordination, subordinating and correlative conjunctions; indefinite, interrogative, relative and total number of pronouns; an sentences starting with articles, prepositions, auxiliary verbs, general verbs, (coordination, correlative and subordinating) conjunctions and (indefinite, interrogative and relative) pronouns.

Readability Features we computed ARI, Coleman-Liau, Flesch Reading Ease, Flesch Kincaid, Gunning Fog Index, Lasbarhets index and SMOG Grading.

3.3.2 Settings

We trained our Coordinate Ascent learn-to-rank approach with 5 random restarts, 25 iterations to search in each dimension, 0.001 of tolerance and normalizing input features using z-score. The training data for the ensemble of methods was produced with nested cross-validation in the training set, thus avoiding any potential risk of data leakage problems from test to training.

3.4 Fine-tuned Approach

All the embedding approaches described in Section 3.2 and MUSE (Section 3.2.3) were used in a zero-shot learning setup, i.e. they were not trained specifically to our domain and, in the case of the embedding-based approaches, nor even to a semantic retrieval task such as RQE.

In order to have a fine-tuned embedding-based approach in our analysis, we used a neural classifier based on BERTimbau (in its large and cased version) as a Portuguese RQE approach about Diabetes. Given a premise question and a candidate question-answer pair, BERTimbau works by first encoding both documents. Following other fine-tuning studies with BERT (Devlin et al., 2019), for each document, we chose its embedding representation based on its special token [CLS]. Finally, we fine-tune the model by computing the cosine embedding loss function as in Equation 1:

\[
loss(x, y) = \begin{cases} 
1 - \cos(x_1, x_2), & \text{if } y = 1 \\
\max(0, \cos(x_1, x_2)), & \text{if } y = 0 
\end{cases}
\]

where \(x_1\) and \(x_2\) are the [CLS] vector representations of the premise question and the candidate question-answer pair, and \(y\) is the gold-standard label indicating whether they are similar or not. We treat the problem as binary, merging perfect match and relevant cases of our benchmark as positive instances, whereas the irrelevant ones as negatives. During training, the model backpropagates the gradients of the neural network using the AdamW optimizer with learning rate of 1e-5 and batch size of 4.

4 Evaluation

We evaluated the proposed approaches as a ranking problem. Given a premise question from the described benchmark, our goal is to investigate which model can better rank “Perfect Match” and “Relevant” candidate question-answer pairs ahead of “Irrelevant” ones. Following Nakov et al. (2016, 2017), we treated the problem as a binary one, not distinguishing “Perfect Match” and “Relevant” candidate questions.
Table 1: MAP@5 and MRR@5 results of the approaches measuring the similarity among premise questions and candidates through Question-Question, Question-Answer and Question-Question+Answer. Ranking was computed based on pair-wise comparisons among the MAP@5 models with the Wilcoxon Signed-Rank test. Best results are in **bold**, including statistical ties.

## Metrics
We evaluated the approaches using two popular ranking measures: the Mean Averaged-Precision (MAP) as the main metric and the Mean Reciprocal Rank (MRR) as the secondary one. Since each premise question of our benchmark is attached to 5 candidates, we used this length to compute the metrics (e.g., MAP@5 and MRR@5).

## Comparing Strategies
The task of Recognizing Question Entailment (RQE) traditionally works by measuring the similarity between two questions. However, in the Semeval task 3 shared-task about Community Question-Answering (Nakov et al., 2016, 2017), some of the leading approaches worked by measuring the similarity of a premise question taking into account both the candidate question and the answer. Moreover, approaches such as Yang et al. (2020) performs the Question-Answering task as a “Recognizing Answer Entailment” style, where the representation of a premise question is directly compared to the representations of the candidate answers. In this study we investigate the three comparing strategies: Question-Question, Question-Answer and Question-Question+Answer.

## Cross-validation
The approaches were evaluated using cross-validation using 5 folds. The obtained results were averaged across the folds and statistically tested according to the Wilcoxon Signed-Rank test in MAP@5.

## 5 Results
### Overall Analysis: Ranking of Methods
Table 1 displays the MAP@5 and MRR@5 results of the approaches in the Question-Question, Question-Answer and Question-Question+Answer strategies. Best results are marked in **bold**, including statistical ties. Regarding the proposed approaches, results show the advantage of MUSE, being the only method together with the ensemble with semantic features (e.g. L2R Semantic) to rank first in the three strategies according to the MAP@5. Although there is a tie between both methods, MUSE is a single model, whereas the latter is an ensemble of all our semantic similarity, demanding much more computational resources. For this reason, we assume MUSE as the model with the best results in our benchmark. Interestingly, MUSE was applied to the problem of Portuguese QA about Diabetes Mellitus in a zero-shot learning setup, i.e. it was not optimized to the task and, even so, was ranked first in all the strategies.

### Traditional Token-Based Methods
The “old-school” BM25 had very competitive results. The approach ranked first in the Question-Answer and Question-Question+Answer strategies and second in the Question-Question one. Besides effective, this approach has the advantage of not demanding a high volume of computational resources.

### Word Embeddings and BERT
Traditional context-free word embeddings, represented by Wang2vec, did not have a good performance in the evaluation, being outperformed by traditional methods such as BM25 and TF-IDF cosine. Regarding context-sensitive word embedding methods, we evaluated a multilingual version of BERT and two Portuguese focused ones: BERTimbau and BioBERT pt. BERTimbau, a general Brazilian Portuguese-focused model, was the one which performed best among the three, ranking second in the strategies where the candidates were represented by their questions (Question-Question and Question-Question-Answer). BioBERT pt is a Portuguese model pretrained in clinical texts, which we thought would be an advantage of the model.
However, although pretrained on texts in a domain similar to ours, the nature of the texts seems to be different. The clinical texts used to pretrain the method are more technical and focused on healthcare professionals, whereas our corpus is more related to healthcare patients and the way they pose their questions about Diabetes in social media. We also believe that the small datasets’ size in which those methods were originally pre-trained did not benefit the transformer-based approaches, as been reported in the literature (Cunha et al., 2020, 2021).

Fine-tuned Approach Except for the traditional approaches, the embedding-based ones and MUSE were not trained in our benchmark, being evaluated in a learning setting called zero-shot. Another popular learning strategy aims to fine-tune the weights of a pre-trained large neural network, such as BERT, in a downstream task. In order to know how a fine-tuned approach would perform as a Portuguese RQE method about Diabetes, we have developed and tuned the weights of an RQE classifier based on BERTimbau. Together with MUSE and L2R Semantic, this fine-tuned approach (Fine-tuned) ranked first in the Question-Question strategy, outperforming its non-tuned version (e.g., BERTimbau). However, its performance lowered for the other two strategies with results similar to BERTimbau. We believe that the results of our fine-tuned approach was not better in these two strategies, which take candidate answers into account, due to the fact that we trim the input texts with a maximum length of 128 tokens, possibly affecting the representation of the answers in exchange of a faster performance. We leave a deeper analysis of this issue for future work.

Learn-to-rank Ensemble We also sought to investigate whether ensembling (stacking) the semantic similarity measures computed by the proposed RQE approaches could leverage better ranking results. This did not seem to be the case and, in the best situations, the ensemble had comparable results to single approaches such as BM25 and MUSE. Relying on Dalip et al. (2012), we also investigated whether quality assessment features could positively influence the ranking process. In fact, results do not confirm this hypothesis with L2R All, with semantic and quality features underperforming when compared to L2R Semantic, with semantic features only, in the Question-Question and Question-

Question+Answer strategies.

Comparing Strategies Regarding the three compared strategies, results are inconclusive about which one is the best due to a high variation among the approaches. Due to the variability in terms of ranking precision between the three strategies, a choice of strategy could be made based on efficiency. In this case, the Question-Question strategy will be chosen, since, in our benchmark corpus, candidate questions have an average of 22 tokens, being much faster to process than candidate answers, with an average length of 94 tokens.

5.1 Failure Cases Analysis

We also conducted a failure cases analysis when leveraging the best-evaluated method (MUSE). A failure case happens when a non-relevant candidate question or answer is ranked at the top. Once identified, these cases were contrasted with the success cases (when a relevant candidate appears in the first position of the ranking) according to the following criteria: input length distribution, number of relevant candidates and separability.

Input Length Distribution defines the amount of processing required to understand the sentence semantics. Longer sentences require understanding more context and demand more memory to connect different concepts distributed over the sentence. In all strategies mentioned in Section 4, the length of questions and answers of the failure cases are larger than the success cases, as showed in Table 2. In the third quartile, for instance, the questions are 34.48% longer for the failure cases when compared to the success cases.

![Figure 1: Number of relevant candidates per failure/success cases.](image)
Number of Relevant Candidates  the number of relevant candidates also has an important impact on the model’s effectiveness since with less relevant candidates, it is more challenging to place a relevant result in the first ranking position. As demonstrated in Figure 1, the majority of failure cases (75%) had at most 3 relevant candidates with 50% of the samples having at most 1 relevant candidate. On the other hand, in success cases, there were at least 3 relevant candidates for 50% of the samples, with 25% having 5 relevant candidates.

Separability  separability has to do with the ability to generate representations for similar sentences that are closer in the embedding space than semantically dissimilar sentences. We measured the amount of dispersion of similarity scores across all three strategies and the failure cases are up to 25% less separable than success cases. Since with a lower separability is harder to distinguish relevant from non-relevant candidates, the ranking produced by the model diverges from the optimal form.

Summarizing, failure cases seem to be those in which the semantic meaning is more distributed on longer sentences, containing a smaller number of relevant candidates and that are less separable.

6  Related Work

Recognizing Question Entailment (RQE) has been extensively investigated in the field so that it was included as a shared task in SemEval-2016/2017 (Task 3 - Subtask B) (Nakov et al., 2016, 2017). Under the domain of the Qatar Living corpus, the task consisted of reranking 10 candidate question-answer pairs retrieved by Google for a premise question about Qatar. Among the promising participant approaches, we highlight SimBOW (Charlet and Damnati, 2017), the winner of the shared-task in SemEval 2017. The approach works by computing the semantic similarity over the vector representations of a premise question and a corresponding candidate question-answer pair using the SoftCosine metric. Another promising participant was KeLP (Filice et al., 2016), an approach based on Tree Kernels and SVMs which provided top results in the task. After the shared-tasks, Kunneman et al. (2019) conducted a study with these approaches in order to understand the effects of particular design choices, such as the adopted preprocessing methods and word-similarity metrics.

In the medical domain, Wang et al. (2016) proposed an answer recommendation algorithm for medical community question answering. Given a user query, the system starts by looking for similar archived questions using a paragraph vector based language model (PVLM) as a similarity metric. This metric measures the distance between a premise question and a candidate one by multiplying the cosine distances among the word embedding of each word of the premise question with the paragraph vector of the archived question. In the same year, Abacha and Demner-Fushman (2016) proposed a supervised machine learning approach which classifies whether or not a candidate question can be inferred from a premise question. The questions were represented based on lexical and semantic features. More recently, Ben Abacha and Demner-Fushman (2019) proposed a siamese neural network to predict whether a candidate question is a perfect match, a relevant one or an irrelevant one to a premise question.

7  Conclusion

This study investigates Recognizing Question Entailment approaches to build a Community Question Answering about Diabetes Mellitus. Unlike previous studies in the field, ours focuses on a language other than English. Specifically, we focused on the Portuguese language. Due to the lack of resources for the language in this domain, we built a benchmark corpus, which was used to test several RQE models ranging from traditional information retrieval methods to novel large pre-trained language models and ensemble techniques using learn-to-rank techniques. Results show the power of multilingual and multi-task large neural networks such as the MUSE. This sentence encoder obtained the best results of our evaluation in a zero-shot learning setup, i.e. this means it was not optimized to the target task. Results of the evaluation also show that BM25, a traditional and light information retrieval method, can obtain competitive results in the task.

Different from what was expected, state-of-art fine-tuned methods such as our BERTimbau classifier did not perform better than our MUSE zero-shot approach. We believe this may be caused by lack of training data, since our benchmark is relatively small. In future work, we plan to overcome this problem by collecting more data and expanding the corpus to other conditions related to Diabetes, such as hypertension. Like Yang et al. (2020), we also plan to augment our Portuguese training corpus by translating English questions from corpora such as MedQuad into Portuguese.

Abstract

For many tasks, state-of-the-art results have been achieved with Transformer-based architectures, resulting in a paradigmatic shift in practices from the use of task-specific architectures to the fine-tuning of pre-trained language models. The ongoing trend consists in training models with an ever-increasing amount of data and parameters, which requires considerable resources. It leads to a strong search to improve resource efficiency based on algorithmic and hardware improvements evaluated only for English. This raises questions about their usability when applied to small-scale learning problems, for which a limited amount of training data is available, especially for under-resourced languages tasks. The lack of appropriately sized corpora is a hindrance to applying data-driven and transfer learning-based approaches with strong instability cases. In this paper, we establish a state-of-the-art of the efforts dedicated to the usability of Transformer-based models and propose to evaluate these improvements on the question-answering performances of French language which have few resources. We address the instability relating to data scarcity by investigating various training strategies with data augmentation, hyperparameters optimization and cross-lingual transfer. We also introduce a new compact model for French FrALBERT which proves to be competitive in low-resource settings.

1 Introduction

Recent advances in the field of Natural Language Processing (NLP) have been made with the development of transfer learning and the availability of pre-trained language models based on Transformer architectures (Vaswani et al., 2017), such as BERT (Devlin et al., 2019). As they provide contextualized semantic representation they contribute both to advance the state-of-the-art on several NLP tasks and also to evolve training practices through the use of fine-tuning.

The trend of recent years consists in training large pre-trained language models on ever larger corpora, with an ever-increasing amount of parameters, which requires considerable computational resources that only a few companies and institutions can afford. For example, the base model of BERT with 110 million parameters was pre-trained on 16 gigabytes (GB) of text, while the GPT-3 model (Brown et al., 2020) was pre-trained on 45 terabytes (TB) of text and has 175 billion parameters.

In fact, deploying ever-larger models raises questions and concerns about the increasing magnitude of the temporal, financial, and environmental cost of training and usability (Strubell et al., 2019; Moosavi et al., 2020). Typically, due to their resource requirements, these models are trained and deployed for industrial operations on remote servers. This leads to a high use of over-the-air communications, which are particularly resource-intensive (Gündüz et al., 2019). In particular, some NLP applications (speech recognition, speech to text, etc.) have some known problems related to network latency, transmission path difficulties, or privacy concerns. To reduce the impact of these communications, there is a solution that is to allow these models to run directly on peripheral or mobile devices, that is, in environments with limited resources that require lightweight, responsive models and energy efficiency. Reducing the size of the models is therefore one of the increasingly favoured avenues, especially for the reduction of memory resources and computation time involved in training and use.

To meet these constraints, compact models represent one of the most promising solutions. As far as we know, they have only been evaluated on the comprehension tasks covered by GLUE (Wang et al., 2018).
et al., 2018) and the question-answering task with the SQuAD corpus (Rajpurkar et al., 2016) with abundant data, in English. The improvements resulting from the algorithmic optimizations of the models, although significant, raise questions about their effectiveness on lower-scale learning problems on poorly endowed languages. The works of Zhang et al. (2021) and Mosbach et al. (2021) have furthermore shown degraded performance in these conditions. These two reflections are at the origin of a double question which our contribution attempts to answer. On the one hand, what is the behavior of a Transformer-based model in the context of a question-answering task in French, a task that is poorly endowed in this language? On the other hand, what are the impacts of algorithmic improvements of these same models in this context?

To answer these questions, we first establish in section 2 a state-of-the-art that is meant to be broad enough to have a shallow overview depicting the ins and outs and issues around the usability of Transformer-based models whose breadcrumb trail is the issue of resources. Then, we present in the section 3 the recent progress of the question-answering task, through the use of these latest models. In sections 4 and 5 we introduce our model and present our experiments on the usability of Transformers models in a question-answering task for French, on FQuAD (d’Hoffschmidt et al., 2020) and PIAF (Keraron et al., 2020) corpora. We propose to address the instability relating to data scarcity by investigating various training strategies with data augmentation, hyperparameters optimization and cross-lingual transfer. Finally, we present a new compact model for French based on ALBERT (Lan et al., 2020)\(^1\), and compare it to existing monolingual and multilingual models, large and compact, under constrained conditions (notably on learning data).

2 Usability of Transformers

In this section we present the ins and out of the Transformer models to understand how the approaches meet the need for better usability.

2.1 Architecture and pre-trained models

The Transformer architecture (Vaswani et al., 2017) is based on a stack of encoder-decoder blocks, composed at a high level of forward propagation networks and multi-headed self-attention operations. The self-attention layer is the core element of its architecture that enables its efficiency in modeling the semantic context interdependencies between the units or sub-units of the input sequence.

Transformer-based language models such as BERT (Devlin et al., 2019) are pre-trained on large-scale data collections sourced from Wikipedia or Common Crawl (CC) with one or multiple training objectives (masked language modeling, next sentence or sentence order prediction). This pre-training can be followed by supervised fine-tuning according to the tasks, whether generatives (machine translation, abstractive summarization) or discriminatives (classification, question-answering). The ensuing fine-tuning phase allows for better initialization of the models parameters while requiring less task-specific data so as to make the training of subsequent tasks faster.

Recently, Zhang et al. (2021) and Mosbach et al. (2021) have nevertheless shown that the commonly adopted practices (the number of iterations, the choice of model layers) when fine-tuning Transformers-based language models are inappropriate under resource constrained conditions and adversely affect the stability of models performances as overfitting, label noise memorization or catastrophic forgetting. Added to this, because the pre-training process is particularly constraining, various works have been oriented towards the research and training of efficient models, both in terms of available capacities and resources and in terms of environmental footprint.

2.2 A search for efficiency

Reducing the cost of training Transformers-based models has become an active research area. To this end, methods based on compression techniques or on architecture improvements have been introduced in order to build compact models with comparable performances to large models.

Many works address the issue of model compression with quantization, pruning, knowledge distillation or a combination of these approaches. The idea of quantization (Shen et al., 2020) is to take advantage of the use of lower precision bit-width floats to reduce memory usage and increase computational density. Following the same objective, pruning (Michel et al., 2019) consists in removing parts of a model (weight bindings, attentional heads) with minimal precision losses. Finally, knowledge distillation (Sanh et al., 2019) enables the generation

\(^1\)Available at HuggingFace’s model hub page.
of models that mimic the performance of a large model (or set of models) while having fewer parameters.

Another axis of development concerns the use of neural architecture search (Elsken et al., 2019) which allows to optimize a model by progressively modifying the design of the network through trial and error, eliminating insignificant operations. To avoid the unnecessary large number of parameters, adapters (Houlsby et al., 2019) were introduced to allow fine-tuning of the set of parameters specific to the task of interest rather than the entire model.

Other architectural improvements highlighted with the introduction of the ALBERT model (Lan et al., 2020) such as the factorization of the attention matrix or parameter sharing. Indeed, the most time-consuming and memory-intensive operations concerns the forward propagation and attention computation operations. The self-attention layer of BERT pretrained models grows quadratically in respect to the input sequence length. One common approach to this issue consists of approximating the dot-product attention for example by using hashing techniques (Kitaev et al., 2020) to accelerate the training and inference phases when long sequence lengths are used. However these solutions have demonstrated they suffer from important computational overheads for tasks with smaller lengths, such as question-answering.

3 The Question-Answering task

Question-Answering (QA) based on machine reading comprehension corresponds to the task of extracting an answer given a question and a context document such as from a news or Wikipedia article.

3.1 General QA Architecture

Until recently, most of the proposed approaches have relied on an architectural complexification of LSTM-based neural networks and attention mechanism. At a high level, their architectures are all composed of three layers with:

(a) an encoding layer that projects the inputs, as each word within the context, question and answer triples in a latent semantic space;

(b) an interaction layer that models the semantic interdependencies between the embedded inputs through the use of attention mechanisms.

(c) an output layer that extracts the answer to the input question within the related context.

The interaction layer is the core element of the architecture for which several kinds attention mechanisms has been developed to improve the QA matching process such as bi-attention (Seo et al., 2017), co-attention (Xiong et al., 2017, 2018), multi-level inter-attention (Huang et al., 2018) or re-attention (Hu et al., 2018), to name just a few.

Recent advances through the availability of Transformer-based pre-trained models and the development of transfer learning methods have enabled to remove the recurrence of previous architectures in order to achieve parallelization efficiencies. This simplified the QA architecture and its training process, replacing the encoding and the interaction layers with attention-based Transformer layers.

Another advantage is that it provides pre-computed contextual word representations. QA models based on LSTMs are built on top of static word embeddings models such as GloVe (Pennington et al., 2014). Even these models have up to 40 times fewer parameters than a BERT-based model, they rely on LSTM-based encoders to produce contextual embeddings which considerably lengthens the time required for training and makes the dependence on supervised data more important.

The standard approach introduced by Devlin et al. (2019) we rely on this study, consists in introducing and updating parameter vectors corresponding to the start and end positions of the answer span. Specifically, the start and end position probability distributions are computed by softmax over the dot products between the representation of the tokens and the start and end vectors. In sum, all of the Transformer parameters as well as the two introduced parameter vectors are optimized together.

Despite the fact that there is a number of large-scale QA datasets in English, with tens of thousands of annotated training examples, porting a system to a new language with fewer annotated resources (low-resource languages) requires approaches that go far beyond the simple act of retraining the models.

3.2 Low-Resourced QA

In recent years, low-resource NLP has drawn an increasing amount of attention with solutions ranging from developing new data collection methodologies either via crowdsourcing or through the use of machine translation (MT), to cross-lingual and transfer learning approaches for which information is shared across languages or tasks.
3.2.1 MT-based data collection

Neural MT as made considerable progress in recent years such as translating large-scale datasets from a high-resourced to under-resourced languages or conversely has become an intuitive way of generating annotated datasets in a cost-effective and rapid manner.

Automatically translating the context, question and answer triples from a high-resource language, such as English (called source domain) to low-resource languages (called target domains) have enabled the evaluation of models for languages with no training data available but also the creation of large-scale MT-based QA corpora for the Italian (Croce et al., 2018), Spanish (Carrino et al., 2020), Arabic (Mozannar et al., 2019) and Korean (Youngmin Kim, 2020) languages.

Another approach consists of translating the QA triples of the target domain into the source domain, so the model trained on the source language can be directly applied on the translated target language testing data. As an example, Asai et al. (2018)’s method consisted of combining the alignment attention scores from a MT model with an English QA model to guide the answer extraction process.

The performance of MT-data approaches depends strongly on the quality of the MT models. Thus, due to the lack of reliable models for some language pairs, approaches that foster the transfer of knowledge from other languages or tasks while requiring less data have been developed.

3.2.2 Pre-training and Transfer approaches

The exploitation of pre-trained models followed by task-specific fine-tuning have pushed the state-of-the-art forwards, while requiring much less computational and data resources. The idea behind pre-training is to reuse the weights parameters trained on a set of source tasks and continue to fine-tune them on under-resourced target tasks to achieve knowledge transfer. Dai and Le (2015) were the first to propose to pre-train RNNs using auto-encoders and language models as part of their QA encoding layer. Min et al. (2017) and Wiese et al. (2017) pre-trained QA models before applying the fine-tuning process between the source and the target domains. Other efforts focused on pre-training Transformer-based models multilingually such as the multilingual version of BERT (called mBERT) (Devlin et al., 2019) or XLM-R (Conneau et al., 2020) to learn cross-lingual representations which are transferable across languages.

3.2.3 Usability concerns

Studies on the usability of Transformer-based models (Section 2) from standard resource efficiency concerns towards a broader set of problems related to their generalizability.

Recently, Pires et al. (2019) and Conneau et al. (2020) have shown that multilingual models underperformed, when applied on poorly endowed languages. Additionally, as mentioned in subsection 2.1, recent works (Zhang et al., 2021; Mosbach et al., 2021) have highlighted the limitation of Transformer-based transfer learning with strong instabilities arising from the small-scale learning.

French is a poorly endowed language since we do not have enough annotated data to train a deep learning model on QA tasks. Moreover, unlike the only two large monolingual French models: CamemBERT (Martin et al., 2020) and FlauBERT (Le et al., 2020), the English BERT model has become a branching point from which a growing number of large and compact English pre-trained models have emerged. These French monolingual models, although they provide good performances, do not reflect the rapid evolution of the field.

Consequently, in this paper we propose a new compact model FrALBERT for French we present in the following section alongside with the other available pre-trained language models on which we base our experiments.

4 FrALBERT and Transformer models considered

As mentioned in the previous section there is no compact model for French. We therefore decided to pre-train a new version of ALBERT from scratch we called FrALBERT, thus overcoming some of the discussed limitations.

ALBERT is based on parameter sharing/reduction techniques that allows to reduce the computational complexity and speed up training and inference phases. Compared to previous compact models such as DistilBERT (Sanh et al., 2019), Q-BERT (Shen et al., 2020) or TernaryBERT (Zhang et al., 2020), ALBERT is to the date the smallest pre-trained models with 12 million parameters and <50 megabyte (MB) model size.

FrALBERT is pre-trained on the French version of the Wikipedia encyclopedia of 04/05/2021, i.e. 4 GB of text and 17 million (M) sentences. Beyond concerns about the rights to use data from Common

Table 1: Characteristics of the pre-trained models used in the proposed small-scale QA framework.

Our experiments are also based on the large monolingual French model CamemBERT (Martin et al., 2020) as well as on the two large multilingual models: XLM-R (Conneau et al., 2020) and mBERT (Devlin et al., 2019), both pre-trained from massive corpora dataset in more than 100 languages such as the Common Crawl (CC-100) or Wikipedia (Wiki-100). We also exploit two compact multilingual models with a distilled version of mBERT: distil-mBERT (Sanh et al., 2019) and small-mBERT (Abdaoui et al., 2020), a mBERT model whose the original vocabulary has been reduced to two languages (English and French). Table 1 gives a comparison of the models.

5 Experiments

We propose an assessment of the comparative advantage gains in performance when using different training strategies (data augmentation, hyperparameter search and cross-lingual transfer) over monolingual and multilingual pre-trained models, larges and compacts for a QA task in French under resource constraints.

5.1 QA Datasets

We conduct experiments on four QA datasets whose descriptives are presented in Table 2, with:

- **SQuAD** (v1.1) (Rajpurkar et al., 2016) (we called *SQuAD-en*) the reference corpus to evaluate QA models’ performances in English, consisting of 100K+ QA pairs sourced from 442 English Wikipedia articles;

- **FQuAD** (v1.0) (d’Hoffschmidt et al., 2020), a recently released French QA dataset consisting of 25K+ crowdsourced QA pairs based on 135 articles on French Wikipedia;

- **PIAF** (v1.0) (Keraron et al., 2020), a small-scale dataset in French with only 3K+ pairs of QA pairs in 191 Wikipedia articles; and

- **SQuAD-fr<sub>train</sub>**, our French translated version of *SQuAD-en*. We used the Transformer architecture as described in Vaswani et al. (2017) from the Open NMT framework (Klein et al., 2017) (Open-Source Neural Machine Translation) implementation of the network to train our neural MT system. When translating QA corpora, the problem we face is that the translated answer may not be present in the translated context. Thus, simple techniques such as segment matching are inadequate to retrieve the answer. We have developed an answer extraction process that is based on

Table 2: Descriptives of *SQuAD-en*, FQuAD and PIAF datasets.
ChrF (Popović, 2015) a character n-gram precision and recall enhanced with word n-grams. Since answers are largely made up of entities, ChrF score integration is only performed when the answer span is not present in the related context. In order to evaluate the quality of the translation, we manually corrected the translation errors in the output of a subset of the corpus composed of 890 QA pairs and 107 contexts. We obtain a BLEU score (Papineni et al., 2002) of 68.89 and 72.38 for questions and contexts respectively. SQuAD-fr \(F_{\text{train}}\) serves as a means of data augmentation on FQuAD and PIAF benchmarks, with 90K+ translated QA training pairs.  

We also explore mixed datasets training strategy with SQuAD-en \(F_{\text{train}}\) for training models on a concatenation of the training data covering French-English language pairs to test the cross-lingual transfer ability of multilingual models.

### 5.2 Evaluation and validation

The performance of QA models are evaluated using the Exact Match (EM) and F1 scores. The EM score is the percentage of system outputs that match exactly with the ground truth answers. The F1 score is a combined measure of precision and recall that is less strict than EM. The evaluation process involves post-processing identical to that presented by d’Hoffschmidt et al. (2020) and inspired by that proposed for English by Rajpurkar et al. (2016), which consists of the removal of punctuation marks and determiners as well as a down-casing of the answers (ground truths and predictions).  

To address our considerations related to resource constraints we perform a hyperparameter optimization, that has proven to lead to better solutions in less time. It is based on a population-based learning (Jaderberg et al., 2017) in which a population of models and their hyperparameters are jointly optimized. To this end, we build a validation set by randomly extracting 10% of the training data.

---

2We share our SQuAD-fr corpus on request and on dataset sharing platforms to support further research in this area.

3The experiments reported in (d’Hoffschmidt et al., 2020) concern version 1.1 of the FQuAD corpus. Ours are based on the only version available to date (v1.0). Moreover, the test sets are not made public, so we use the development set instead.

4Determiners are le, la, les, l’, du, des, au, aux, un, une.

### 5.3 Results

Table 3 presents the results on the French QA task evaluated on FQuAD \(F_{\text{dev}}\) and PIAF \(F_{\text{dev}}\). This table shows the scores obtained with Transformer-based models on the baseline training (FQuAD \(F_{\text{train}}\)), using hyperparameter optimization approach (FQuAD \(F_{\text{train}}\) w/ opt) and with data augmentation approach (FQuAD \(F_{\text{train}}\) + SQuAD-fr \(F_{\text{train}}\)). Cross-lingual performances are presented in table 4, on the same French QA tasks FQuAD and PIAF as baseline the English corpus SQuAD-en \(F_{\text{train}}\), on which we applied hyperparameter optimization (SQuAD-en \(F_{\text{train}}\) w/ opt) and performed data augmentation by adding the French corpus FQuAD to the English QA training corpus (SQuAD-en \(F_{\text{train}}\) + FQuAD \(F_{\text{train}}\)).

#### 5.3.1 Baseline results

The results obtained from monolingual models with CamemBERT \(\text{base} \) which has more layers, hidden units and attention heads and Camembert \(\text{base} \), both pre-trained with a larger and more diverse amount of data achieve results are better than Camembert \(\text{base} \) pre-trained on only 4 GB Wikipedia. The highest F1 score is 81.2 on FQuAD \(F_{\text{dev}}\) and 68.1 on PIAF \(F_{\text{dev}}\).  

The F1 performances of the FrALBERT \(\text{base} \) model are close to those of the CamemBERT \(\text{base} \) model, both pre-trained on the French content of Wikipedia (4GB). Their results turn out to be competitive and of the same order of magnitude as those reported by Lan et al. (2020) on SQuAD-en with 1 point difference on F1 scores when evaluating a BERT \(\text{base} \) model (90.4 F1) and a compact ALBERT \(\text{base} \) model (89.3 F1) pre-trained on the same texts (BookCorpus and Wikipedia). Interestingly, these EM scores are higher than those of the Camembert \(\text{base} \) achieving the EM score of 55.1, an increase of 5 points on the FQuAD \(F_{\text{dev}}\).

#### 5.3.2 hyperparameter results

Automatically tuning the hyperparameter tends to make QA models more accurate with gains in terms of EM scores that are very expressive. Highest F1 / EM scores are 90.2 / 75.5 on FQuAD \(F_{\text{dev}}\) and 71.0 / 44.8 on PIAF \(F_{\text{dev}}\). Improvement are variable accruing the model considered, especially the French BERT one which have the highest improvement using this approach (from 6 to 9 F1 points and from 11 to 20 EM points) which is quite impressive. FrALBERT stay behind of 5 F1 points of the Camembert \(\text{base} \) trained with the same data (wiki
4 GB) but regarding the EM scores, FrALBERT is better of 3 points. Surprisingly, multilingual models are close to the French BERT models. The small-mBERT is better than FrALBERT around 2.5 F1 points, while the French one have a better EM score (+2.6 points), while distil-mBERT is lower in both F1 and EM scores.

### 5.3.3 Data augmentation results

Training strategies based on data augmentation got nearly the best results in both F1 and EM scores except for the CamemBERT large. Apart from CamemBERTbase (wiki 4 GB) and FrALBERTbase models, results are comparable with an average difference of 1 point regardless of the metric. More generally, the performance gains are up to 11 and 20 of F1 and EM points, respectively, on FQuADdev and up to 4 points on both metrics on PIAFdev.

### 5.3.4 Cross-lingual transfer results

The cross-lingual transfer-based approaches using multilingual models outperform the monolingual approaches on FQuAD and PIAF corpora (table 4). Once again the large model XLM-R achieves better results than its base version. XLM-R pre-trained with a dual LM objective lens scores better than the mBERT model every time. The highest F1 score is 86.8 on FQuADdev and 70.4 on PIAFdev.

There is a significant performance drop between the large multilingual models and their respective compact models. The compact multilingual models based on mBERT substantially underperform, obtaining lower F1 and EM scores than the large models regardless of the training strategy. In the zero-shot configurations where no French data is used for training (SQuAD-en_train and SQuAD-en_train + FQuADtrain) using F1-measure (F1) and Exact Match (EM), on two French QA tasks (FQuADdev and PIAFdev).

### 5.3.5 General observations

In all configurations, the performance in terms of EM and F1 on PIAF remains significantly lower than that obtained on FQuAD since the PIAF corpus does not include multiple responses as pointed out by d’Hoffschmidt et al. (2020). Unsurprisingly, PIAFdev offer a more challenging evaluation set, where the answer extraction performance are lower. Indeed, the corpus is more diversified with questions on 191 different Wikipedia articles, whereas on FQuADdev it only covers 18.

According results, we can confirm that data aug-

---

**Table 3:** Results obtained with French and multilingual Transformer models on the baseline training (FQuADtrain), using hyperparameter optimization (FQuADtrain w/ optim) and with data augmentation (FQuADtrain + SQuAD-frtrain) using F1-measure (F1) and Exact Match (EM), on two French QA tasks (FQuADdev and PIAFdev).

**Table 4:** Cross-language transfer results obtained with multilingual Transformer models only on the baseline (SQuAD-en_train), using hyperparameter optimization (SQuAD-en_train w/ optim) and with data augmentation (SQuAD-en_train + FQuADtrain) using F1-measure (F1) and Exact Match (EM), on two French QA tasks (FQuADdev and PIAFdev).
mentation is the better way to improve results, even if data comes from another language. We observe from multiligual results that combining training data gives better results with similar performance whether data are translated or not.

5.4 Analysis
In this section, we conduct an analysis of our results to understand what remains as challenges for state-of-the-art models, with a focus on the usability concerns of Transformers under resource constraints.

The success of supervised methods depends heavily on the availability of large-scale training data. Pre-training large models on massive corpora using unsupervised language modeling and fine-tuning the model with pre-trained weights requires less task-specific data. Our experimental results are in line with this, since we obtain satisfactory results with transfer learning when large and high quality annotated data are not available. The highest F1 score is 81.2 on FQuAD\textsubscript{dev} and 68.1 on PIAF\textsubscript{dev}. Nevertheless, the performance of the models can benefit from several training strategies.

Effect of MT-data augmentation The lack of human-annotated datasets for languages other than English can be overcome by enriching our training data with the translated version of SQuAD\textsubscript{-en}\textsubscript{train}. Regardless of the pre-trained model used, their performance are competitive on FQuAD\textsubscript{dev} and PIAF\textsubscript{dev}, close to human performance.

Effect of hyperparameter tuning A generally unstated assumption is that pre-trained linguistic models are under-optimized and that practices commonly adopted for the fine-tuning stage can be detrimental to performance (Zhang et al., 2021; Mosbach et al., 2021). This is quite apparent in all settings, with better gains through hyperparameter optimization stages. Fine-tuning CamemBERT\textsubscript{large} on the French dataset yields 90.2 / 75.5 F1 / EM on the FQuAD dev set. By means of comparison, CamemBERT\textsubscript{large} scores were 81.2 / 55.9 F1 / EM on the same set with no hyperparameter tuning.

Crosslingual QA Pre-training language models on the concatenation of multiple languages has proven to be a competitive approach for cross-lingual language modeling. If monolingual models often perform better than multilingual models, we observe that, for comparable model sizes this is not the case in our task where the performance gap is smaller. This gap is further reduced when the strategies are combined. Scores of fine tuned XLM-R\textsubscript{base} is 82.1 / 66.8 on FQuAD\textsubscript{dev} and 65.0 / 39.6 on PIAF\textsubscript{dev}.

The zero-shot experiments show that multilingual models can reach strong performances on the task in French when the model has not encountered data of the French language. For example, the XLM-R\textsubscript{base} model fine-tuned solely on SQuAD\textsubscript{-en}\textsubscript{train} reaches a performance on FQuAD just a few points below the performance obtained when fine-tuning is performed on FQuAD\textsubscript{train}.

Finally, our results suggest that data-driven augmentation, either by translating datasets from high resource languages or by concatenating the available corpora are a particularly appropriate strategy to exploit the potential of cross-lingual transferability of models and data for improving model performances.

Improvements over a small scale dataset With resource-limited training data we obtain an average F1 score of 74.2 on FQuAD\textsubscript{dev} and 61.7 on PIAF\textsubscript{dev} when we fine-tuned FrALBERT — higher performance than any of the compact multilingual models, but slightly below the performance of the large monolingual models. We believe that the lower performance of small multilingual models is not due to their lower number of parameters, but to the usability of these models which is dependent on the reduction technique used. This can be seen very clearly since the performance of the FrALBERT model is close to that of the large models.

Here again, these performances can be boosted via the use of translated data or hyperparameter search which allows us to bring the maximum performances obtained with FrALBERT\textsubscript{base} and CamemBERT\textsubscript{base} pre-trained on 4 GB Wikipedia closer in a consistent way. Their scores remain slightly below those obtained with models pre-trained on more data suggesting limitations related to the corpus domain of the language model.

Computational costs Compact models provide alternatives to high-energy consumption models by showing comparable performance while reducing their size and computational complexity. Decreasing the environmental impact of NLP model training, as a research topic, is very recent (Moosavi et al., 2020). We decided to monitor our experiments conducted on one NVIDIA V100 GPU with 16GB of memory using
Table 5: Comparison of models by computational costs on FQuAD_{train}.

</table>

The footprint of the large versions of XLM-R_{large} and CamemBERT_{large} models is 3 times more than their base versions. Their training time is also significantly longer, over 5 hours. Finally, in terms of watt usage, carbon emissions and training time, FrALBERT is two times less the distilled version of BERT.

6 Conclusion and outlook

Recently, important progress has been made in neural language modeling using Transformer networks. Its popularity now well established lies in its effectiveness in modeling long-term dependencies. In this study, we have shown that a number of significant shortcomings of usability have recently been pointed out and that some solutions have been drawn up with compact models. We have also overviewed how the use of Transformer-based pre-trained language models have sparked a paradigmatic shift in question-answering training practices from task-specific architectures to the use of transfer learning through fine-tuning.

Comparing performances on a French question-answering task using large and compact models provides insight into the usability of these models for under-resourced languages. As others, we argued that large and compact models cannot be used with limited data. Our experimental results suggest that training strategy such as hyperparameter tuning or data augmentation can help to alleviate the data-gathering burden, with performances close to those of a high-resourced language such as English.

Finally, we present a new compact model for French FrALBERT (12M parameters), which proves to be as competitive as the large monolingual model CamemBERT (110M parameters) pre-trained on the same amount of text. In term of computational cost, we shown this compact model is twice less greedy than the BERT_{base} models. We also release a high-quality translated version of the SQuAD corpus in French consisting of around 90K+ QA pairs.

In a future work, we aim to continue this study from a meta-learning perspective with a model-agnostic approach generalizable to low-resource languages. We also plan to extend our model to other languages and to evaluate it on other NLP tasks such as named entity recognition or natural language understanding.

Abstract

A major challenge in analysing social media data belonging to languages that use non-English script is its code-mixed nature. Recent research has presented state-of-the-art contextual embedding models (both monolingual s.a. BERT and multilingual s.a. XLM-R) as a promising approach. In this paper, we show that the performance of such embedding models depends on multiple factors, such as the level of code-mixing in the dataset, and the size of the training dataset. We empirically show that a newly introduced Capsule+biGRU classifier could outperform a classifier built on the English-BERT as well as XLM-R just with a training dataset of about 6500 samples for the Sinhala-English code-mixed data.

1 Introduction

Social media has become very popular among people across the world during the last decade, mainly due to the popularity of smart mobile phones. For low-resource languages, this social media data has become a major source of text in building Natural Language Processing (NLP) applications. Most of the content in social media tends to be informal. When the users are (at least to a certain degree) multilingual, the informal content they publish in social media tends to be code-mixed. Code-mixed data is a result of code-switching, which denotes a shift from one language to another within a single utterance (Sitaram et al., 2019).

Recent work on text classification with code-mixed data has used contextual embedding models such as BERT (Devlin et al., 2019a), and their multilingual versions, such as mBERT or XLM-R (Aguilar et al., 2020; Kumar et al., 2020). However, using these pre-trained models for code-mixed text classification, in particular the domain-specific data in low-resource languages poses many challenges. Contextual embedding models such as BERT need large volumes of monolingual data to train. On the other hand, not every language is included in the pre-trained multilingual models, and low-resource languages are underrepresented in those models (due to the smaller amounts of low-resource language data used in contrast to high-resource languages when training these models). In fact, there is a line of research that has shown even simple classifiers such as Logistic Regression proving to be more effective than the multilingual embedding models (Chakravarthi et al., 2020).

In this paper, we empirically show that the success of contextual embedding models on code-mixed text classification depends on multiple factors, and they can indeed be sub-optimal compared to text classification based on neural models other than transformer based ones.

We selected Sinhala and Malayalam, which are low-resource languages. In the recent language categorization by Joshi et al. (2020), Sinhala belongs to class 0 (i.e. it has exceptionally limited resources). Malayalam is categorised as 1, (i.e. it has some unlabelled data, however collecting labelled data is challenging).

A food recipe dataset with about 3000 samples (Kazhuparambil and Kaushik, 2020) was used as the Malayalam-English code-mixed data. For Sinhala-English code-mixed data, a corpus of 10000 user comments in the domain of telecommunication was annotated with two types of information: aspects related to the telecommunication domain, and overall sentiment of the comment.

We fine-tuned English-BERT and XLM-R (Conneau et al., 2019) models on both datasets. Then we implemented a novel Capsule+biGRU network for the same tasks. Results show that the Capsule+biGRU model consistently outperforms English-BERT and XLM-R models for the Sinhala-English dataset that had more data and less code-mixing complexity than the Malayalam-English dataset. With this, we establish the argument that the performance of contextual embedding mod-
els depends on multiple factors such as the code-mixing level, size of the dataset used to train the contextual embedding models, and the size of the dataset used in fine-tuning. Further experiments with the Sinhala-English dataset showed that this Capsule+biGRU model is superior to recurrent models as well. The annotated dataset, as well as our code are publicly released 1

2 Related Work

2.1 Deep Learning based Text Classification

Aspect identification and sentiment classification tasks used in this paper are essentially text classification problems. Thus, without any loss of generality, in this section we look at Deep Learning solutions applied for text classification. Minaee et al. (2021) identified several Deep Learning techniques for supervised text classification. The simplest technique is the Feed Forward networks, which treats the input text as a bag of words. Subsequently introduced Recurrent Neural Models have the ability to capture the sequential dependencies between words. Long-Short Term Memory Networks (LSTMs), and Gated Recurrent Units (GRUs) were introduced to solve some of the shortcomings of the RNN models. LSTMs, in particular bi-LSTMs have been very commonly used. There have been several LSTM variants employed in text classification such as tree-LSTM (Tai et al., 2015), multi-timescale LSTM (Liu et al., 2015), and sentence-state LSTM (Zhang et al., 2018). It is common to use pre-trained word embedding models such as Word2Vec or fastText to be used as the input representation of these recurrent models. Attention mechanism is employed on top of architectures such as GRUs (Yang et al., 2016), or LSTMs (Liu et al., 2016). Convolutional Neural networks (CNNs) is another model used for text classification. Similar to LSTMs, different CNN variants such as character-level CNNs (Zhang et al., 2015), and multi-layer CNNs (Pang et al., 2016) have been employed. However, CNN has a problem of information loss with respect to its pooling operation. More recently, capsule networks were introduced to address this problem, and have been reported to outperform CNN based text classification systems (Yang et al., 2019), as well as those based on recurrent models like LSTMs (Senevirathne et al., 2020). Recently introduced Transformers (Vaswani et al., 2017) are now being commonly used to build extremely large language models (also known as contextual embedding models). The most popular contextual embedding model is BERT (Devlin et al., 2019a), and there have been subsequent improvements to it. Text classification with pre-trained language models has now become the state-of-the-art for Text Classification (Bao et al., 2020).

2.2 Classifying Code-Mixed Data

Research on code-mixed data spans across tasks such as language identification (Gundapu and Mamidi, 2018), Part of Speech tagging (Vyas et al., 2014), speech recognition (Shah et al., 2020) and text classification. In this discussion, we only focus on text classification of code-mixed data. Out of the aforementioned Deep Learning techniques, code-mixed data classification has been mainly implemented using LSTMs, and contextual embedding models. English-BERT was employed because in code-mixed data, foreign language text is written in English script. Moreover, multilingual contextual embedding models s.a. LASER (Artetxe and Schwenk, 2019), mBERT (Devlin et al., 2019b) and XLM-R have been employed. Related research reported mixed observations on the performance of these techniques. Aguilar et al. (2020) showed that mBERT performs better than biLSTM that has one-hot vector representation as the input, while Yadav and Chakraborty (2020) showed that an LSTM trained with domain-specific embeddings as input representations performed better than LASER. Interestingly, some research reported that Machine Learning algorithms such Logistic Regression and Random Forest were able to outperform BERT and even mBERT (Chakravarthi et al., 2020; Javdan et al., 2020). Compared to monolingual text classification, the number of code-mixed datasets is limited. The most notable one is the Spanish-English and Hindi-English code-mixed datasets released for the SemEval 2020 task (Javdan et al., 2020). Other than that, there are code-mixed datasets available between Malayalam-English (Kazhuparambil and Kaushik, 2020), and Tamil-English (Chakravarthi et al., 2020). Interestingly, other than the Spanish-English dataset, all the other datasets we identified involve Indic languages.

Aspects are specific to the telecommunication domain, as discussed below.

A mini-survey was conducted with the help of 150 users of the telecommunication companies through the social media. First, a detailed list of aspects was identified by analysing user comments. An online form was distributed among social media users and they were asked to select the most important aspects from the aspect list. After that, the highly rated set of aspects was selected as the aspects to be annotated in the corpus. Six aspects, namely network, billing or price, package, customer service, data, and service or product were identified as the final aspects using that mini-survey.

Data was extracted from public forums in Facebook. All these FaceBook pages can be accessed without logging into FaceBook, and are indexed by search engines. All the company names and people names included in the comments were manually removed from the dataset.

Two annotators were employed for the aspect and sentiment annotation. 10000 comments were annotated with the aspects and the sentiment. The sentiment distribution and aspect distribution are shown in the Figure 2 and Figure 3, respectively. Also a sample of the telco data is shown in Table 3. This dataset only contains English and Sinhala written in English script. Overall, about 10% of the corpus is English words.

3 Datasets

3.1 Malayalam-English Dataset

The Malayalam-English dataset was obtained from a food recipe dataset with about 3000 samples Kazzuparambil and Kaushik (2020). Figure 1 and the Table 1 show the class distribution and few samples of the Malayalam-English dataset, respectively. Each comment is tagged with one of the seven classes. Most of the comments in the dataset belong to the undefined class. Comments written in the Malayalam characters were removed from the dataset, and the resulting dataset had 3434 records. Thus the dataset has English words, as well as Malayalam words written in English script. Overall, about 25% of the corpus is English words.

3.2 Sinhala-English Dataset

This dataset was newly created by us. Telecommunication domain has been identified as a low-resource domain. We are not aware of any dataset or research that considered text data in this domain. This dataset was annotated for the following two text classification tasks.

- Document-level sentiment classification, where each user comment is annotated with its sentiment - positive, negative, and neutral.
- Aspect extraction, where each comment is annotated with the aspect term it refers to.
4 Methodology

4.1 Pre-Processing

The Sinhala-English dataset was pre-processed to reduce the noise. Initially, punctuation characters were removed from the text. After that, URLs, mobile phone numbers, and Emails were removed from the text. Also, social media comments contain many emojis in the comments. Those were converted to the word format. The Hashmark was removed from the hashtag as another pre-processing step. After doing all the above-mentioned steps, words were converted to their lowercase form, and the sentences were tokenized. After that basic text pre-processing steps such as converting to lowercase and stop word removal were done to the both datasets.

4.2 Classifying Code-Mixed Social Media Data

In the sentiment analysis problem, only one class is predicted from the positive, negative or neutral classes. But in the aspect prediction mode, more than one class may be predicted if that comment contains more than one aspect. Because of that, sentiment analysis problem was resolved as a multi-class classification problem while the aspect prediction problem was resolved as a multi-label classification problem.

Firstly, in order to setup the baselines, we used recurrent deep learning models on the Sinhala-English dataset. These include RNN, LSTM, GRU, and BiLSTM. fastText and Word2Vec models were trained from a raw corpus of 100000 words extracted from the same sources that were used to create the Sinhala-English annotated dataset. These embeddings were used as the input representation of all these neural models.

Secondly, various improvements were carried out on these models as described below:

- Regularization strategies such as dropout, L1/L2 regularization, and early stopping.
- Integration with CNN models, because CNNs are known to be able to extract more coarse-grained features.
- Stacked models with the aim of extracting rich contextual knowledge from the network’s upper layers. These stacked models contain additional higher layers that extract valuable contextual information from both past and future time sequences (Zhao et al., 2018).

Thirdly, a capsule network was implemented. Capsule networks were selected because they have performed better than LSTM,RNN,Bi-LSTM, etc with Sinhala text classification (not on code-mixed data) (Senevirathne et al., 2020). The capsule network was introduced as an upgrade to CNNs, to be used in NLP applications such as text classification (Sabour et al., 2017). The ability to record context level information in its precise sequence using a vector representation of the capsules is a crucial aspect of the capsule architecture. The dynamic routing mechanism of the capsule network is known to overcome drawbacks of CNNs such as high computational cost and information loss caused by the widely utilized max pooling approach. This basic capsule network architecture...
was combined with LSTM, GRU, BiLSTM, and biGRU models. However, only the combination with the biGRU model gave better results than the recurrent and CNN models, thus only that result will be reported.

Figure 4 shows the Capsule+biGRU network we employed. According to that, firstly raw comments were pre-processed using the text-processing techniques (see Section 4.1). After that, the above trained CBOW word embeddings were used as the first layer of the neural network followed by the Bi-Directional GRU layer. Output from the GRU layer was used in the capsule layer. Finally, a flatten layer was implemented followed by a fully connected Softmax of Sigmoid layer.

Finally, we experimented with the pre-trained contextual embedding models. We experimented with English-BERT and XLM-R. mBERT was not used because it does not include Sinhala. A text classification layer was added on top of both English-BERT and XLM-R models, and they were fine-tuned with the English-Sinhala training data.

To further establish the performance of Capsule+biGRU with respect to English-BERT and XLM-R, these models were tested on the Malayalam-English dataset. Recurrent and CNN models were not tested, as their performance lagged behind the Capsule+biGRU model for Sinhala-English. BERT-uncased model\(^2\) was used as the pre-trained model in all the experiments.

5 Experiments and Evaluation

5.1 Experiment Setup

All experiments were carried out using Google Colab and kaggle. Python was used as the main programming language while Keras was used to build deep neural networks. Three-fold cross-validation was used in every experiment. After that, the best model was trained with the hold-out-based method and hyper-parameter tuning was carried out. Hyper-parameters used in the capsule+biGRU model are shown in the Table 4. The dataset was split into train and validation sets with ratios of 5:1 when doing the hold-out based experiments. Accuracy, precision, recall and F1 were reported as the weighted average for each experiment on the cross-validated dataset.

5.2 Word Embedding Models

The first experiment was to identify the best word embedding models for Sinhala. Both Word2Vec (CBOW) and fastText models were tested for 100, 200, 300, 400 and 500 dimensions. 100000 comments extracted from the same dataset were used to build the word embeddings. CNN model was used as the model to find the best word embedding technique and embedding size, as doing this experiment for all the models is not possible.

According to Table 5, Word2Vec (CBOW) word embedding model with 400 embedding size showed the highest weighted F1 score compared to the

\(^2\)https://huggingface.co/bert-base-uncased
The aspect prediction model also suggested the same thing. Because of that, CBOW with 400 embedding size was used in all experiments.

Table 6 and Table 7 show the results for the two Sinhala-English tasks and the the Malayalam-English task, respectively. Note that the Malayalam-English dataset was used only to compare the Capsule+BiGRU against English-BERT and XLM-R models.

In the sentiment classification task, the Capsule+BiGRU model significantly outperforms English-BERT and XLM-R based solutions. However, the gain in the aspect identification task is not that significant. The result with the Malayalam-English dataset is quite the opposite—the capsule+BiGRU model significantly lags behind English-BERT and XLM-R models.

We can think of multiple reasons for this observation. First and foremost, Sinhala-English dataset was much larger than the Malayalam-English dataset. We believe the number of training samples in the latter dataset was not sufficient to train the Capsule+BiGRU model. In contrast, the pre-trained models could cope with this lack of data. On the other hand, the Malayalam-English dataset had a much higher number of English words compared to the Sinhala-English dataset, which could have been an advantage for the English-BERT model, as well as the XLM-R model that has a significant presence of English. Another reason could be the complexity of the Malayalam-English dataset. Despite the task, XLM-R is consistently lagging marginally behind English-BERT. We attribute this observation to the fact that Sinhala and Malayalam being underrepresented in the XLM-R model. Though we do not know exact size of the commoncrawl corpus used to train the XLM-R model, according to the latest commoncrawl statistics, Sinhala and Malayalam representation was just 0.0070% and 0.0211 %, respectively.

### Conclusion

The objective of this research was to critically analyse the performance of English-BERT and XLM-R models for classifying code-mixed data. We identified that the performance of these models depends on factors such as the size and composition of the code-mixed data. We were able to introduce a novel Capsule+BiGRU model that could outperform the other model.
English-BERT and XLM-R models with a moderate dataset of Sinhala-English 10000 comments (Note in 3-fold cross-validation, about 6600 samples are used for training). This result suggests that, at least for text classification on code-mixed data that involves extremely low-resource languages that are under-represented in the large multilingual embedding models, traditional Deep Learning solutions are still a viability. This research can be considered as one of the very few works that comparatively analysed the performance of these different techniques for code-mixed data with respect to multiple factors and languages. Furthermore, this research publicly released a code-mixed dataset that can be used for two text classification tasks for the extremely low resource language Sinhala. We believe that further research should be conducted with respect to more languages in order to properly determine the impact of the aforementioned factors on classification of code-mixed text.

Abstract

Character-based word-segmentation models have been extensively applied to agglutinative languages, including Thai, due to their high performance. These models estimate word boundaries from a character sequence. However, a character unit in sequences has no essential meaning, compared with word, subword, and character cluster units. We propose a Thai word-segmentation model that uses various types of information, including words, subwords, and character clusters, from a character sequence. Our model applies multiple attentions to refine segmentation inferences by estimating the significant relationships among characters and various unit types. The experimental results indicate that our model can outperform other state-of-the-art Thai word-segmentation models.

1 Introduction

Thai running text has neither essential word delimiters nor sentence periods. However, spaces are arbitrarily allowed to separate words, phrases, clauses, and sentences. These characteristics make word segmentation in Thai more difficult than in other languages, such as English, German, and Finnish, which have spaces and periods to identify word and sentence boundaries. Thai word segmentation can be categorized as a sequential-labeling task that assigns a word-boundary label to each character in a fine-grained tagging scheme such as BIES (beginning, inside, end, and singleton) (Xue, 2003), as shown in Figure 1.

Neural-network models have been applied and perform well on character-based Thai word segmentation. Jousimo et al. (2017) applied bidirectional recurrent neural networks with gated recurrent units, while Chormai et al. (2019) proposed an AttaCut, a convolutional-neural-network (CNN)-based model that mainly provides faster and more accurate word inferring motivated by DeepCut (Kitintaranadorn et al., 2019).

Despite the fact that neural-network models with linguistic knowledge can perform almost perfectly, adapting models with pre-trained neural networks, such as word vectors and language models, is still useful (Shao et al., 2018). Seeha et al. (2020) proposed a transfer-learning approach for Thai word segmentation by using a pre-trained character language model for character-based word segmentation. Although it exhibited state-of-the-art performance regarding Thai, it merely uses characters and does not use other information such as word and subword (Sennrich et al., 2016; Kudo, 2018). Additional linguistic knowledge, such as Thai character clusters (CCs) (Theeramunkong et al., 2000) and subword units, has also been successfully used for word segmentation and related tasks (Suntayawalee et al., 2014; Lapjaturapit et al., 2018; Nararatwong et al., 2018; Yang et al., 2019; Li et al., 2019). An attention mechanism (Bahdanau et al., 2015) has been successfully applied to various downstream tasks, particularly a sequence-labeling task (Higashiyama et al., 2019; Tian et al., 2020).

We propose a character-based Thai word-segmentation model with multiple attentions that jointly uses corresponding words and CCs. Our model is based on the bidirectional long short-term

Figure 1: Thai word segmentation as sequence-labeling task on BIES (beginning, inside, end, and singleton) tagging scheme
memory with conditional random field (BiLSTM-CRF) architecture, which is the baseline model for this study, because it has been successfully applied in sequence-labeling tasks for Thai and other languages (Jousimo et al., 2017; Nararatwong et al., 2018; Higashiyama et al., 2019; Seeha et al., 2020; Tian et al., 2020). Our contributions are as follows:

- We use word, subword units, and CCs with multiple attentions to estimate the relationships of characters in character-based Thai word segmentation.
- Our model outperforms the state-of-the-art models in Thai word segmentation, showing the validity of using CCs over subword units.
- Our code will be made publicly available.¹

2 Background and Related Work

2.1 Thai Word Segmentation Revisited

In the early stage of Thai word segmentation, dictionary-based learning techniques had been used along with machine-learning techniques, for instance, Markov models (Kawtrakul and Thumkanon, 1997), decision trees (Sornlertlamvanich et al., 2000; Theeramunkong and Usanavasin, 2001), and CRFs (Haruechaiyasak et al., 2008). CRFs have been shown to be particularly suitable for Thai sequence-labeling tasks (Kruengkrai et al., 2006; Haruechaiyasak and Konyoung, 2009; Kruengkrai et al., 2009; Nararatwong et al., 2018).

In parallel with CRFs, neural-network models, e.g., CNNs (Kittinaradorn et al., 2019; Chormai et al., 2019), LSTM (Treeratpituk, 2017), and BiLSTM (Jousimo et al., 2017), have been applied and performed excellently for character-based Thai word segmentation. Using additional knowledge, such as CC (Lapjaturapit et al., 2018; Nararatwong et al., 2018), transfer learning (Seeha et al., 2020), and stacking ensemble (Limkonchotiwat et al., 2020), along with neural-network models could improve performance.

2.2 Character Clusters in Thai Word Segmentation

Compared with English, the Thai language has various types of characters, i.e., consonants, vowels, tones, and special characters. A word can be formed from a combination of these characters. Thai also has unique linguistic phenomena, for example, some sequential characters tend to be indivisible units. Thus, Theeramunkong et al. (2000) introduced the concept of a CC, which is a set of predefined rules for an indivisible unit on the basis of the Thai writing system.

A CC is smaller than a word but larger than a character. This concept is roughly comparable to a subword unit that is also in the middle of a character and word in terms of length. Using subword units, as well as CCs (Theeramunkong and Tanhermhong, 2004; Sutantayawalee et al., 2014; Lapjaturapit et al., 2018; Nararatwong et al., 2018), in word-segmentation tasks could yield good segmentation performance (Yang et al., 2019; Li et al., 2019). However, decomposing subword units from words requires appropriate parameters and training data, while CCs provide a greater advantage by not requiring any additional parameters. A CC helps avoid segmenting that might violate a writing system (Limcharoen et al., 2009), while subword units will likely not thoroughly exploit morphology (Provilkov et al., 2020), which could generate noise and weaken segmentation performance. This generally makes CCs smaller than subword units, as shown in Figure 2, which enables a comparison of zero-shot segmentation from coarse to fine (top-down) information.

2.3 Attention Mechanism

An attention mechanism was initially proposed by Bahdanau et al. (2015) for neural machine translation focusing on proper parts in sentences, particularly long sentences. It has been successfully applied to downstream tasks, including machine translation (Luong et al., 2015; Vaswani et al., 2017), constituency parsing (Kitaev and Klein, 2018), and sequence labeling (Higashiyama et al., 2019).

3 Proposed Model

Incorporating candidate words with an attention mechanism into the character-based BiLSTM-CRF architecture could yield superb segmentation performance (Higashiyama et al., 2019). An attention mechanism has the advantage of being flexible for use with additional linguistic knowledge such as CCs and subword units. Thus, we use the concept of CC with an attention mechanism in character-based word segmentation, as shown in Figure 3, by extending the BiLSTM-CRF architecture with word attention from Higashiyama et al. (2019).

Our model estimates CC-integrated character vectors $z$ are incorporated on top of word-integrated character vectors $g$, which are almost identical in architecture. We discuss the major components of our model, i.e., the character-embedding layer, word- and CC-embedding layers, BiLSTM layers for character representation, attention integrations with the BiLSTM layers for integrated representations, and CRF layer.

3.1 Character-embedding Layer

Given a sentence $s$ with $n$ characters that can be represented as $x_{1:n} \equiv (x_1, x_2, \ldots, x_n)$, each character $x_i \in x_{1:n}$ is transformed into a character embedding $e_i^c$ of a $d_c$-dimensional vector (Bengio et al., 2003; Collobert et al., 2011) using lookup-table operation. The lookup table is defined as $E^c \in \mathbb{R}^{d_c \times |V_c|}$, where $d_c$ denotes the dimension of embeddings and $V_c$ denotes a character vocabulary.

3.2 Word- and CC-embedding Layers

Using the word embedding layer as an example, let $V_w$ be a word vocabulary.

Given the character sequence $x_{1:n}$, words are searched on the basis of $V_w$ within a maximum word length $K$ of the character subsequence. A candidate word list $\mathcal{W}_x \equiv (w_1, \ldots, w_m)$ of size $K$ with $m$ candidate words is then obtained, as shown in Figure 3. Each word $w_j \in \mathcal{W}_x \subseteq V_w$ is transformed into a word embedding $e^w$ of a $d_w$-dimensional vector. The word-embedding matrix is defined as $E^w \in \mathbb{R}^{d_w \times |V_w|}$, where $d_w$ denotes the dimension of embeddings. This procedure is also applied to obtain a candidate CC list $\mathcal{C}_x$, which is transformed into a CC-embedding layer $e^c$ of a $d_{cc}$-dimensional vector. The CC-embedding matrix is defined as $E^c \in \mathbb{R}^{d_{cc} \times |V_{cc}|}$, where $d_{cc}$ denotes the dimension of embeddings and $V_{cc}$ denotes a CC vocabulary.

3.3 BiLSTM Layers for Character Representation

The character embedding sequence $e_{1:n}$ is provided to the BiLSTM (Hochreiter and Schmidhuber, 1997; Gers et al., 2000) layers to contextually acquire character context vectors $h_{1:n}$.

A current character context vector $h_i^l \in h_{1:n}$ of the $l$-th layer BiLSTM can be computed bidirectionally:

$$h_i^l = \text{BiLSTM}(h_{i-1}^l, i)$$

$$\equiv \text{LSTM}_f(h_{i-1}^l, i) \oplus \text{LSTM}_b(h_{n-1}^l, n - i - 1),$$

where $h_0^{1:n} = e_{1:n}$, LSTM$_f$ denotes forward LSTM, LSTM$_b$ denotes backward LSTM, $\oplus$ denotes concatenation, and $h \in \mathbb{R}^{2d_r}$ and $d_r$ are hyperparameters.

3.4 Attention Integrations with BiLSTM Layers for Integrated Representations

We use two attention integrations, including word attention and CC attention, to respectively estimate a word-integrated summary vector $a_i^w$ and
CC-integrated summary vector $\mathbf{a}_{i}^{cc}$ for each character in the character sequence. These integrations, which are equal in architecture, accordingly summarize the relationship among characters, words, and CCs.

We apply the composition function weight concatenation (WCON) (Higashiyama et al., 2019) to estimate both summary vectors. This function produces a word-integrated summary vector on the basis of the relationship between a character and their corresponding candidate words. It also can be used to implicitly produce a CC-integrated summary vector on the basis of the relationship between the character with its corresponding candidates words and candidate CCs.

Starting with word-attention integration, we estimate the word-importance score $u_{ij}^{w}$ and word-attention weight $\alpha_{ij}^{w}$ on the basis of the character context vector $\mathbf{h}_{i}$ and candidate word embedding $\mathbf{e}_{j}$ as

$$u_{ij}^{w} = \mathbf{h}_{i}^{T}W_{a}^{w}\mathbf{e}_{j},$$

$$\alpha_{ij}^{w} = \delta_{ij}\exp(u_{ij}^{w}),$$

where $W_{a}^{w} \in \mathbb{R}^{2d_{c} \times d_{w}}$ denotes a trainable weight matrix and $\delta_{ij} \in \{0, 1\}$ indicates whether character $x_{i}$ is included in candidate word $w_{j}$. The word-integrated summary vector $\mathbf{a}_{i}^{w}$ for character $x_{i}$ can be calculated as

$$\mathbf{a}_{i}^{w} = \text{WCON}^{w}(x_{i}, \{w_{j}\}_{j=1}^{m}) = \bigoplus_{l=1}^{L} \alpha_{i+l}^{w}\mathbf{e}_{i+l}^{w},$$

where $\{w_{j}\} = \mathcal{W}_{w}$. Let $K_w$ be the maximum word length, $L_w = \sum_{k=1}^{K_w} k$, $\bigoplus$ denote concatenation, and $i_{l}$ is the corresponding index of potential word list $\mathcal{W}_{w}$ for character $x_{i}$ that is $\{w_{1}^{l}, \ldots, w_{K_w}^{l}\} \equiv \bigcup_{k=1}^{K_w} \bigcup_{s=-k+1}^{0} \{x_{i+s}\}_{s=0}^{k-1}$. A zero vector is applied to Equation 4 when $w_{l}^{l} \notin \mathcal{V}_{w}$.

We then use the BiLSTM layers for transforming the word-integrated summary vectors $\mathbf{a}_{i}^{w}$ into word-integrated character vectors $\mathbf{g}_{i}$. The operation of word-integrated character vector $\mathbf{g}_{i}$ is computed using the BiLSTM layers on the basis of word-integrated summary vector $\mathbf{a}_{i}^{w}$ with its corresponding character context vector $\mathbf{h}_{i}$ as

$$\mathbf{g}_{i} = \text{BiLSTM}(\mathbf{h}_{i} \oplus \mathbf{a}_{i}^{w}).$$

However, the candidate CCs that correspond to the character are used on top of $\mathbf{g}_{i}$ as

$$u_{ip}^{cc} = \mathbf{g}_{i}^{T}W_{a}^{cc}\mathbf{e}_{i}^{cc},$$

$$\alpha_{ip}^{cc} = \delta_{ip}\exp(u_{ip}^{cc}),$$

where $W_{a}^{cc} \in \mathbb{R}^{d_{c} \times d_{cc}}$ denotes a trainable weight matrix and $\delta_{ip} \in \{0, 1\}$ indicates whether character $x_{i}$ is included in the candidate CC $cc_{p}$. The CC-integrated summary vector $\mathbf{a}_{i}^{cc}$ for character $x_{i}$ can be calculated as

$$\mathbf{a}_{i}^{cc} = \text{WCON}^{cc}(x_{i}, \{cc_{p}\}_{p=1}^{L_{cc}}) = \bigoplus_{l=1}^{L_{cc}} \alpha_{i+l}^{cc}\mathbf{e}_{i+l}^{cc},$$

where $\{cc_{p}\} = \mathcal{CC}_{x}$. Let $K_{cc}$ be the maximum CC length, $L_{cc} = \sum_{k=1}^{K_{cc}} k$, and $i_{l}$ is the corresponding index of potential CC list $\mathcal{CC}_{x}$ for character $x_{i}$, i.e., $\{cc_{i_{1}}, \ldots, cc_{i_{L_{cc}}}\} \equiv \bigcup_{k=1}^{K_{cc}} \bigcup_{s=-k+1}^{0} \{x_{i+s}\}_{s=0}^{k-1}$. A zero vector is applied to Equation 8 when $cc_{l_{i}} \notin \mathcal{V}_{cc}$.

Next, we use additional BiLSTM layers to transform the CC-integrated summary vectors $\mathbf{a}_{i}^{cc}$ into CC-integrated character vectors $\mathbf{z}_{i}$ on the basis of a cluster-integrated summary vector $\mathbf{a}_{i}^{cc}$ and its corresponding word-integrated character vector $\mathbf{g}_{i}$ as

$$\mathbf{z}_{i} = \text{BiLSTM}(\mathbf{g}_{i} \oplus \mathbf{a}_{i}^{cc}).$$

A CRF is finally used to estimate the probability of the optimal label sequences $y$.

### 3.5 CRF Layer

A CRF (Lafferty et al., 2001) along with explicitly considering the correlations between adjacent labels has been successfully applied for sequence-labeling-related tasks (Collobert et al., 2011). Let $A \in \mathbb{R}^{|T| \times |T|}$ be a transition matrix for correlations between adjacent labels, where $T$ denotes a set of all possible label sequences, for instance, $T = \{B, I, E, S\}$. The CC-integrated character vector $\mathbf{z}_{i}$ is transformed into an un-normalized label score $\mathbf{s}_{i}$ of the $|T|$-dimensional vector for character $x_{i}$ as

$$\mathbf{s}_{i} = W_{s}\mathbf{z}_{i} + \mathbf{b}_{s},$$

where $W_{s} \in \mathbb{R}^{|T| \times 4d_{c}}$ denotes a trainable weight matrix, and $\mathbf{b}_{s} \in \mathbb{R}^{|T|}$ denotes a trainable bias. Given the input sequence $x_{1:n}$, the corresponding scores for the label sequence $y_{1:n}$ are computed on the basis of transition matrix $A$ and the segmentation label scores $\mathbf{s}$ as follows:

$$\text{score}(x, y) = \sum_{i=1}^{n} (A_{y_{i-1},y_{i}} + \mathbf{s}_{i}[y_{i}])$$
Table 1: Data lengths of BEST2010 corpus, including length of sentences (S), words (W), vocabulary (V), and characters (Ch). “Ency” denotes encyclopedia.

| Domain | |S| | W| | V| | Ch| |
|---|---|---|---|---|---|---|
| Article | 16732 | 1018907 | 25658 | 4178690 |
| Ency | 50629 | 1041067 | 26466 | 4231447 |
| News | 31225 | 1448604 | 37076 | 6174642 |
| Novel | 50134 | 1522258 | 22062 | 5428205 |
| Total | 148720 | 5030836 | 81688 | 20012984 |

The probability of the label sequence can then be obtained as

$$P(y|x) = \frac{\text{score}(x, y)}{\sum_{y' \in T^n} \text{score}(x, y')}.$$  \hspace{1cm} (12)

We can obtain the optimal label sequence $y^*$ by maximizing the sentence score with the Viterbi algorithm:

$$y^* = \arg \max_{y \in T^n} \text{score}(x, y)$$ \hspace{1cm} (13)

The loss function $\mathcal{L}$ is minimized by back propagation during the training process:

$$\mathcal{L}(x, y) = - \log P(y|x)$$ \hspace{1cm} (14)

4 Experiments

4.1 Dataset

We trained and evaluated several versions of our model on the BEST2010 corpus\(^2\), which is the most well-known Thai word-segmented corpus. It contains 5 million words with 20 million characters. The categories and their data lengths are listed in Table 1. We randomly split this corpus into three sets\(^3\): 80% for a training, 10% for a validation, and 10% for a test.

4.2 Subword-unit Integration

Although subword units have been successfully applied to word-segmentation tasks, they might generate noise that decreases segmentation performance when the word dictionary already exists. Therefore, we conducted a comparison of using either subword units or CCs due to their similarity on the different versions of our proposed model.

Let $V_{sw}$ be a subword vocabulary decomposed from the dataset. We simply replace the CC vocabulary $V_{cc}$ with the decomposed subword vocabulary $V_{sw}$. Thus, a candidate subwords list can be acquired and used for the subword-attention integration by applying Equations 6 and 8.

4.3 Integration Order

Considering the flexibility of attention integration, the integration order in our model can be switched. For instance, our model executes CC-attention integration to estimate the relationship between characters and CCs before word-attention integration. This might affect segmentation performance because each integration provides different knowledge. Thus, we implemented a swapped version of our model (Swap) that switches the integration order for comparing the segmentation performance.

4.4 Compared Models

We evaluated the following models:

• **Baseline** A character-based BiLSTM-CRF architecture.
• **Baseline w/ Word** An extension of Baseline that integrates word attention (BiLSTM-CRF with word attention) (Higashiyama et al., 2019).
• **OURS** Our proposed model that integrates word and CC attentions (BiLSTM-CRF with word and CC attentions), as shown in Figure 3.
• **OURS w/o Word** Our proposed model that removes word attention (BiLSTM-CRF with CC attention).
• **OURS w/o CC w/ Sub** Our proposed model that replaces the CC with various sizes of subword units (800-12,800) (BiLSTM-CRF with word and subword attentions).
• **OURS Swap** Our proposed model that swaps the order of word and CC attentions.
• **OURS w/o CC w/ Sub Swap** OURS w/o CC w/ Sub model that swaps the order of word and subword unit attentions.
• **Others** Reproduced Thai word-segmentation models, including well-known models and the state-of-the-art Thai word-segmentation model (Seeha et al., 2020).

---

\(^2\)https://thailang.nectec.or.th
\(^3\)https://resources.aiat.or.th/thwcc-attn/datasets
We used CCs with publicly available libraries, including Phatthiyaphaibun et al. (2016) and TCC-SEG\(^4\), to build the CC vocabulary \(V_{cc}\). To generate the subword vocabulary \(V_{sw}\), we decomposed raw sentences from the dataset into various sizes of subword units using byte-pair encoding (Sennrich et al., 2016) implemented by SentencePiece (Kudo and Richardson, 2018).

We used the common hyperparameters for training the different versions of our proposed model (hereafter, our models), as shown in Table 2. Dropout (Srivastava et al., 2014) was applied to the BiLSTM layers to avoid overfitting as well as non-recurrent layers (Zaremba et al., 2015). We also optimized the model parameters using the Adam optimizer (Kingma and Ba, 2015). We trained our models up to 20 epochs and chose the best one on the basis of the validation process involving the CoNLL\(^5\) evaluation.

We evaluated our models on the test data by using three evaluation metrics, i.e., CoNLL (word-level evaluation), BIES tagging scheme (character-level evaluation), and Bound (boundary-level evaluation) (Seeha et al., 2020). Although the CoNLL and BIES tagging schemes are often used for evaluating the performance of sequence-labeling tasks, the boundary-level evaluation has been used in Thai word-segmentation evaluations. Thus, we also used the boundary-level evaluation in our experiments. Note that our \(F_1\) scores are based on the micro-averaged \(F_1\) score for all evaluation matrices. We conducted a statistical significance test using paired bootstrap resampling (Koehn, 2004) on our results. We set the resampling size to 100,000 iterations and sample size for each resampling to 10% of the test data.

### 4.5 Main Results\(^6\)

Table 3 illustrates the evaluation results among the compared models.

The best of our models, i.e., OURS, achieved the state-of-the-art performance compared with all the other models. From the statistical significance test results, we concluded that OURS surpasses the state-of-the-art model. However, using subword units could slightly improve its performance on average compared with using CCs. This indicates that CCs are more beneficial than subword units, which might generate further noise. OURS, which uses word and CC information, outperformed Baseline w/ Word, which indicates that CCs can be used to complement linguistic knowledge, particularly word information.

#### 4.6 Analysis

**Subword-integration Performance:** We implemented OURS w/o CC w/ Sub on various vocabulary sizes of subword units, as shown in Table 4. The results indicate that the vocabulary size clearly affects subword-integration performance improvement. Specifically, by providing more subword vocabulary to the model, we could consistently increase the overall performance. It may reach the performance of OURS when the subword vocabulary size is enormous. However, it might be difficult to appropriately determine the vocabulary size that will benefit the model. For instance, OURS w/o CC w/Sub with 12,800 subword tokens (OURS w/o CC w/ Sub12800) failed to improve in performance compared with those with 3,200 and 6,400 subword tokens. Thus, the size of subword vocabulary is a crucial parameter that affects the performance for this model.

We chose the best subword-integration model on the basis of validation performance to compare it with OURS, as shown in Table 3. Both subword and CC integrations tended to act as an additional filter layer for word-integrated character

\(^6\)We implemented an additional model that replaces the BiLSTM layers with Transformer layers (Vaswani et al., 2017) in Baseline. However, the results were noticeably lower than all other models. Note that we used the hyperparameters for the Transformer layers by referring to Vaswani et al. (2017).

Table 2: Common hyperparameters for Baselines and our models (top/middle) with exclusive values for our models (bottom). CC hyperparameters can be applied to subword integration.
Table 3: Comparison among our models, baselines, and Others. Best score for each metric is indicated in bold. Our models were significantly better than state-of-the-art model Thai word segmentation model (underline scores) at p-level < 0.01 in pairwise comparison. All models were evaluated on basis of same dataset division. Scores were obtained from mean of two runs. Ours w/o CC w/ Sub scores were reported on the basis of best validation performance among various subword vocabulary sizes. ○ indicates reproduced Thai word-segmentation models.

Table 4: Results of our subword-integration model (OURS w/o CC w/ Sub) with various subword-vocabulary sizes from 800 to 12,800 tokens. underline indicates model that obtained best score in validation process.

representations and improve segmentation performance. However, OURS outperformed OURS w/o CC w/ Sub for every evaluation matrix. We think the main reason is that subword units contain noise while CCs do not. For example, the unit “ก”, which is included in the subword vocabulary, does not exist in Thai word vocabulary and violates the Thai writing system, whereas CCs will not include this type of unit.

Order-of-integration Performance: We compared the performance of our model when the order of attention integrations are swapped.

Table 3 shows that the swapped models decrease segmentation performance compared with their original models, especially the swapped subword-integration model. We argue that subword integration initially adds noise to the character representations, e.g., a subword unit that does not exist in Thai word vocabulary. Therefore, it is difficult for the model to complement such representations in the word-attention integration afterwards. The swapped CC-integration model slightly decreased in performance compared with subword integration because CC vocabulary consists of smaller units that reflect the Thai writing system and includes no noise information. This indicates that OURS outperformed both swapped models and the word information is the priority knowledge to complement a character representation, whereas fine-grained information, i.e., CCs and subword units, are suitable for use after word information as an additional filter layer.

Case Study: Figure 4 shows examples of segmentation results among four models, i.e., Baseline, Baseline /w Word, OURS, and OURS w/o CC w/ Sub. OURS could perfectly segment the example sentence; however, the other models yielded incorrect results. Specifically, the word “ปิย์” violates the Thai writing system by combining the two consonants “ปี” in the word. We think that CC integration filters this type of violation out of the word-integrated character representations, enabling OURS to outperform the other models.

5 Conclusion

We proposed a character-based Thai word-segmentation model that uses multiple attentions on various types of linguistic knowledge, i.e., words, subwords, and CCs. The best version of our model achieved Thai state-of-the-art performance by using the word attention along with CC attention in the BiLSTM-CRF architecture. Further analysis also indicates that using CC can be more beneficial than using subword units in word-segmentation tasks.

Abstract
With the emergence of pre-trained multilingual models, multilingual embeddings have been widely applied in various natural language processing tasks. Language-agnostic models provide a versatile way to convert linguistic units from different languages into a shared vector representation space. The relevant work on multilingual sentence embeddings has reportedly reached low error rate in cross-lingual similarity search tasks. In this paper, we apply the pre-trained embedding models and the cross-lingual similarity search task in diverse scenarios, and observed large discrepancy in results in comparison to the original paper. Our findings on cross-lingual similarity search with different newly constructed multilingual datasets show not only correlation with observable language similarities but also strong influence from factors such as translation paths, which limits the interpretation of the language-agnostic property of the LASER model.

1 Introduction
Multilingual joint embeddings map language units from different languages into the same embedding space in order to make them comparable, which facilitates cross-lingual transfer. Being essential for building NLP models of low resourced languages, such an integrated representation is also useful for cross-lingual tasks like machine translation, especially when multiple languages are involved or there is a lack of appropriate data.

While word embeddings are widely used in NLP tasks, sentence representations become quite important for capturing underlying semantic relations in texts across different languages. Hence, instead of simply pooling word representation together, various neural network methods have proposed to produce more coherent sentence representations. Recent advances in multilingual sentence embedding modeling (Schwenk and Douze, 2017; Feng et al., 2020; Hirota et al., 2020) begin to show strong performance on many multilingual NLP tasks, but it does not always work equally well for all languages. We repeat the cross-lingual similarity search task with LASER (Schwenk and Douze, 2017) with more challenging corpora in order to identify what affects the actual performance. Based on our findings, we propose directions for future development of such models.

2 LASER
LASER (Language-Agnostic SEntence Representations) (Schwenk and Douze, 2017; Artetxe and Schwenk, 2019) is contextualized language model based on a BiLSTM encoder trained using a translation objective on parallel data from Europarl (Koehn, 2005), United Nations (Ziemski et al., 2016), OpenSubtitles2018 (Lison et al., 2018), Global Voices (Prokopidis et al., 2016), Tanzil and Tatoeba mostly available on the OPUS website (Tiedemann, 2012). The LASER model is able to handle 93 different languages.

Also Schwenk and Douze (2017) has proposed a similarity-search-based framework in order to evaluate multilingual joint representations. With a collection of $S$ parallel sentences for a given language pair, a multilingual similarity search is performed for the closest target sentence for each of the source sentences, and an error is counted if it is not the reference translation of that sentence in the target language. This approach requires calculating $S^2$ distance metrics. Duplicate sentences need to be removed from the experiment, otherwise the error rates are senseless. In order to have a meaningful comparison across $N$ languages, a similarity search must in addition be performed on an $N$-way parallel sentence set. As the similarity search mainly evaluates the multilingual closeness prop-
erty of multilingual joint sentence embeddings, the representations of the same sentence for different languages should be as similar as possible within the joint representation space.

Table 1: Pairwise error rates (%) of similarity search of 5 languages (WMT2012).

Table 1 gives detailed similarity search error rates of LASER on the news test set from WMT2012\(^1\). The set consists of 3003 N-way parallel sentences in 5 European languages. Despite the significant differences between these languages, the error rates vary only slightly from the average of 1.06 with the highest error rate at 1.27. The results are consistent with those previously reported in (Artetxe and Schwenk, 2019), i.e. with the base for claiming that the model is language agnostic.

Being able to process 93 languages within a unified framework, supposedly without bias, LASER clearly has limitations. The evaluations have been executed with multilingual data that is either in-domain or fairly close to domains of training data. The applications have focused on a small subset of relatively high resource languages. Also the training data consist of more informational controlled translations, like official documents. It is unclear whether the agnostic property still holds for new domains, for different genres or for all language. After all, languages and translations in reality are much more diverse and robust than the available parallel corpora.

Therefore, we conduct a series of evaluations to examine the framework from different angles, to understand its disadvantages and to find paths for future development.

3 Similarity Search on Multilingual Corpora

We apply the LASER toolkit to two multilingual corpora that are not part of the training data used to build the pre-trained embedding models: the TED corpus (Cettolo et al., 2012) and the appropriate part of the Russian National Corpus (RNC) (Apresjan et al., 2006).

3.1 TED

We first perform a cross-lingual similarity search with the TED corpus (Cettolo et al., 2012), which contains about 17 thousand transcripts, corresponding to around 1000 English talks into 80 languages. As the distribution of translations over these 80 languages is not even and the similarity search requires N-way parallel corpus, we only consider a set of 23 languages (253 possible pairs). After excluding duplicates and limiting the sentence length to 50 tokens, we extract 10 thousand sentences that are 23-way parallel.

TED was not included for training LASER sentence encoders, while covering a large subset of languages that are supported by LASER. Unlike Europarl and UN corpora from documents mainly in the parliament and public office domain, TED involves larger varieties of domains and topics. Based on transcriptions of public presentations, TED corpus is style-wise closer to Europarl, but still differs from the parliament debates in many ways.

Table 2 displays the detailed search error scores (in percent) for 272 out of 506 language pairs in total. The results are quite different from those reported in Section 2 (Table 1) and in (Schwenk and Douze, 2017). The overall error rate for 23 languages is 18.54, almost 9 times as much as the previous ones. Korean and Chinese turned out to be clear outliers among all languages, with search error rates as high as 43.59, while language pairs involving English tend to have less errors than the rest.

Overall, the search error rates in the table appear to correlate with language similarities between the languages. For example, among all language pairs from and to Ukrainian, which is a relatively more difficult language for the cross-lingual search task in general, the two pairs with Bulgarian and Russian perform significantly better than the rest of the language pairs. We observed similar results for Italian to French and Spanish.

It is quite clear that such multilingual sentence representation models are not equally applicable for all language pairs.

3.2 Russian National Corpus

To further explore LASER models, we apply them to the Russian National Corpus (RNC) (Apresyan et al., 2006), the multilingual section of which includes literary translations of several classical novels into different languages, which makes the RNC fundamentally different from many other parallel corpora. This is because in addition to rendering the information for the reader, a literary translation also needs to recreate the artistic imagery of the respective original work. The translator must produce a rendition in the target language, taking into account various specific features of the text, sometimes even rewriting it completely. The translations in the RNC are mostly in Slavic languages, some of which are considered low resourced for multilingual NLP tasks. Another distinctive feature of the multilingual section of the RNC is that for some of the novels there are multiple translation into the same language.

The texts in the multilingual RNC are all paragraph-aligned. We segmented the paragraphs into sentences and then align them pairwise with Hunalign (Varga et al., 2007). Then, the pairwise alignments are intersected with a relatively high alignment confidence threshold to produce a N-way parallel set. Unaligned sentences and duplicates are removed. We describe a few experiments with the multilingual RNC in the following subsections.

### 3.2.1 “The Little Prince”

Error rates for cross-lingual similarity search performed on the French novel “The Little Prince” in 12 languages are listed in Table 3. There are 867 sentences for each of the languages.

Similar to English in Table 2, French, the language of the original work, corresponds to significantly lower error rates except for between French and Russian. As a matter of fact, Russian tends to have higher error rates in this experiment. It is possibly due to the fact the Russian translator Nora Gal, a primarily English-Russian translator, could well have been influenced by other versions of the novel.

Furthermore, for each source language, the highest error rate can be more than 10 higher than the lowest and the differences do not seem to be random. The lowest search errors usually happen between languages that are more similar to each other. For instance, with Czech sentence embedding inputs, more Slovak sentences than in any other language are correctly retrieved. Likewise, the Russian-Ukrainian pair exhibits a similar property. The same pattern also exists for Bulgarian, Coati, Macedonian and Serbian. That is, using this matrix of search error rates, we are able to divide the investigated set of Slavic languages into 3 groups:

- Eastern Slavics: Czech, Slovak;
- Western Slavics: Russian, Ukrainian;
- South Slavics: Bulgarian, Coati, Macedonian and Serbian.

In other words, the cross-lingual similarity search task tends to be easier in case of closely related languages. As for the multilingual sentence embedding models, the distances between vectors representing the same sentence in different languages are clearly affected by language similarities. When applying available pre-trained models to other cross-lingual tasks, it is necessary to take into considerations that linguistic distances could affect the performance.

3.2.2 “Alice in Wonderland”

For some of the classical novels, the RNC includes more than one edition for the same language. “Alice in Wonderland” is one of them: there are 3 Russian translations and 2 Polish translations. The respective publishing dates and translators are not provided in the corpus. From the multilingual section of the RNC, we extracted 356 sentences that are parallel in 11 languages and repeated the cross-lingual similarity search on these sentences. Table 4 shows partial results from the experiment.

The novel is originally written in English. While the scores concerning English are frequently lower than expected, there are clear exceptions. When using sentence embeddings generated from two alternative Polish translations to retrieve original English sentences, the error rates range from 5.06% to 23.88%, almost a 400% increase. Apparently, one version (pl2) consists of sentences that are closer to the English original than the other version when mapped to the joint multilingual sentence representation space. The same holds for the three Russian translations. In the English target column, we can see that the three scores related to Russian alternative translations are about 10% apart. Interestingly, the version (ru4) has lower error rates if we search for Ukrainian sentences rather than for English sentences. This brings us to speculate that this Russian version might have served as a source for producing the Ukrainian translation instead of English.

Obviously, there are further factors affecting the language independence of the multilingual sentence representations. The ontological differences from original untranslated texts and translation path appear to keep translations distinguishable from the originals. The literacy translators’ freedom to recreate the work in a new language somehow amplifies the issue. Different translations may differentiate from the original source in so many different ways, This is clearly an interest field to explore with multilingual representations.

3.2.3 Belorussian and Ukrainian

After carrying out the similarity search experiments with all 9 novels in RNC, we summarize the error rates by language in Table 5. The columns “A”–“I” represent the nine novels. Most of the languages have an average error rate around 20%, but Ukrainian and Belorussian has much higher error. In particular, the search error rates of Belorussian experiments rise up to 73.60%. In addition to their distinctive linguistic features, it is likely due to the relatively smaller amount of parallel data that is available for training the LASER models, which are not effective for all languages.

4 Similarity search on different translation paths

As we have discussed in previous sections, the majority of multilingual parallel corpora are collections of translations of the same source documents into different target languages, between which cross-lingual similarity search appears to be more difficult. To investigate the underlying factors that affect similarity search by sentence embeddings, we construct new 4-way parallel data by adding translations from different paths to an existing 3 way parallel set in the following manner: we first select 8 TED talks from the recent online release so as to minimize the translator’s prior knowledge of the talks. All the talks have been transcribed in English and translated into both German and Chinese. There are 629 sentences for each of the 3 languages. The texts are sentence aligned across all 3 languages manually. We sent the sentence segmented German translations as source documents to 4 German-Chinese profes-

Table 283
sional translators and asking them to produce Chinese translations and to stay close to the German texts semantically as much as possible. Accordingly, the translators might not have as much creative space to improvise in the process as a normal freelance translator. Since the German texts have been sentence segmented before the translation, the resulting Chinese texts can be easily aligned back to the 3-way parallel set after review. The newly translated Chinese texts are then added into the set as yet another separate copy, and we perform cross-lingual similarity search on the updated set using LASER as shown in Table 6.

This data set includes two Chinese versions of the same English presentations that may be considered paraphrases to each other: one is directly translated from the original English transcription and the other is pivotally translated through German. In this setup, a perfect language agnostic embedding model should be able to map the sentences into vector clusters, each of the clusters representing an English sentence with its German translations together with two variants of Chinese translations. However, our results contradict this assumption.

The distance between the English original and the English-Chinese translations is not far from that between the English and the German ones. The differences in error rate are within 1, around 6 sentences out of 629. The German-Chinese translations did turn out to be much closer to the German texts in the sentence representations. We believe it is due to the strict requirements given to the translator. Despite being translations into the same language, the two Chinese texts lead to the highest search error rates.

Figure 1 illustrates an example from this data set. The dots represent vectors generated for each of the sentences with the LASER toolkit in a joint sentence embedding space and the edges connecting the dots are labeled with distances. Notably, the German translation uses period instead of “—” at the end of the sentence, which is clearly not possible to recover in the German-Chinese translation. This is reflected in the distances between these representation vectors. The German-Chinese translation is closer to the German sentence rather than to the English or the Chinese sentence. Similar examples are fairly common in this set, which also explains the distinctive performance of cross-lingual similarity search for the translations into the same language we discussed in Section 3.2. It is inevitable that translation introduces distortions into texts. Even though the ultimate goal of building up a multilingual sentence representation model is to allocate sentences with the same meanings regardless of their languages as close to each other as possible, translation distortions are still visible in the state-of-the-art multilingual sentence representations. Potentially, the joint sentence embeddings may be one way to identify translation paths or even to quantify translation distortions.

5 Conclusion

Neural embeddings have been widely applied in all fields of natural language processing. Multilingual embeddings with shared representation space enable few-shot and zero-shot transfer from one language to another with minimum additional training or data requirement. Recent developments on multilingual sentence representations such as LASER have opened up new path towards competitive NLP performance across high- and low-resource languages.

Yet, our evaluation of LASER reveals many constraints when applied in realistic and challenging scenarios. The performance of the framework is largely influenced by the similarity between languages in the multilingual application. Not all languages work equally well currently. Low performance on specific languages is attributed to the small training data size.

These observations caution the interpretation of language-agnostic property of such cross-lingual sentence representations and their application in multi-lingual NLP applications. The newly constructed multilingual corpus in this paper can be used as a new evaluation benchmark for future cross-lingual representation learning research. We
plan to release the data set to the research community.

Abstract
This paper details experiments we performed on the Universal Dependencies 2.7 corpora in order to investigate the dominant word order in the available languages. For this purpose, we used a graph rewriting tool, GREW, which allowed us to go beyond the surface annotations and identify the implicit subjects. We first measured the distribution of the six different word orders (SVO, SOV, VSO, VOS, OVS, OSV) in the corpora and investigated when there was a significant difference in the corpora within a given language. Then, we compared the obtained results with information provided in the WALS database (Dryer and Haspelmath, 2013) and in Östling (2015). Finally, we examined the impact of using a graph rewriting tool for this task. The tools and resources used for this research are all freely available.

1 Introduction
Language typology has proven to be useful in natural language processing (NLP) (Bender, 2016; O’Horan et al., 2016), for example for improving performance in language transfer (Naseem et al., 2012; Ahmad et al., 2019) and joint learning.

As noted by O’Horan et al. (2016) “WALS is currently by far the most commonly-used typological resource in NLP due to its broad coverage of features and languages”. However, the WALS database (Dryer and Haspelmath, 2013) has been compiled from the work of 55 linguists1 and is not systemically based on a large quantity of data. Moreover, it does not provide all the considered features for all the languages it covers.

On the other hand, the Universal Dependencies (UD) framework (Nivre et al., 2016) provides a large number of corpora annotated in dependency syntax (in version 2.7, there are 183 corpora for 104 languages).

We decided to automatically extract from the UD corpora one of the most used features in NLP, the dominant word order, i.e. the way the subject (S), verb (V) and object (O) are ordered in a language (feature 81A in WALS). To do so, we use a freely available graph rewriting tool, which allows us to perform complex searches, to take into account the context of the construction and to add or modify the existing annotations to expose relations which are not directly accessible in the corpora.

These experiments led us to define what is a dominant word order, to observe the distribution in word orders within the corpora of a given language, to determine the frequency of the different word orders in all the considered corpora, and to compare the obtained results with those of existing databases, including WALS.

2 Previous Work
2.1 UD-based Typology
Dependency treebanks have already been used to investigate the order of subject and object in different languages. Liu (2010) presented a statistical overview of several binary parameters including SV vs VS, OV vs VO on 20 languages and compared their results with WALS’. However, their experiments were conducted before the UD framework, on treebanks with different annotation schemes.

To our knowledge, the closest work to ours is that of Östling (2015). He considered word order typology based upon the translated and aligned new testament in almost 1,000 languages and compared his results with WALS data. The main difference

---

1See: https://wals.info/author.
with our work is that for us, identifying the dominant word order is our goal and not just a production allowing the evaluation of a system. Besides, the data used in his experiment was generated automatically, rather than (at least partially) manually annotated. The produced data is available, so we were able to compare our results with his.

UD treebanks were also used to study word order freedom. Futrell et al. (2015) and Berdicevskis and Piperski (2020) examined the word order freedom of subjects and objects, focusing on the correlation with case marking.

More recently, Alzetta et al. (2018) applied a plausibility assessment algorithm to the UD treebanks to assess its usability in identifying typological features. They focused on the subject-verb and adjective-noun orders and experimented with three languages, English, Italian and Spanish. While their analysis is quite thorough, the algorithm they employed is not available, so their work cannot be extended.

Finally, Gerdes et al. (2019b) tested some of Greenberg’s universals on UD. Their work does include word order information but focuses on only two classes (the verb is before or after the object/subject). Besides, they decided to merge the treebanks for multi-corpora languages.

### 2.2 Enriching UD Annotations

There is no easy way to decide which dependency relations should be taken into account in order to observe word order dominance. In basic UD annotations, the tree restriction of usual dependency annotation frameworks impose some arbitrary choices: it is not possible to consider that the same token can be used twice as subject of different verbs. In our study, we try to overcome this limitation by making explicit some “syntactic” relations which cannot be expressed in UD (see Section 4.3). In Section 7, we compare what we observe using what we call implicit subjects with the same analysis on basic UD annotations only.

Similar types of enrichment have been proposed before, namely the Enhanced Universal Dependencies and the Deep Universal Dependencies.

Enhanced Universal Dependencies (EUD) were proposed in Schuster and Manning (2016). The goal of this work is to create an annotation which is more suitable for natural language understanding.

The goal of the Deep Universal Dependencies (DUD) (Droganova and Zeman, 2019) is also to provide annotations adapted to natural language understanding. DUD expresses relations that are closer to predicate-argument structure than the annotations of EUD, using relations names (arg1, arg2, ...) borrowed from semantic frameworks like the Abstract Meaning Representation (AMR) (Banarescu et al., 2013). DUD is built automatically from EUD when annotations are available or with an automatic production of EUD for other corpora.³

### 3 Methodology

#### 3.1 Taking the Corpora as Basis

Our study is based on the version 2.7 of UD, with 183 corpora and 104 languages available. Since our experiments consist in the extraction of statistics from data in corpora, we chose to eliminate corpora with fewer than 1,000 sentences, since we consider them too small to be representative of the language. Once this filter was applied, we obtained 141 corpora in 74 languages, which constitute the UD 2.7K corpus.

We decided to compile statistics at the corpus level rather than the language level, in order to observe variations between corpora of a given language and to compare the significance between them. 29 languages are represented by more than one corpus and for the 45 remaining ones we consider that “corpus equals language”.

¹See: https://universaldependencies.org/u/overview/enhanced-syntax.html.
³At the time of writing, DUD annotations are not available for version 2.7.
3.2 Defining a Dominant Word Order

Describing an order as a language’s dominant order can have two meanings: either the order is the only possible one for the language, or the language exhibits several different orders and one is more frequently used.

In our experiments, we count the occurrences of the six possible orders in UD 2.71K, which means that our results are based only on the occurrence frequencies of the orders and therefore depend heavily on the composition of the corpora. Although we are aware of possible biases due to the corpus’s degree of representativeness, our purpose is to determine a dominant order per corpus from raw data and to check whether we obtain results which are consistent with those of descriptive grammars.

Inspired by Dryer (2013), we consider the most frequent order as the dominant order for a given corpus provided that it is at least twice as frequent as the next most frequent. This means that for each corpus, we observe the ratio between the number of occurrences of the most frequent order with respect to the number of occurrences of the second most frequent order; if the ratio is greater than or equal to 2, the most frequent order is the dominant order, else we consider the corpus to be NDO (No Dominant Order). This allows us to classify as NDO corpora exhibiting little differences between two orders (for example, GERMAN-GSD with implicit subjects shows 35.7% SOV and 34.8% SVO). When the results differ among corpora of a given language, we study the corpora on a case by case basis.

3.3 Dealing with UD Specifics

In UD (Nivre et al., 2016), a given label can be ambiguous with respect to syntactic relations. For example, the labels xcomp and ccomp are used for both direct and indirect objects. Because of this limitation, we restrict our study to nominal objects, i.e. to obj relations. A similar difficulty arises with subjects. In UD, a personal subject is annotated with a relation subj, while an impersonal subject is annotated with the relation expl, which is also used for other relations with expletives. This ambiguity leads us to ignore impersonal subjects in our study.

Due to the tree constraint, some relations are not explicitly given in the data. In our study, this can affect subjects that can be shared by several verbs in coordination or through control of raising verbs. We call these hidden relations implicit relations.

For instance, consider the Polish sentence:

Kuba tego nie potrzebuje ale ma to od Kuba this not need but has this from
mamy mom
Kuba does not need this, but has it from her mother

There is an implicit subject relation between ma and Kuba which is not represented in the UD annotation. In our experiments, we ran an extended search on UD data with implicit subjects that can be predicted from surface syntax. Implicit objects also exist but it is not possible to recover them automatically from surface syntax. In the previous example, tego is the object of potrzebuje but it is not possible to determine if tego is an implicit object of ma.

Besides these issues, UD 2.7 includes two code-switching corpora: Turkish-German and Hindi-English. They were added as new “languages” and we therefore consider them here as such.

4 Going Deeper with Graph Rewriting

4.1 GREW

GREW is a graph rewriting tool dedicated to NLP applications, which can be used to query treebanks using graph patterns written with a specified syntax. Given a set of queries and a set of corpora, a script produces a table with the number of occurrences of each query in each corpus (see Section 4.2, for examples). An online interface to the tool is available, which enables users to observe examples in context within corpora and to interactively design and debug the patterns before running the script.

GREW also allows users to describe a set of transformations and to apply them to each item in a corpus. In this paper, we use this feature to enrich the available annotations (see Section 4.3).

4.2 Extraction Patterns

The patterns we use to extract data in UD 2.71K include two syntactic relations: subject and object. As explained in Section 3.3, only nominal
objects can be reliably recovered from UD annotations. To be consistent, we use the same restriction for the subject relation and focus only on nominal subjects (nsubj), without considering clausal subjects (csubj). For instance, the GREW pattern for SVO is presented in Figure 1.

```
pattern {
  V [upos=VERB];
  V -[1=nsubj|isubj]-> S; V -[1=obj]-> O;
  S << V; V << O
}
```

Figure 1: GREW pattern for SVO.

In UD, it is possible to include subtypes in relations, for instance the relation nsubj:pass can be used for a regular nominal subject in a passive construction. However, as these extensions are defined at the language level, we do not consider them here. The GREW syntax 1=subj|isubj allows to capture all relations that are either subj or isubj with or without subtypes.

4.3 Enriching UD Annotations

When used on UD annotations, the aforementioned extraction patterns present some limits as they only identify cases where the subject and the object are syntactically directly related to the same verb. However, there exist constructions admitting a subject and an object with two different governors. In our study, we consider two cases where the information can safely be recovered from surface annotations by adding implicit subjects, isubj, in an enriched UD annotation (see Section 3.3).8

The first case is coordination: when two clauses involving the same subject are linked by a coordinating conjunction with an ellipsis of the subject to the head of the second clause. More technically, this is described by the rule in Figure 2: if two verbs V1 and V2 are linked by a conj relation and V2 does not have its own subject; then add the subject S1 of V1 as an isubj of V2. For instance in a sentence “He obtains these things, but loses the ability to manage them,” a relation isubj will be added from loses to He.

The second case we consider is control or raising. In UD, this is annotated with the relation xcomp between the two verbs. We can use a rule that is similar to the one in Figure 2 with xcomp instead of conj. In the sentence “I should like to address

```rule conj {
  pattern {
    V1 [upos=VERB]; V2 [upos=VERB];
    V1 -[1=conj]-> V2;
    V1 -[1=nsubj]-> S1;
  }
  without { V2 -[1=nsubj]-> S2; }
  commands { add_edge V2 -[isubj]-> S1; }
}
```

Figure 2: GREW rule adding the isubj relation.

one final point.”, the enriched annotation will show a relation isubj from address to I.

5 Determining Dominant Word Order in Multi-Corpora Languages

We detail here the results obtained for multcorpora languages. For the mono-corpus languages, we examine our results as compared to WAL$S$ and Östling (2015) in Section 6.

5.1 Intra-language Consistency

We obtain the number of occurrences of each of the six possible orders for each corpus in UD 2.71K. This data can be used to determine whether different corpora of a given language exhibit similar distributions. For this purpose, we compute the cosine between the 6-dimensional vectors for each corpus. This technique of comparing two feature vectors as a means of comparing two languages has already been used in several works on language typology (Georgi et al., 2010; Berzak et al., 2014). We expect two corpora of the same language to display similar distributions and therefore expect a cosine value close to 1.

The lowest value we observe is for two corpora of Romanian. Table 1 illustrates the vectors describing the distribution of the six possible orders for the three Romanian treebanks and Figure 3 represents as a heatmap the cosine values between these vectors.

Figure 4 reports the minimum cosine value among all possible pairs of corpora for the 29 multcorpora languages.

Ten languages have a value below 0.95 and three have a value below 0.8 (Romanian, Hindi, Arabic). We present below a basic analysis of these results, either by seeking an explanation in the description of the corpora on the UD website or by asking language experts to examine the data.

Different text genres Four languages present corpora in different text genres, which could

Figure 4: Multi-corpora (number in parenthesis) languages ordered by minimum cosine value.

explain the low cosine value: Dutch (0.928), French (0.912), Romanian (0.729) and Slovenian (0.947). One corpus in Romanian (Romanian_NONSTANDARD) is dedicated to non-standard usage of that language (see Figure 3). Some corpora focus on specific types of texts: questions (French-FQB, which clearly stands out in Figure 5) and/or material from test suites and sentences from a reference grammar (Dutch-ALPINO). French and Slovenian present corpora of spoken language (French-SPOKEN and Slovenian-SSL). In Czech (0.925), one of the corpora (Czech-FicTree) contains only fiction and shows a higher proportion of SOV, while the four other Czech treebanks are clearly SVO.

Different text periods For two dead languages (Latin and Ancient Greek), corpora gather texts from very different historical periods, which could explain the differences. Latin texts range from 1st century BC (Latin-PERSEUS) to 13th century Medieval Latin (Latin-ITTB). For Ancient Greek, very different kinds of text are mixed: Ancient.Greek-PROIEL contains both Herodotus (5th century BC) and Bible texts; the other corpus (Ancient.Greek-PERSEUS) is a larger mix of several periods from Homer (8th century BC) to Athenaeus (late second century). Undoubtedly, the fact that Latin and Ancient Greek are considered free word order languages amplifies the phenomenon. As for German, two corpora are NDO and two are SOV, German-HDT with a low ratio (2.01) and German-LIT. The latter is the only corpus to be composed of 18th century texts.

---

9 The cosine between these two subcorpora is 0.907.
Non-standard annotations In one of the two Hindi corpora (HINDI-HDTB), there is a large percentage of SVO cases (82.5%) where the object is a verb, in contradiction of the UD guidelines. If we consider only nominal subjects and objects in the patterns, the cosine value rises to 0.993.

Language specifics In Arabic (modern standard), the basic order is VSO. However, SVO is used in cases of topicalization of the subject and in completives. The PADT corpus contains many titles of news articles featuring topicalization, which could explain the prevalence of SVO.

5.2 Dominant Word Order in Multi-Corpora Languages

For all multi-corpora languages with a minimum cosine value above 0.95, the dominant word order ratio consistently produces the same dominant order for all corpora of the language, except for Estonian which presents a SVO corpus (ESTONIAN-EDT) and a NDO corpus (ESTONIAN-EWT), corresponding to different text genres (fiction, news, nonfiction, academic vs blog, web, social). 14 multi-corpora languages are thus identified as SVO (Chinese, English, Faroese, Finnish, Galician, Icelandic, Indonesian, Italian, Norwegian, Polish, Portuguese, Russian, Spanish and Swedish) and four multi-corpora languages as SOV (Japanese, Korean, Persian and Turkish).

Out of the 10 multi-corpora languages with a minimum cosine value below 0.95, two present a clear dominant order SVO: French and Czech. As for Dutch and Ancient Greek, they both are NDO, but with inconsistent main orders: SOV/SVO and SVO/SOV. The six other languages present inconsistent dominant word orders. However, Romanian and Slovenian are both SVO in their standard or written form, even though one of their corpora is NDO (SVO/SOV). As for German, two out of four corpora are NDO (SOV/SVO) and two corpora are SOV. However, this result can be attributed to a threshold effect, since these two corpora present a SOV order at low ratios (2.01 for GERMAN-HDT, 2.53 for GERMAN-LIT).

Two corpora of Arabic are NDO (one is SVO/VSO and the other VSO/SVO) and one corpus is VSO. For the reasons explained in Section 5.1, we consider that the dominant order is most probably VSO. Hindi has one SOV and one NDO (SOV/SVO) corpus, but if we remove SVO occurrences probably due to annotation errors (i.e. O is a verb) in the latter, both corpora are clearly SOV. Latin is the language with the most heterogeneous corpora, with three NDO corpora (one SVO/SOV, two SOV/SVO) and one SOV corpus. These differences can probably be explained by the time range among texts.

Regarding the two code-switching languages, Hindi-English is considered NDO (SVO/SOV) which is consistent since English is SVO and Hindi SOV. As for Turkish-German, the corpus presents a SOV order, Turkish and German having this order in common.
6 Comparison with other Sources

Amongst the 74 languages available in UD 2.71K, WALS does not cover the seven dead languages, nor the two code-switching “languages”. In addition, WALS does not provide Feature 81A for six languages. In Östling (2015), 22 languages are not in the database and seven are in neither sources, Galician, Hindi-English, Turkish-German and four dead languages (Old French, Old Russian, Sanskrit, Akkadian).

</table>

Table 2: Differences with WALS (for UD 2.71K, we detail by corpora).

We compare our results with Feature 81A (Order of Subject, Object and Verb) in WALS. We have 59 languages in common and we consistently observe the same dominant word order for 48 of these. In Table 2, we detail the remaining 11 languages where our observations are not fully consistent with WALS classification. Taking into account the explanations in Section 5.2 about multi-corpora languages, we have five languages with one corpus where we disagree with WALS: Amharic, Belarusian, Greek, Mbya Guarani and Urdu.

Belarusian and Greek can be considered relatively free word order languages, hence the NDO order in WALS. In our results, Belarusian is SVO with a ratio of 10.43, however the BELARUSIAN-HSE corpus is based on texts included in the Belarusian-Russian parallel subcorpus of the Russian National Corpus. Russian being a SVO language, this may explain the high proportion of SVO.

Moreover, it is more common to find the SVO order as the basic order in written Belarusian. Similarly, the basic order in Greek being SVO, this may explain the ratio of 7.31 of SVO order in our results.

As for Mbya Guarani and Urdu, the most frequent order corresponds to the order in WALS. Mbya Guarani is NDO (SVO/SOV) with a ratio of 1.25 and Urdu NDO (SOV/SVO) with a ratio of 1.52. Finally, Amharic has an OVS order as the most frequent order, contrary to WALS’.

There are six languages present in WALS which do not have the Feature 81A: Galician, Faroese, Kazakh, Maltese, Naija and Slovak. Our results could therefore be used to enrich WALS’ data.

6.2 Differences with Östling (2015)

</tr>
</tbody>
</table>

Table 3: Differences with Östling (2015) (for UD 2.71K, we detail by corpora).

The data presented in Östling (2015) is computed from the automatically aligned New Testament. The corpora are homogeneous and the data on which the dominant order is computed can sometimes be very small (for Hungarian, 127 structures vs 876 in our experiment). Moreover, Östling (2015) considers the single most prevalent order as the dominant one, without taking into account the difference with the second one.

We have 52 languages in common and observe the same dominant order for 38 of these. Table 3 reports what we observe for the 14 other languages. Out of these languages, 9 NDO languages have the same first order as Östling (2015). The 5 remaining ones (Amharic, Ancient Greek, Basque, Latin and Welsh) present different first orders.

---

10We are aware that WALS and Östling (2015) classifications only deal with transitive clauses, however the UD annotations do not allow us to extract them precisely.

11See: https://wals.info/feature/81A.
7 Influence of Implicit Subjects

As said earlier, we decided to enrich the basic UD annotations, but the choice we made is quite arbitrary. In order to evaluate how this may have impacted our observations, we conducted the same experiment without taking into account the implicit subjects.

Table 4 lists the five languages for which the two experiments predict a different word order for at least one corpus or different first rank in NDO ordering. Adding isubj changes the dominant word order in four corpora: CZECH-FiC TREE, ESTONIAN-EWT, GERMAN-HDT and TURKISH-GERMAN-SAGT. However, we note that in the four cases, one of the two ratios is close to the threshold. We observe an unexpected change for LATIN-LLCT which remains NDO, but with different top ranks (SOV/SVO with isubj and OSV/SVO without isubj). Latin is the language where we see the most important changes as can be observed by comparing the heatmaps in Figure 6.

Table 5 reports the corpora where the two experiments show a high difference (more than 5%) in term of first rank word order prediction. Only the WELSH-CCG corpus has a significant lower first rank with isubj, other corpora with a large difference present an higher first rank when isubj are taken into account. Again, the LATIN-LLCT exhibits a strange behavior with different first rank word order.

8 Conclusions and Perspectives

The main outcome of these experiments is the determination of the dominant word order for 74 languages, based on large amounts of annotated data. This result can be used for NLP applications. On the linguistic side, our findings could be used to reinforce the results published in WALS and complete them in some cases. However, our results differ from WALS’ for 11 languages, and for these, a more thorough analysis should be conducted by specialists of said languages. We are planning to experiment using graph rewriting to explore other universals, like Greenberg’s (Greenberg, 1963) or other missing features in WALS.

Graph rewriting can be used to enrich the UD annotations but it can also be used to reorganise more deeply the tree dependency graph. In Gerdes et al. (2019b), the observations were done on such a deeper reorganisation of the dependency tree structure, proposed in Surface Syntactic Universal Dependency (Gerdes et al., 2019a) which was already produced using GREW-based graph rewriting.

Our experiments can be replicated and extended: all the tools and resources are freely available and we also provide the patterns and scripts to be used\(^{12}\).

Acknowledgements

We thank the reviewers for their useful remarks. We also wish to thank the colleagues who kindly took the time to answer our questions concerning some of the results we obtained in languages we do not speak: Sashi Narayan and Lydie Lemoine for Hindi, Hilda Mock for Arabic, Kim Gerdes for German and Vincent Vandeghinste for Dutch. The internship of the first author, during which this work has been done, was funded by the Lorraine Université d’Excellence OLKI research project\(^{13}\).

Abstract
In Romanian language there are some resources for automatic text comprehension, but for Emotion Detection, not lexicon-based, there are none. To cover this gap, we extracted data from Twitter and created the first dataset containing tweets annotated with five types of emotions: joy, fear, sadness, anger and neutral, with the intent of being used for opinion mining and analysis tasks. In this article we present some features of our novel dataset, and create a benchmark to achieve the first supervised machine learning model for automatic Emotion Detection in Romanian short texts. We investigate the performance of four classical machine learning models: Multinomial Naive Bayes, Logistic Regression, Support Vector Classification and Linear Support Vector Classification. We also investigate more modern approaches like fastText, which makes use of subword information. Lastly, we fine-tune the Romanian BERT for text classification and our experiments show that the BERT-based model has best performance for the task of Emotion Detection from Romanian tweets.

Keywords: Emotion Detection, Twitter, Romanian, Supervised Machine Learning

1 Introduction
Romanian language is a very little explored language in terms of Natural Language Processing (NLP) and Natural Language Understanding (NLU), but social media is full of data and people sharing their opinions about diverse topics, thus some opinion mining tools would be very useful.

Opinion mining is defined in Ravi (2015) as “the task of detecting, extracting and classifying opinions, sentiments and attitudes concerning different topics, as expressed in textual input”. In NLP tasks, there are two major subcategories of opinion mining: Sentiment Analysis (SA) and Emotion Detection (ED). The main difference between these two is that sentiment analysis categorizes opinions between positive or negative, with degrees of polarity, while emotion detection aims to extract the specific emotion a text gives to the reader.

English language is rich in NLP resources - we can see not only that there are many manually labelled datasets, with a large variety of emotions, but there also exist datasets with tweets labeled by emotion intensity (for example, WASSA dataset by Mohammad and Bravo-Marquez (2017) which was first presented at the 2017 Shared Task on Emotion Intensity). Detecting emotions can be a subjective task, even psychologists didn’t agree upon what the main emotions of a human being are. Plutchik (1973) identified eight primary emotions: ecstasy, admiration, terror, amazement, grief, loathing, rage and vigilance, while Ekman (2005) said that the primary emotions are: joy, sadness, fear, disgust, surprise and anger. Inspired by the work of Mohammad and Bravo-Marquez (2017), we decided to collect tweets from Twitter and manually annotate them for four emotions: fear, anger, joy, sadness, and also add a neutral class. We show the quality of the overall dataset by computing statistic descriptors and finally we train machine learning classifiers in order to create the first qualitative Romanian tool for emotion detection.

The usefulness of having a tool that detects emotions from texts varies from exploring customer opinions in order to ensure business growth, to improving human-computer interactions (HCI) in applications like onboarding chatbots and personal digital assistants (Strapparava and Mihalcea (2008)).

2 Recent Works
It has been shown by Acheampong et al. (2020) that text based ED research studies have been given less attention than other modes of ED, for instance
multimodal emotion detection including speech, body language, facial expressions, and so on.

There are two principal ways of assessing the ED problem: by using rule construction techniques to identify emotive words and word combinations, and machine learning approaches, which can be supervised or unsupervised. While unsupervised methods learn from unstructured data and could provide important clustering insights in opinion mining tasks, supervised methods give better detection rates (Canales and Martinez-Barco (2014)), but only if there exist some quality labeled data to give as input to the classifier. Combining these two main approaches gives a third way of detecting emotions from text - the hybrid approach, which takes the advantages of rule-construction and amplifies them with the power of machine learning. The latter was used in this paper.

Alotaibi (2019) used the ISEAR dataset to train a supervised model of emotion detection with Logistic Regression. The ISEAR (International Survey on Emotion Antecedents and Reactions) dataset was first introduced in the work of Scherer and Wallbott (1994) and contains 7666 emotional sentences labelled with 7 types of emotions: anger, disgust, fear, sadness, shame, joy and guilt. Abdel Razek and Frasson (2017) used the same dataset to test their dominant meaning approach in detecting emotions in chat messages.

For detecting emotions in tweets, Shah et al. (2019) proposed a hybrid approach consisting of lexical based approaches that use WordNet-Affect and EmoSenticNet with supervised classifiers trained on AIT-2018 dataset for English. This dataset was introduced in Semeval-2018 Task 1: Affect in Tweets by Mohammad et al. (2018) and consists of tweets annotated in 3 languages, for anger, fear, joy and sadness.

Ghanbari-Adv and Mosleh (2019) presented an ensemble classifier based on NLP techniques like Doc2Vec and 1500 k-Nearest Neighbor, Multilayer Perceptron and Decision Tree basic classifiers optimized with Parzen Tree Estimator (TPE), to detect emotions from ISEAR and OANC datasets, and also from an unstructured dataset of tweets from Crowdflower. Their results show an outstanding accuracy of 99.49% for regular sentences and 88.49% for irregular sentences.

Polignano et al. (2019) tried emotion detection in text using word-embeddings like Word2Vec, GloVe and FastText on their designed model, having as training datasets ISEAR, AIT-2018 and SemEval-2019 Task3 dataset. Their research concluded that FastText had slightly better performances.

Huang et al. (2019) investigated fine-tuning BERT (Bidirectional Encoder Representations from Transformers) on two datasets: EmotionLines with dialogues from Friends Sitcom, and Emotion-Push containing Facebook messenger chats. Their model obtained a micro f-score of 0.815 on Friends and 0.885 on EmotionPush. Acheampong et al. (2020) fine-tuned BERT with a Bi-LSTM classifier and obtain an average f-score of 0.73 on the ISEAR dataset. Chiorrini et al. (2021) also investigated the use of BERT for both sentiment analysis and emotion detection in Twitter data, using WASSA dataset (Mohammad and Bravo-Marquez (2017)), a shorter version of AIT-2018 containing 6755 tweets annotated for: sadness, fear, anger and happiness.

For more exotic languages, however, researchers had to manually annotate sentences or words in order to have a high quality dataset to work on. For Arabic, Almanie et al. (2018) developed a dataset of 4000 emotional words, including emojis, which they used to classify real-time tweets into 5 types of emotions (happy, sad, angry, scared, surprised). Grover and Verma (2016) used a hybrid approach to detect emotions from Punjabi texts - first they consider a rule-based engine to detect if the sentence has an emotion or not, and then they applied Support Vector Machine (SVM) and Naïve Bayes (NB) classifiers to detect 6 emotions: happy, fear, anger, sadness, disgust and surprise. Jayakrishnan et al. (2018) created a corpus of manually labelled Malayalam texts (an Indian dialect) into emotions like: sad, happy, anger or fear. Further they used a SVM classifier to create emotion detection models.

For Romanian language, there were some studies conducted on speech datasets with annotated emotions. For instance, Feraru and Zbancioc (2015) presented a method for emotion detection in Romanian speech that use Largest Lyapunov exponent of the Mel-frequency energy bands, with SVM and WKNN (Weighted K-Nearest Neighbors) classifiers, trained on the SRoL dataset (developed by Feraru et al. (2010)). Franti et al. (2017) created a deep learning model of Convolutional Neural Networks (CNN) trained on a set of recordings in Romanian language. Pavaloi et al. (2014) used three sets of recordings in Romanian language, annotated for positive and negative emotions, and trained
models using k-NN and SVM classifiers. In terms of text data, Lupea et al. (2021) present an unsupervised clustering approach used to mine emotional patterns in Mihai Eminescu’s poetry, based on the Romanian Emotion Lexicon created by Lupea and Briciu (2019) for feature extraction. In terms of sentiment analysis for Romanian language, Istrate and Ciobotaru (2021) created a dataset of tweets annotated for positive/negative sentiment and trained several classifiers on it, both classical and modern. There also exist some lexicon based approaches for Romanian sentiment analysis, like BabelSenticNet, a multilingual concept-level knowledge base described in Vilares et al. (2018).

Inspired by some of the works presented in this section, we created the first dataset of Romanian tweets labelled with five different emotions (anger, fear, sadness, happiness and neutral), in order to obtain a solid tool for detecting emotions in texts.

3 Data

In this section we present in detail our novel dataset, RED (Romanian Emotion Detection).

3.1 Scrapping Process

We considered the work of Mohammad and Bravo-Marquez (2017) where they explained their methodology of creating the first annotated datasets for fear, anger, joy and sadness, and we create a similar dataset, but for the Romanian language. In our work we construct the same four classes of emotions and also add a neutral class, as it has been previously shown by Al-Rubaiee et al. (2016) the importance of having a neutral class when classifying sentiments or emotions. This way, the classifier will not be forced to classify information he wasn’t trained to recognize, in one of the four classes created.

First, we create lists of query words correspondent to each of the class of emotions, which are:

- synonyms of the word defining the class - synonyms for “fear”, “anger”, “joy”, “sadness” and “neutral”, extracted from two synonym sources: an online dictionary1 and the work of Bulgar (1995), and
- jargon and commonly used words that express a certain feeling matching the class of emotion for which the scrapping process is conducted.

The total number of query words gathered for each class is detailed in Table 1. These main words are further expanded into their word families by adding prefixes and suffixes to their stem-words. Moreover, all morphological variants are generated for each resulted word. In this way, for each query-word a list or words is generated, and the resulting lists of words were further used for scraping tweets, using Snscrape2 python library.

Tweets were gathered from Twitter in the time-frame: 1st of February 2020 - 1st of February 2021, and checked for Romanian language using langdetect3 python library.

All gathered tweets were scraped from public accounts. Still, to protect confidentiality and anonymity of Twitter users, we removed usernames and also all proper nouns from tweets in the final dataset, using preprocessing techniques described in Section 3.3.

3.2 Annotation Process

The annotation process involved 3 annotators: Annotator 1 and Annotator 2, native Romanian speakers who decided over the same tweets, and Annotator 3, a psychologist, also native Romanian speaker, who tipped the scales regarding the tweets where Annotator 1 and Annotator 2 did not agree upon.

The result of the scraping process for each query word was a spreadsheet containing all the tweets found in the mentioned time-frame, having in their composition at least one word expanded from the query word. These spreadsheets were shuffled and manually checked by Annotator 1 if tweets indeed represented the emotion conveyed by the class they were scraped for. Maximum 50 tweets were kept for each query word, in order not to bias the classification process. An important rule for annotating was to annotate tweets that clearly expressed the researched emotion.

After the work of Annotator 1 was done, a number of approximately 1000 tweets resulted per class. In order the create a high quality dataset, these tweets were double-checked by Annotator 2 in order to make sure that the tweets indeed represent the emotion labelled by the first annotator. The two annotators disagreed upon 223 tweets for Anger, 251 for Fear, 309 for Joy, 279 for Sadness and 210 for Neutral class. These selected tweets were checked by Annotator 3, who gave his verdict regarding their conveyed emotion. Further, tweets

---

1https://www.sinonime.com/dex
2https://github.com/JustAnotherArchivist/snscrape
3https://pypi.org/project/langdetect/ version 1.0.8
were checked for duplicates and shuffled. The final number of remaining tweets is shown in Table 1. It can be observed that classes remain balanced after the quality check involved in the annotation process.

Table 1: Number of query words and final number of labelled tweets per class

<table>
<thead>

</tr>
<tr>
<td>Sadness</td>
<td>29</td>
<td>781</td>
</tr>
<tr>
<td>Neutral</td>
<td>24</td>
<td>805</td>
</tr>
</tbody>
</table>

3.3 Dataset Preprocessing

In order to have a high quality dataset, suitable for machine training, we performed some text preprocessing by removing unnecessary information from tweets that could potentially bias the classification:

- usernames in the form of @username;
- hiperlinks;
- hashtag sign (#), but the hashtag word was preserved, as it can contain relevant information for the classification problem;
- artefacts like &amp and \n;
- proper nouns, using Named Entity Recognition pipeline for Romanian from spacy\(^4\) (ro_core_news_sm).

The first four preprocessing steps were performed using regex. Emoticons, emojis, as well as all punctuation marks were left untouched by preprocessing techniques, as they convey emotions per se.

Final dataset was created by gathering all labelled tweets and shuffling them all. Further, the dataset was split into 3237 tweets for training, 405 tweets for validation and 405 tweets for testing, and this split was used for training all classifiers presented in Section 4.

3.4 Dataset Analysis

In Figure 1 we show the distribution of tokens per tweet for each class of emotions, in order to make sure all five classes have approximately the same distribution. As it can be seen, Fear, Joy and Neutral have approximately the same distributions, while Anger differs the most.

In Table 2 we compute descriptive statistics using R function aggregate. It can be seen that the longest tweet pertains to the Joy class, with 75 tokens, while the majority of tweets lie under 35 tokens, as the highest median is of 30 tokens, belonging to the Anger class. Mean and median are close to each other for this class, but for Sadness class, for instance, mean and median are very different, and we can see that for this class, the majority of tweets are shorter than for the other classes, meaning that Twitter users express sadness using less words in Romanian. Extrapolating, we can also state that Twitter users seemingly express anger in Romanian using more words than they would when expressing other emotions, like fear or joy.

Table 2: Descriptive statistics of token distributions in tweets.

Figure 1: Distribution of tokens per tweet for each class of emotions.

4 Models

In this section we describe the tried models in order to generate the first supervised emotion detector for Romanian short texts. First, we create a benchmark
composed of classical machine learning models, and second we try two more modern approaches, which make use of word embeddings: one that uses Facebook’s fastText word embeddings and a fine-tuned BERT classifier.

4.1 Classical Machine Learning Models

Classical machine learning models can sometimes have good results for modern problems. Thus, before diving into more modern solutions we first investigate Support Vector Classification (SVC), Linear Support Vector Classification (LinearSVC), Logistic Regression and Multinomial Naive Bayes (MultinomialNB) algorithms.

For feature extraction we use Term Frequency - Inverse Document Frequency (tf-idf) to represent tweets in vector form, which is a measure that tries to estimate the importance of tokens in the dataset by computing two statistics: term frequency (the number of appearances of a word in the whole dataset - see Eq.1) and inverse document frequency (the number of tweets in relation to the number of tweets containing the word - see Eq.2), as explained in Sammut (2010).

\[ tf = \frac{\text{No. Of Word Appear. in Tweet}}{\text{No. of Words in Tweet}} \]  
Eq.1

\[ idf = \frac{\text{No. Of Tweets}}{\text{No. of Tweets with Word}} \]  
Eq.2

The final result of the tf-idf is obtained by multiplying Eq.1 and Eq.2 (AlZoubi et al. (2020)):

\[ tf - idf = tf \times idf \]  
Eq.3

Practically, we convert tweets into a matrix of tf-idf features using TfidfVectorizer\(^5\), with the following characteristics:

- sublinear_df parameter is set to True in order to use a logarithmic form for term frequency, because it seems unlikely that twenty occurrences of a term in a document truly carry twenty times the significance of a single occurrence (Manning Christopher (2008)). Thus, Eq. 3 becomes:

\[ wtf - idft,d = wtf_{t,d} \times idft \]  
Eq.4

where:

\[ wtf_{t,d} = \begin{cases}  
\log tf_{t,d} & \text{if } tf_{t,d} > 0 \\
0 & \text{otherwise} 
\end{cases} \]  
Eq.5

- min_df parameter is set to 5, being the minimum number of tweets a word must be present in to be kept in the feature vector;
- ngram_range parameter is set to (1, 2) to indicate that we want to consider both unigrams and bigrams in our vector representation.

For label encoding we used Sklearn LabelEncoder\(^6\).

4.2 FastText Based Model

FastText\(^7\) is an open-source library, developed by Facebook AI Research lab with the purpose of text classification and representation. As Bojanowski et al. (2016) described in their work, fastText creates word representations based on the skipgram model, where each word is represented as a bag of character n-grams. A vector representation is associated to each character n-gram, words being represented as the sum of these representations. Using character level information helps capture the meaning of shorter words and allows the embeddings to map suffixes and prefixes.

The character n-gram selection is done using a sliding window between the minimum value of the character n-gram and the maximum value of the character n-gram. The word is stored in memory like the sum of character n-grams. For classification, word representations are averaged into a text representation to form a hidden variable, which is in turn fed to a linear classifier (Joulin et al. (2016)).

4.3 BERT Based Model

Another modern approach for text encoding is using pretrained vector representations. BERT (Bidirectional Encoder Representations from Transformers), introduced by Devlin et al. (2019) in their work, is considered state-of-the-art in many natural language processing tasks that use language representation. We fine-tune BERT model in order to obtain an emotion detection classifier.

BERT-base model contains an encoder with 12 Transformer blocks, 12 self-attention heads, and the hidden size of 768 (Chi et al. (2019)). To use a pre-trained BERT model, we first need to convert the input data into an appropriate format so that each sentence can be sent to the pre-trained model in order to obtain the corresponding embedding.

\(^7\)https://fasttext.cc/
For this task we use HuggingFace’s transformers package, and in particular the tokenizer for Romanian and the BERT pretrained model for Romanian described by Dumitrescu et al. (2020). The Romanian model was trained on three Romanian corporuses: OPUS, OSCAR and Wikipedia.

BERT tokenizer adds special tokens to the input text, converts all tokens into their corresponding IDs in the model, and adds the attention mask. The attention mask is a vector of 1 and 0 which tells the model which tokens should be taken into consideration and which should not. The resulted vectors are used to train the model.

5 Experiments and Results

In this section we present the results obtained on the test set for the previously described models.

5.1 Classical Machine Learning

The investigated algorithms are SVC, LinearSVC, Logistic Regression and Multinomial NB. For training we use sklearn off-the-shelf functions, without any other parameter modification. The accuracies we obtained for each model are shown in Table 3.

Table 3: Comparison between four classical machine learning models

<table>
<thead>
<tr>
<th>Model</th>
<th>Accuracy</th>
</tr>
</thead>
<tbody>
<tr>
<td>LinearSVC</td>
<td>82.96%</td>
</tr>
<tr>
<td>LogisticRegression</td>
<td>78.77%</td>
</tr>
<tr>
<td>MultinomialNB</td>
<td>76.79%</td>
</tr>
<tr>
<td>SVC</td>
<td>76.30%</td>
</tr>
</tbody>
</table>

According to the results, LinearSVC has the best accuracy, 82.96%. It can be seen that the best model between the four models in Table 3 is LinearSVC, with a surprisingly high accuracy of almost 83%. Second comes Logistic Regression with an accuracy of 78.77%. For LinearSVC we compute the confusion matrix and the normalised confusion matrix and show results in Appendix, Figure 2. Normalization of the confusion matrix is useful in the case of not such perfectly balanced classes, to be able to visual interpret which class is being misclassified the most. It can be seen in the normalized confusion matrix in Appendix, Figure 2, that Sadness class is being misclassified most frequently, and the Neutral class is being classified correctly most often.

We also analyze precision, recall and f-score for each class, which are computed in Table 4, using classification_report method. In accordance with the confusion matrix, Neutral class has the highest precision, recall and F-score scores (not surprisingly, these values are also equal), while Sadness class has lowest scores.

<td>80</td>
</tr>
<tr>
<td>Macro avg</td>
<td>0.82931</td>
<td>0.83095</td>
<td>0.82972</td>
<td>405</td>
</tr>
</tbody>
</table>

Combining the results from Appendix, Figure 2 and Table 4 we see that out of 80 tweets labelled with Sadness, the model correctly classified only 64, 8 being classified as Joy, and out of 89 tweets labelled with Joy, the model correctly classified only 69, 7 being classified as Sadness. This means that the model confuses Joy with Sadness and vice-versa, which is counter-intuitive.

5.2 FastText Based Model

To train the fastText based model we used the train_supervised method from fasttext library, with the word n-grams parameter set to 2, because for the classical machine learning models considered previously we have also used word n-grams of 2 during encoding. We conducted a set of four experiments for the fastText based model, two experiments using pretrained vectors for the Romanian language, and another two experiments where we let the model autotune on the validation set, without taking into consideration pretrained word vectors. Results are shown in Table 5, along with the hyperparameters used for each model, which are:

- \( \text{lr} \) - learning rate;
- \( \text{vectors} \) - fastText pretrained vectors for Romanian were trained on Common Crawl and Wikipedia using CBOW with position-weights, in dimension 300, with character n-grams of length 5, a window of size 5 and 10 negatives;
- \( \text{ws} \) - size of the context window;
- \( \text{wNgrams} \) - maximal length of word n-gram;
- \( \text{epoch} \) - number of epochs used for training.

Table 5: FastText Based Model

Combining the results from Appendix, Figure 2 and Table 4 we see that out of 80 tweets labelled with Sadness, the model correctly classified only 64, 8 being classified as Joy, and out of 89 tweets labelled with Joy, the model correctly classified only 69, 7 being classified as Sadness. This means that the model confuses Joy with Sadness and vice-versa, which is counter-intuitive.
• autotune - time set for autotuning on the validation file;
• minm - minimum length of character n-gram;
• maxn - maximum length of character n-gram.

As seen in Table 5, models trained without making use of pretrained vectors for Romanian had better performances than the models trained with these vectors, but this can be due to the fact that experiments without pretrained vectors were done using hyperparameter autotuning on the validation set, and might not be necessarily related to using pretrained vectors or not. At the time these experiments were conducted, train_supervised method from fastText library didn’t allow autotuning of hyperparameters using pretrained vectors.

</tbody>
</table>

For Model 4 we compute the confusion matrix (Appendix, Figure 3), both classic and normalized. We can see from the normalized confusion matrix that the model has an overall best performance on the Anger class, and worst performance on the Neutral class. But if we examine performance in detail, we see in the classification report (Table 6) that although Anger class has the highest recall, it lacks precision, and while the Neutral class has high precision, it lacks recall. Also, analyzing the confusion matrix we observe many high values of missclassification, for each class: from 89 tweets labelled Joy the model classified 6 as Sadness; from 72 tweets labelled Fear, the model classified 7 as Anger; from 83 tweets labelled as Anger, the model classified 6 as Sadness; from 81 tweets labelled Neutral the model classified 8 as Joy, and from 80 tweets labelled Sadness the model classified 6 as Anger. We can conclude that the fastText based model may have an overall good performance taking into account all classes at once, but behaves poorly in discrete mode.

5.3 BERT Based Model

To train the BERT model we preprocessed data as explained in Section 4.3, using the tokenizer.encode_plus method from Huggingface. We fine-tuned BERT model by adding a classifier for the task of emotion detection, comprised of:

- a drop-out layer with probability 0.3. As explained in Hinton et al. (2012), drop-out layers are used for regularization and preventing the co-adaptation of neurons;
- a fully connected layer that applies a linear transformation to data;
- a transformation of the output using Softmax function.

Training was done using Cross Entropy loss function with an AdamW optimizer for the learning rate. Although BERT authors have some recommendations in their paper, Devlin et al. (2019), we opted for a batch size of 8 and 5 epochs, because our 16GB GPU card couldn’t handle a bigger batch size, and in 5 epochs the model already reached its highest accuracy. The maximum utterance length was set to 100.

For fine-tuning BERT we chose Cross Entropy loss function and Softmax optimizer, as these are usually used with multiclass classification problems.

The confusion matrices, both simple and normalized, are shown in Appendix, Figure 4. It can be observed on the normalized confusion matrix that Sadness class has been misclassified most often, while Joy and Fear have best accuracies per class. On the simple confusion matrix we can see that misclassifications don’t have such high values like on the other tried models’ confusion matrices, none exceeding 5 wrong classifications.

The overall accuracy for the BERT based model is 90.37%, fact that can also be observed in the confusion matrix, by summing up the values on the diagonal and dividing to the whole number of samples (405 tweets in the test set).

This model’s classification report is presented in Table 7. The macro averaged precision, recall and F-score are very similar, and to the overall accuracy of the model as well. Best precision, recall and F-score belong to the Joy class, worst precision and F-score to Anger class, and worst recall to Sadness class.

5.4 Comparisons

Retrospectively, although LinearSVC had a high overall accuracy, it confused Joy and Sadness, but had good performance on the Neutral class. On the other hand, the fastText based model had worst performances on the Neutral class, and performed best when classifying Anger, but had an overall better accuracy than LinearSVC. Lastly, our BERT-based model outperforms all the other models considered, as seen in Table 8, where we aggregate all our results and compare models using accuracy, macro averaged precision, recall and F-score. We can see that the BERT-based model came out best regarding all measures, fastText based model came out second, and classical LinearSVC on the last place. A probable explanation for such good results is that pre-trained BERT learned contextual relations between words and fine-tuning the model makes use of these relations when classifying.

6 Conclusions and Future Works

In this article, we presented our novel dataset for emotion detection, the first dataset of its kind for the Romanian language. We researched the state-of-the-art and created a benchmark of machine learning models in order to obtain an automatic emotion detector from tweets, having the purpose of being used in real-life tasks, adjacent to the field of opinion mining.

Although the dataset is not very large, it provided enough data to generate a text emotion detection model with an accuracy of 90.37%. In the future, we plan to enlarge this dataset with more tweets per class, an action that most probably will increase accuracy of the models. Also, we plan on adding more classes of emotions, to generate an even more fine-grained dataset for detecting emotions in Romanian content.

7 Acknowledgments

We would like to thank Nicu Ciobotaru and Ioana Alexandra Răducanu for their help with the annotation process, Ligia Maria Bătrîncu for proof reading and suggestions, as well as the anonymous reviewers for their time and valuable comments.

Assessing the Eligibility of Backtranslated Samples Based on Semantic Similarity for the Paraphrase Identification Task

Jean-Philippe Corbeil and Hadi Abdi Ghavidel
Polytechnique Montreal
{jean-philippe.corbeil,hadi.abdi-ghavidel}@polymtl.ca

Abstract

In the domain of natural language augmentation, the eligibility of generated samples remains not well understood. To gather insights around this eligibility issue, we apply a transformer-based similarity calculation within the BET framework based on backtranslation, in the context of automated paraphrase detection. While providing a rigorous statistical foundation to BET, we push their results by analyzing statistically the impacts of the level of qualification, and several sample sizes. We conducted a vast amount of experiments on the MRPC corpus using six pre-trained models: BERT, XLNet, Albert, RoBERTa, Electra, and DeBerta. We show that our method improves significantly these “base” models while using only a fraction of the corpus. Our results suggest that using some of those smaller pre-trained models, namely RoBERTa base and Electra base, helps us reach F1 scores very close to their large counterparts, as reported on the GLUE benchmark. On top of acting as a regularizer, the proposed method is efficient in dealing with data scarcity with improvements of around 3% in F1 score for most pre-trained models, and more than 7.5% in the case of Electra.

1 Introduction

Natural language processing (NLP) tasks require sufficiently large datasets to achieve the maximum robustness of the trained models. Low sizes of data pose the risks of hindering the models’ convergence during the training process, which leads to less accurate predictions (e.g. classification) or generations (e.g. translations). On the other hand, the provision of high-quality labelled data is often very expensive both in terms of money and time. As a result, NLP scientists seek alternative methods to tackle this issue. One of the solutions is the application of data augmentation techniques. These methods help considerably to alleviate insufficiencies regarding the quantity of labelled data and the expertise to annotate the data. These augmentation techniques are also proved to induce a regularization effect during the training of NLP models to avoid overfitting, most notably, on surface cues.

In this paper, we examine the impact of adding a post-processing stage after applying such data augmentation technique to assess the eligibility of the generated samples. We intend to run our analysis in automated paraphrase identification. In this regard, we increase the size of the paraphrase data through a backtranslation method called BET (Corbeil and Abdi Ghavidel, 2020). In particular, we conduct the following experiments:

- We take randomly several samples of the original train set and augment them with back-translation.
- After augmenting the textual data, we assess the eligibility by applying a similarity filter. We report the results for three criteria: 0.8, 0.9, and 0.95.
- We examine six pre-trained transformer models: BERT, XLNet, RoBERTa, ALBERT, Electra, and DeBerta.
- We run ten times each experiment randomizing the random seed to measure the averaged metrics and their p-values.

The remainder of this paper is structured as follows. In section 2, we describe the previous works in natural language augmentation. In section 3, we explain our methodology in terms of the dataset and our overall pipeline. Next, we illustrate and discuss the results. Finally, we summarize our findings and talk about the possible future research avenues.
Figure 1: Experimentation pipeline schema to generate the training set from a sampled version of the MRPC — $N$ randomly selected samples for each experiment — on top of which we add the eligible backtranslated examples. Using sentence-transformers $\vec{e}$ to encode the utterances as vectors, we estimate the qualification given a threshold $T$ by measuring the cosine similarity $\text{sim}$ between the generated sentences and the original ones. The utterance named Sentence 2 corresponds to the column name inside the MRPC dataset, which is identified as the paraphrase.

2 Related Work

Data augmentation has been intensively explored in computer vision given its straightforward geometrical nature, especially image processing. According to Feng et al. (2021), the popular techniques in this field are cropping, flipping, and colour jittering. From a natural language processing standpoint, many authors noted that the natural language augmentation methods (NLA) either attempt to preserve the meaning and structure after the data augmentation process (Corbeil and Abdi Ghavidel, 2020; Tong et al., 2019; Coulombe, 2018; Sennrich et al., 2016; Anaby-Tavor et al., 2019; Radford et al., 2019) or to modify the tokens without taking into account the overall structure of the language (Wei and Zou, 2019; Coulombe, 2018). Feng et al. (2021) classified the techniques into the following categories:

- **Rule-Based techniques**: In these techniques, the original examples are changed (rewritten) based on a set of pre-defined rules. For instance, Wei and Zou (2019) applied random insertion, deletion, and swap on the tokens of the sentences.

- **Example interpolation techniques**: These techniques, also called mixed sample data augmentation, either interpolate the feature vectors (Zhang et al., 2017) or fuse the original examples into pairs (Ghiasi et al., 2020).

- **Model-Based techniques**: This set of techniques are concentrated on training models to generate diverse examples out of the original counterparts. Paraphrase generation (Sennrich et al., 2016) is a widely-known example of such techniques.

To the best of our knowledge, none of the papers in the aforementioned categories has analyzed the effect of a post-processing stage so far. Only Coulombe (2018) and Corbeil and Abdi Ghavidel (2020) highlighted the necessity for filtering out the backtranslation outputs to assess the data augmentation validity, without conducting any specific experiment to support the claim.

In the current paper, we closely set our work on the BET framework proposed by (Corbeil and Abdi Ghavidel, 2020), on top of which we enrich the meaning preserving aspect with a semantic similarity stage. Their original approach uses a model-based technique by applying backtranslation on ten intermediary languages to obtain a soft data augmentation. Thus, they generate ten times the amount of original data. Then, they analyzed the
resulting improvements on the paraphrase detection task as external validation. They tested various pre-trained models: BERT (Vaswani et al., 2017), XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019) and ALBERT (Lan et al., 2019). In this work, we carry out the experiments with the same pre-trained models adding the most recent ones: Electra (Clark et al., 2020) and DeBerta (He et al., 2020). There are still other closely related works such as (Shakeel et al., 2020), but the authors used neural network architectures such as LSTMs and CNNs through exploiting a set of hand-crafted features on the MRPC, Quora and SemEval datasets.

3 Methodology

3.1 Dataset

In this paper, we focus our experiments on the MRPC\(^1\) corpus. This paraphrase corpus is included in the GLUE benchmark (Wang et al., 2019). It consists of a pair of sentences (sentence and paraphrase), which are pulled from online news sources. Overall, 4076 pairs were allocated to the train set and 1725 to the test set. We further split the MRPC train set into a smaller train set (90%, 3,668 pairs) and a validation set (10%, 408 pairs).

3.2 Data Augmentation Pipeline

As illustrated in Figure 1, our pipeline includes a backtranslation process based on BET using the Google Translate API and a filtering process using the sentence-transformers bi-encoder approach (Reimers and Gurevych, 2019).

On the basis of BET, we selected ten languages for the backtranslation procedure. These intermediary languages are: Chinese (zh), Spanish (es), Arabic (ar), Japanese (ja), Telugu (te), Javanese (jv), Korean (ko), Vietnamese (vi), Turkish (tr) and Yoruba (yo). In this regard, we augment only the paraphrases (e.g. the column Sentence 2) through backtranslating them into English from one of the aforementioned languages.

Our filtering module is mainly based on the sentence-transformers bi-encoder approach (Reimers and Gurevych, 2019). It is built to compute a unique sentence representation by pooling all the transformer’s contextual word embeddings — applying the mean. It is optimized under cosine loss in a Siamese neural network fashion. We choose the stsb-distilroberta-v2 model, which is a lightweight version. Formally, we note it as a function \(\vec{e}(s)\) with \(s\) being the sentence to encode into a sentence embedding. Then, we calculate the cosine similarity (see equation 1) between the original sample and the backtranslated one. Finally, we opt-out the ones which are below various thresholds \(T \in \{0.95, 0.9, 0.8\}\).

\[
sim(s_1, s_2) = \frac{\vec{e}(s_1) \cdot \vec{e}(s_2)}{||\vec{e}(s_1)|| \cdot ||\vec{e}(s_2)||} \tag{1}
\]

We show that different thresholds \(T\) influence drastically the outcome of our transformer-based paraphrase identifiers. We can approximate the effect of the semantic filtering as a paraphrase verification \(para(\cdot, \cdot)\) like in equation 2. We hypothesize that, by adding this filtering stage, we can reinforce the preservation of meaning into BET up to some specific threshold \(T\).

\[
para(s_1, s_2) \approx \begin{cases} 
1 & \text{if } \sim(s_1, s_2) \geq T \\
0 & \text{else}
\end{cases} \tag{2}
\]

3.3 Adjusting the Thresholds for Understanding the Similarities

In Figure 2, we present the histograms representing the distributions of similarities between the original sentence and the backtranslated ones. We displayed one histogram for each intermediary language. Giving the proximity of our setup with the original BET setup, we observe that the amount of generated examples with a similarity above 0.95 — as it is sorted in Figure 2 — correlates with the results reported by original BET experiments (Corbeil and Abdi Ghavidel, 2020). For instance, the authors mentioned that Spanish (es) and Vietnamese (vi) are among the best intermediary languages to use with BET to achieve the most gain on the performances. From our observations, we conclude that looking at similarity is a better way to analyze the impact of intermediary languages on backtranslation.

Based on those distributions, we also set the three similarity thresholds used in our experiments. We selected 0.8 because it conserves a majority of the generated data while filtering outliers. Afterwards, we chose 0.9 which is a compromise between quantity and quality. Finally, 0.95 is the strictest threshold keeping only the most similar examples. We won’t extend our analysis to a threshold of 0 — equivalent to the original BET — since

\(^1\)Microsoft Research Paraphrase Corpus
0.8 encompasses most of the data and the rest should be only outliers.

Considering the full MRPC corpus, we further analyzed the total amount of eligible samples after applying the different similarity thresholds $T$ in the bar chart of Figure 3. We can see that the threshold of 0.8 retains most of the generated data. For a threshold of 0.9, a majority of samples are still qualified for the training of the model. The 0.95 threshold drops less than two-thirds of the data taking only the most similar examples to the original sentence. By observing the results of the experiments in the next section, we can conclude about which of the quantity criterion ($T = 0.8$) or the quality criterion ($T = 0.95$) is better to determine the eligibility of a backtranslated text. We externally assessed this qualification by measuring the performances achieved by the models on the paraphrase detection task.

4 Results and Discussion

As we mentioned in section 1, we evaluated our natural language augmentation approach on BERT (Devlin et al., 2018), XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2019), Electra (Clark et al., 2020) and DeBerta (He et al., 2020). We performed our experiments iteratively beginning with the sampling of only 100 random examples from the original MRPC dataset up to reaching the whole trainset. We selected ten sample sizes to cover low-data regime situations (100 - 1,000) and high-data regime situations (1,000 - 3,668). We leveraged the HuggingFace\textsuperscript{2} transformers library and the sentence-transformers library for all our fine-tuning and filtering experiments. We fixed the training configuration to well-known hyperparameters for this task based on HuggingFace’s recommendations. We left a granular optimization of the hyperparameters for future works. Thus, our experimental setup is as follows:

- Batch size: 32
- Learning rate: 3e-5
- Number of runs per experiment (random seeds were randomized at each run): 10
- Number of different experiments: 240
- Sample sizes: [100, 250, 500, 750, 1000, 1500, 2000, 2500, 3000, 3668]

\textsuperscript{2}https://huggingface.co/
• FP16 mode

Overall, we conduct 240 unique experiments. For each of these, we report the average of 10 runs in Figures 4, 7, and 8. Our evaluation metrics are respectively: F-1 score, precision, and recall. We mainly focus on the average of F-1 scores since it is the metric used for the GLUE benchmark and in the literature. Nonetheless, we also inspect the precision and recall — the components of the harmonic mean used to compute the F-1 score — to gain a thorough understanding of our method.

In Figure 4, we illustrate the F-1 scores for all six models across all the sampling sizes. We display four curves: baseline (plain MRPC without BET), BET filtered 0.95, BET filtered 0.9, and BET filtered 0.8. We also added the F1 scores (dashed black lines) reported by their original authors for the corresponding large models. As a first general observation, we observe that all the baseline curves have approximately an S-shaped trend, in which sharp variations occur. In contrast, the BET filtered lines are smooth logarithmic-like growth, mostly all above the baseline curve. We further note that the higher we fix the similarity threshold, the bigger the gains we have. Some models like RoBERTa and DeBERTa have gained between 0.04 and 0.08 in the sample size region between 500 and 1,500 samples.

We directly provided in Figure 6 the F-1 scores gain $G$ in percent computed by comparing the BET filtered 0.95 against the baseline. We used the equation

$$G = 100 \cdot \frac{F_1^{\text{augmented}} - F_1^{\text{baseline}}}{F_1^{\text{baseline}}}$$

(3)

Figure 6: F-1 score gain in percent by comparing the F1-score averages between the BET filtered 0.95 against the Baseline.

We also checked the p-values from the Student's T-test between all the augmented F-1 scores and the baseline ones, in Figure 5. In statistics, we are usually advised for a minimum of about 35 runs to benefit from the law of large numbers. Given the long training times of transformer models and the number of configurations set by our methodology, we limited our experiments to ten runs. However, we note it is already twice the usual five runs used in the literature with these models. The resulting comparison using the p-values is therefore limited. Yet, we observe that in the case of the BET filtered 0.95 mostly all F-1 scores are strongly significant below a p-value of 0.05 (dashed black line). However, we note less significant results at 100 samples, and some at high sample sizes. Those regions, as well as the BET filtered 0.8 and BET filtered 0.9, would require further runs to conclude statistically the T-test. We finally highlight that, in the case of RoBERTa and Electra in the large sample size region (from 3,000 to 3,668), the results reaching near their large counterparts are significant.

To have an idea of the underlying influences behind the reported F-1 scores, we also provide the values for precision and recall in Figures 7 and 8.

In Figure 7, we observe in many cases a reduction in precision. However, in the low sample sizes — below 1,500 samples —, we notice gains in precision between 0.03 and 0.15. Furthermore, we report that the lower the similarity filter is (0.8 and 0.9), the more we tend to degrade the precision compared to the baseline. We remark that all the BET filtered 0.95 curves are surpassing the baseline precision. We mentioned as a first hypothesis that a higher threshold on the similarity scores would
induce a higher quality of the generated samples — leading logically to a rise in precision. Therefore, we confirm the validity of this hypothesis based on its impact on the precision curves.

In Figure 8, we show the sensitivity curves, on which we denote two observations. First, as expected generally with data augmentation in NLP, we note an overall gain in recall when applying BET from a couple of percent up to 0.05. We observe that this gain tends to lower as the similarity threshold gets higher, but remains above the baseline. The pre-trained models that benefit the most in terms of sensitivity are respectively BERT, DeBerta, Albert and RoBERTa. XLNet and Electra obtained very low improvements on the sensitivity metric. When looking below a 1,000 sample sizes, we notice a drastic drop in recall from the baseline to any of the BET curves. Nonetheless, we rationalize that the models tend to declare a paraphrase too often. We conclude that this issue is solved by applying any backtranslation.

Figure 4: F-1 score curves for all experiments, where each point is the average of ten experiments. The dashed black lines are the GLUE benchmark scores reported for the large models. The model names are the ones used by the HuggingFace Model Hub.

Figure 5: P-values of the F1-score curves augmented by the BET framework against the Baseline curve.
5 Conclusion and Future Work

In this paper, we described a method based on back-translation which is followed by a filtering stage to keep the most eligible examples. We increased the F-1 scores on the automatic paraphrase detection task by up to 7.6% compared to the baseline using only a fraction of the original dataset. Furthermore, we demonstrated that this approach limits the gain in recall while avoiding degrading the precision, which results in the best F-1 scores. With the augmentation of the full dataset using RoBERTa base and Electra base, we achieved results that are close to the reported GLUE benchmark scores, while the original authors were using their corresponding large versions. In conclusion, pre-trained transformer models have very good transfer-learning capabilities, but they still largely benefit from the support of high-quality natural language augmentation, both to enrich very small datasets and to alleviate the overfit on surface cues.

In future work, we will extend this work to the other paraphrase corpus as well as to the other NLP tasks such as multi-class classification.

Abstract
This paper presents multidimensional Social Opinion Mining on user-generated content gathered from newswires and social networking services in three different languages: English—a high-resourced language, Maltese—a low-resourced language, and Maltese-English—a code-switched language. Multiple fine-tuned neural classification language models which cater for i) English, Maltese and Maltese-English languages as well as ii) five different social opinion dimensions, namely subjectivity, sentiment polarity, emotion, irony and sarcasm, are presented. Results per classification model for each social opinion dimension are discussed.

1 Introduction
Social Opinion Mining on data obtained from social sources is an evolving research domain tasked with the identification of several opinion dimensions, such as subjectivity, sentiment polarity, emotion, irony and sarcasm, from noisy user-generated social data spread across heterogeneous sources (Cortis and Davis, 2021b). Currently, Social Opinion Mining is used in several real-world scenarios, namely chatbots (Androutsopoulou et al., 2019), adaptive customer online service based on identified customer sentiment and emotion (Yadollahi et al., 2017), tracking of overall customer satisfaction for a product or service (Zhao et al., 2019), and detection of changes in customer opinion towards a brand, product or service (Geetha et al., 2017).

This paper presents multidimensional Social Opinion Mining on user-generated content gathered from newswires and social networking services in three different languages: English—a high-resourced language, Maltese—a low-resourced language, and Maltese-English—a code-switched language. Our aim is use these initial results to improve cross-lingual performance of English-Maltese neural language models. Research applications of the developed classification models include opinion summarisation and fine-grained opinionated search of each dimension. This work is in line with Malta’s Strategy and Vision for Artificial Intelligence (Parliamentary Secretariat for Financial Services and Innovation, 2019), with current investment being made in the development of Maltese language resources and tools to counter the threat of “digital extinction” for the Maltese language, which has low technological support available in comparison with other European languages (Rosner et al., 2012).

We leverage a novel multidimensional and multilingual social opinion dataset in the socio-economic domain, specifically Malta’s annual Government Budget, which comprises social data from the 2018, 2019 and 2020 budgets to fine-tune pre-trained neural language models for benchmarking purposes.

2 Related Work
Nguyen et al. (Nguyen et al., 2020) developed the first large-scale pre-trained language model BERTweet for English tweets, which outperforms its baselines. Experiments were conducted on three NLP tasks, namely Part-of-Speech tagging, Named Entity Recognition and text classification, namely sentiment analysis and irony detection. For the latter task, the authors used the 3-class sentiment analysis dataset from SemEval-2017 Task 4A (Rosenthal et al., 2017) and the 2-class irony detection dataset from the SemEval-2018 Task 3A (Van Hee et al., 2018). The authors in (Croce et al., 2020) propose GAN-BERT which extends the fine-tuning of architectures similar to Bidirectional Encoder Representations from Transformers (BERT) (Devlin
et al., 2018), using unlabelled data in a generative adversarial setting. Experimental results show that around 50-100 annotated examples can still produce good performance in sentence classification tasks. Results are confirmed for sentiment analysis over the SST-5 dataset (Socher et al., 2013) containing 5-class sentiment polarity categories. Babanejad et al. (Babanejad et al., 2020) propose two novel deep neural network models for sarcasm detection by including affective and contextual features in the extended BERT architecture.

Certain studies focused on low-resourced languages, with (Fei and Li, 2020) investigating cross-lingual sentiment classification where the low-resource language does not have any labels or parallel corpus, (Grießhaber et al., 2020) exploring the reduction of trainable model parameters for fine-tuning a model with a small amount of data, (Koto et al., 2020) releasing a new pre-trained language model for Indonesian which was evaluated on several tasks such as sentiment analysis, and (Yimam et al., 2020) using RoBERTa (Liu et al., 2019)–a replication of BERT developed by Facebook– for exploring Amharic sentiment analysis from social media text.

Demszky et al. (Demszky et al., 2020) conduct transfer learning experiments on existing emotion benchmarks to show that the GoEmotions dataset of fine-grained emotions generalises across domains and taxonomies. The authors demonstrate that if little target domain labelled data is available, this dataset can be used as a baseline for emotion understanding. Similarly, the XED multilingual dataset for emotion detection catering for a total of 32 languages has been evaluated using language-specific BERT models (Öhman et al., 2020). Lastly, (Makarenkov and Rokach, 2020) explore several off-the-shelf BERT models, where they show that the complexity and computational cost of BERT does not provide a guarantee for an improved predictive performance for classification tasks. This is especially relevant in cases where small domain-specific datasets are used, which datasets are also imbalanced due to the minority class being under-represented.

3 Dataset

The dataset of multidimensional and multilingual social opinions for Malta’s Annual Government Budget² (Cortis and Davis, 2021a) is used for the work carried out in this paper. This dataset contains 6,387 online posts for the 2018, 2019, and 2020 budgets, which user-generated content was collected from newswires and social networking services. In terms of languages, the majority of the online posts were in English (74.09%), Maltese or Maltese-English (24.99%). Each online post is annotated for the following five social opinion dimensions: subjectivity, sentiment polarity, emotion, sarcasm and irony. Table 1 presents the overall class distribution of online posts for each social opinion dimension and the language annotation. Statistics are provided for the entire dataset (columns 2 and 3), the subset of online posts in English (columns 4 and 5) and subset of online posts in Maltese and Maltese-English (columns 6 and 7).

4 Experiments

All experiments have been carried out on Google Colaboratory³ using a Tesla K80/Tesla T4/Tesla P100-PCIE-16GB Graphics Processing Unit (GPU).

The baseline models experiments have been carried out in the Python programming language using Jupyter Notebook⁴ on a machine with an Intel(R) Core(TM) i7-8550U CPU @ 1.80Hz 1.99 GHz processor and 8.00 GB (7.88 GB usable) installed memory (RAM).

4.1 Setup

We present multiple classification language models which cater for the English, Maltese and Maltese-English languages as well as five different social opinion dimensions, namely subjectivity, sentiment polarity, emotion, irony and sarcasm. We train models using state-of-the-art deep neural network models for each of the five opinion dimensions using the Transformer model architecture introduced by Vaswani et al. (Vaswani et al., 2017), which is based on attention mechanisms and is designed to handle sequential data, such as natural language, for NLP tasks like sentiment analysis and text summarisation.

4.2 Handling Imbalanced Data

As reflected in Table 1, the dataset we use is imbalanced. There are several re-sampling techniques (Cateni et al., 2014; More, 2016) for treating the problem of an imbalanced dataset. For our initial

Table 1: Class distribution for each annotation per dataset

The experiments, we do not address the imbalance or explore whether it influences our classification tasks and if so, which ones. The dataset was divided in a training set of 70%, validation set of 20% and a test set of 10%. The scikit-learn\(^5\) train_test_split function is used to split the sets in a random state.

### 4.3 Models

The following state-of-the-art deep neural network models have been fine-tuned for *subjectivity* (binary), *sentiment polarity* (multi-class), *emotion* (multi-class), *sarcasm* (binary) and *irony* (binary) classification:

- **BERT** (Devlin et al., 2018): A pre-trained model on BookCorpus and English Wikipedia. The BERT-Base uncased, 12-layer, 768-hidden, 12-heads, 110M parameters model is used.
- **DistilBert** (Sanh et al., 2019): A distilled version of the BERT model which is smaller and faster than BERT and is pre-trained on the data. The uncased model which has 40% less parameters than BERT-Base uncased is used.
- **BERTweet** (Nguyen et al., 2020): A large-scale language model pre-trained for English tweets based on the RoBERTa (Liu et al., 2019) pre-training procedure using the same model configuration as BERT-Base. Both bertweet-base (base) and bertweet-covid19-base-uncased (covid-19) models with 135M parameters each are used. The former model is trained on 845M English cased tweets, whereas the latter model is trained on 23M COVID-19 English uncased tweets.

The experiments are carried out using the Hugging Face (Wolf et al., 2019) state-of-the-art Transformer library for Pytorch and TensorFlow 2.0\(^6\). This tool provides general-purpose architectures, such as BERT, RoBERTa and DistilBert for NLP tasks, such as sentiment analysis, where over 32+ pre-trained models are available in 100+ languages. The following hyperparameters are used:

- Optimiser and learning rate scheduler: batch size - 32, Adam (Kingma and Ba, 2014) learning rate - 2e-5, number of epochs - 4, epsilon parameter - 1e-8;
- Method of choosing values and criterion used: Manual tuning based on training and validation loss, learning rates of 5e-5, 3e-5, 2e-5

\(^5\)https://scikit-learn.org/

\(^6\)https://huggingface.co/transformers/
and maximum sentence length of 96, 128 and 256 tokens;

- Fine-tuning classification layer: Rectified Linear Unit (ReLU).

5 Results and Discussion

Results per classification model for each social opinion dimension are presented in Table 2 and further discussed below. Three evaluation metrics are used to measure the classification performance of the fine-tuned models:

- **F1 score weighted**: F1 score is the weighted average of precision and recall. The weighted score calculates the F1 score for each label with their average being weighted by support, that is, the number of true instances for each label. This metric caters for label imbalance.

- **Area Under the Curve Receiver Operating Characteristics (AUC ROC)**: Score shows the model’s true positive rate against the false positive rate and can help you identify how well (score of 1) a model can distinguish between classes.\(^7\)

- **Matthews correlation coefficient (MCC)**: Measures quality of binary and multi-class classifications by taking into account true and false positives and negatives and provides a balanced measure for imbalanced classes.

The following is an overview of the results and some observations.

- **Subjectivity**: For the BERT and DistilBERT models, the training and validation loss converged in epoch 2, whereas both BERTweet models converged in epoch 3. The BERTweet covid19-base-uncased fine-tuned model produced the best performance overall.

- **Sentiment Polarity**: The fine-tuned BERT and DistilBERT models converged in epoch 3, whereas both BERTweet models converged in epoch 4. The BERTweet covid19-base-uncased fine-tuned model also produced the best performance overall.

- **Emotion**: The fine-tuned BERT and DistilBERT models converged in epoch 4, whereas both BERTweet models did not converge by epoch 4 albeit close. An additional experiment showed convergence in epoch 6. In terms of performance, both BERT and DistilBERT fared best overall.

- **Sarcasm**: All fine-tuned models performed similarly in terms of F1 score, with DistilBERT performing best overall. The BERTweet covid19-base-uncased model did not converge in epoch 4 albeit close.

- **Irony**: DistilBERT produced the best results overall, which model converged in epoch 3.

- **Language**: It is interesting to see English-based fine-tuned models adapt to non-English text. This Maltese-English and Maltese subset amounts to only a quarter of the dataset (1596 online posts). Initial results obtained are promising for building language models that are capable of handling code-switched data, which is common practise in countries like Malta. More in-depth experiments and qualitative analysis shall be beneficial to measure the adaptability of the English-based fine-tuned models to code-switched languages, such as Maltese-English.

- **Domain**: A socio-economic dataset (domain specific) has been used, with only 16.75% of the data being off-topic. The results ob-

Table 2: Results of all the pre-trained models

\(^7\)For the sentiment polarity and emotion multi-class models we only display the maximum AUC ROC score for each respective class.
tain in our preliminary work demonstrate that fine-tuning models to new domains is possible when using deep neural network models.

- The DistilBERT model took less time for training and validation for all five classifiers.
- Even though the dataset is imbalanced, the subjectivity and sentiment polarity models produced good results. However, certain resampling techniques shall help increase the performance of the sarcasm and irony fine-tuned models, which class distribution is very unbalanced as reflected by the MCC. The same also applies to the emotion model for certain classes, such as fear, surprise, sadness.
- Several researchers recommend only 2-4 epochs of training for fine-tuning BERT on a particular NLP task. However, certain multi-class classification tasks with a large number of classes such as the emotion 8-class classification fine-tuned model, might require more than 4 epochs when certain models such as BERTweet are fine-tuned.
- Given that the dataset used contains a mix of newswire comments and tweets, the maximum sentence length in the dataset used is 867. Therefore, more experiments should be carried out using a higher maximum sentence length than the 128 tokens used. However, the high computation power needed for training such deep learning models should be taken in consideration to reduce the carbon footprint in terms of finance and the environmental (Strubell et al., 2019).

6 Conclusions and Future Work

We have leveraged a novel multidimensional and multilingual social opinion dataset in the socio-economic domain to fine-tune neural language models targeting English-Maltese social data for different opinion dimensions, namely subjectivity, sentiment polarity, emotion, sarcasm and irony. Even though our results are a work-in-progress, we have been encouraged by Xia et al. (Xia et al., 2020) to provide multilingual benchmarks which can be further used, evaluated and adapted for low-resourced languages. Research applications for the developed classification models include opinion summarisation and fine-grained opinionated search of each dimension.

Abstract

In this paper we investigate the etymology of Romanian words. We start from the Romanian lexicon and automatically extract information from multiple etymological dictionaries. We evaluate the results and perform extensive quantitative and qualitative analyses with the goal of building an etymological map of the language.

1 Introduction

Located at crossroads between East and West, the Romanian language presents a kaleidoscopic etymological picture. Originated from Latin, it suffered the influence of many cultures with which the other Romance languages did not have (much or any) contact, hence its physiognomy became, from a certain point on, different from that of its cognate languages (cf. Niculescu (1965, 1978, 1999, 2003)). The Romanian lexicographers, having to deal with this miscellaneous etymological structure of the language, must perform a fairly complicated task which not rarely ends up by giving in to the difficulty of identifying a word’s origin.

Our analysis, based on a computational systematization of the origins of words, aims to evaluate quantitatively and qualitatively Romanian’s etymological composition. We propose a socio-cultural interpretation of the semantic domains most permeable to borrowings from the various languages with which Romanian had a stronger contact, considering that a systematic perspective on the lexicon’s etymological structure, doubled by statistics on the permeability and needs of the various onomasiological fields, may provide clues for future research concerning still unknown etymologies.

1.1 Preliminaries. Peculiarity of Romanian vs. the Other Romance Languages

Apart from its genetically belonging to the Romance linguistic family, the Romanian language shares certain phonological, morpho-syntactic and lexical features with the Balkan languages, as a consequence of its geographical position. For this reason, it was also included in the so-called “Balkansprachbund” or “Balkan language area” (cf. Rosetti (1968)), together with Eastern South Slavic languages (Bulgarian, Macedonian and Serbian), Albanian and Greek.

There are two significant differences between Romanian and the other Romance languages:

1. According to Sala et al. (1988), the fundamental lexical core of Romanian comprises less words inherited from Latin than the other Romance languages (Ro. 30% vs. It. 44%, Fr. 36%, Sp. 40%, Pt. 45%).

2. At the same time, while the Italo-Occidental Romance languages make use, in their basic lexicon, of at least 25% loanwords from Latin (It. 28%, Fr. 27%, Sp. 27%, Pt. 25%), the Romanian language only counts little more than 1% words borrowed directly from Latin; thus, even if we add the 8% Latin words borrowed via French and Italian, the most Eastern Romance language still does not reach the Occidental proportion of the “cultural superstrate” (cf. Reinheimer Ripeanu (2004)).

By combining these two components (inherited and borrowed words from Latin), considering their proportion in the representative lexicon of the Romance languages, we obtain It. 72%, Fr. 63%, Sp. 67%, Pt. 70%, while in Romanian the Latin element hardly reaches 32% (or 39% if we also consider the Latin words penetrated via French and
A reason for this considerable etymological divergence could be, on the one hand, its late integration and early separation from the Roman Empire: conquered at the beginning of the 2nd century, Dacia was left unconnected with the Empire in the second half of the 3rd century. This could explain the lower proportion of inherited words. On the other hand, the different geographical context had a significant influence on the further development of the Romanian language, because, while the Italo-Occidental Romance languages were passing through a period of re-latinisation, massively borrowing words from Latin, the Oriental Latin descendant had strong contact with the Slavic, Greek and Turkish languages, all of which have left deep marks on the Romanian lexicon.

We must also briefly describe here another particularity of the Romanian lexicon, namely the external multiple etymology, defined as “the provenance of a single word from two or more lending languages, at the same time and on the same territory, or in different times and in different territories” (Celac, 2020). This situation resides in multiple internal and external factors that influenced the Romanian language simultaneously, especially during its modernization period (the 19th century). The “cultural loanwords” (i.e., words related to technology, science, cultural life, mostly corresponding to the international vocabulary items, cf. Moroianu (2015); Celac (2020)) could penetrate more or less at the same time from different source-languages, depending on the foreign language that was used as a source in the borrowing process. As the languages that were used as source for the neological enrichment of Romanian are multiple – besides French and Italian we also count Latin, Modern Greek, Russian and German –, it is not infrequent the case where a word has three, four or even five etymologies.

Moreover, one should take into account the dialectal fragmentation of Romanian before its cultural unification and standardization (starting not before the second half on the 19th century), which led to the same situation of multiple-source borrowing, depending on the contact language of each Romanian province: for example, the Romanian speakers in Moldavia would borrow from the Ukrainian language, while Southern Romania would use Bulgarian or Serbian as source-languages. Thus, one and the same Slavic word could have penetrated through different channels, which results as well in multiple etymology.

While the concept of “multiple etymology” is rather unusual for the other Romance languages, this peculiar situation being almost absent in the rest of the Latin descendants, the Romanian language has a significant number of lexical units borrowed more or less simultaneously from various sources, that reach a proportion of almost 18% of the fundamental lexical core (cf. Sala et al. (1988)).

This situation represents one of the main difficulties that Romanian lexicographers have to face. In our approach, we will provide a statistic of words having from one up to six etymologies. It goes without saying that the possibility of errors cannot be overlooked, as many lexicographers have also dealt with this particular Romanian lexical characteristic by placing at the same level several etymologies, whenever they were simply unsure about the immediate origin of a word.

1.2 Romanian Lexicography – A Brief Survey

In this section we offer a brief overview of the main resources one can use for etymological information concerning the Romanian lexicon. We also present the dictionaries we used for this research, explaining the reasons for our choices.

By comparing the lexicographical resources for Romanian with those created for the other main Romance languages (Italian, French, Catalan, Spanish and Portuguese), one can notice the absence of a substantial etymological dictionary of Romanian, equivalent to the lexicographic instruments we can use, for instance, for French (FEW (Wartburg, 1922–2002)), Catalan (DECat (Coromines, 1980–2001)) or Spanish (DCECH (Coromines and Pascual, 1980–1991)).

Despite various attempts to provide reliable etymological dictionaries, the results have been either incomplete (e.g., Etymologicum Magnum Romaniae (Hasdeu, 1886–1898), ceased at the letter B, or Candrea and Densusianu (1907–1914) – comprising only the words of Latin origin, besides not going further than the letter P), or not fully trustworthy (DER, cf. Hristea (2009)). The thesaurus dictionary of Romanian, DA (Pușcariu, 1913–1949) / DLR (Iordan, 1965–2010), is not consistent in the etymological descriptions it offers: while the first volumes, A-De and F-Lojnită (Pușcariu, 1913–1949), offer solid etymological descriptions, the remaining volumes (Iordan, 1965–2010) – reduce
the etymological explanations to a minimum. The ongoing project of a new complete etymological dictionary, DELR ((Academia Română, 2011–), covering so far the letters A–C), has been criticized not only for punctual shortcomings (cf. Celac (2012)), but for its whole design, being destined only to review the tradition of the etymological research on the lexemes (cf. Ernst (2013); Schweickard (2013)).

Somewhat more reliable sources for Romanian etymology, despite not having been designed to meet this purpose, but as explanatory dictionaries of the language, are Ţăineanu (1929), Scriban (1939) and DEX ((Academia Română, 1996 [1975]), second edition bis 2009, second edition ter 2012).

Since one of the requirements for this research was the use of complete and consistent sources that are, at the same time, available online, we resorted to the following dictionaries, listed below in order of their priority: DEX ’16, DEX ’09, DER (Cioreanescu, 1966), Scriban (1939), Ţăineanu (1929), DEX ’12, DEX ’98, DEX ’96, DEX ’84, DEX ’75, DEX-S (Academia Română, Institutul de Lingvistică din Bucuresti, 1988), DN (Marcu and Maneca, 1986), DLRLV (Costinescu et al., 1987). The order of the sources in our analysis was shaped according to their relative reliability, which was established following the empirical observations regarding the accuracy of the data provided.

2 Extracting and Processing the Data

In this section we describe our procedure for automatically extracting and processing etymological information for the Romanian lexicon.

Table 1: Examples of different formats for representing etymological information in dictionaries covered by dexonline for the Romanian word abajur (meaning lampshade), which is borrowed from the French word abat-jour.

2.1 Data

We identify the etymologies and etymons of Romanian words using dexonline,¹ a machine-readable dictionary which aggregates information from over 30 Romanian dictionaries. Some of these are restricted by license and copyright, but others are publicly available. Dexonline provides the public data as an SQL dump, which we import in a local database server for querying.² By parsing the definitions from the etymological dictionaries listed in the previous section, we automatically extract information regarding words’ etymologies. The definitions are partly formatted, with different formats for different dictionaries. We extract the relevant information using regular expressions. In Table 1 we provide examples of different formats for representing etymological information in dexonline.

When more options are possible for explaining a word’s etymology, dexonline provides several hypotheses. We account for all the given alternatives, enabling our method to issue more accurate results, both when a dictionary considers a word to have multiple etymology (e.g., DEX ’09 provides both French vérisme and Italian verismo as etymologies of verism, meaning “a literary and musical movement developed at the end of the 19th century”) and when different dictionaries provide different languages of origin (e.g., DEX ’09 provides Russian koleaska as etymology for calească (meaning carriage), while Scriban provides French calèche as etymology for the same word).

We introduce the order of priority mentioned in Section 1.2 in case different dictionaries provide different etymons (or different orthographic forms of the same etymon) for a certain word and language of origin (e.g., DEX ’09 provides French abattis as etymology for abatică (meaning abatis), while DN spells the word abbatis).

In cases of homonymy, we take into account all the separate dictionary entries. By homonyms we mean words that have the same form, but different origins (e.g., lac1 meaning lake, and lac2 meaning lacquer; according to DEX ’09, the first lexeme is inherited from the Latin word lacus, while the second one is borrowed from the German word Lack; the form coincidence derives from the historical phonetics of Romanian). All the values reported henceforth refer to words as conjunctions between a phonetic form and a conceptual content, taking into account their origin and history, and not only as raw word forms.

¹https://dexonline.ro

²We use the database backup available on January 17, 2021.
2.2 Processing

We employ several post-processing steps for the etymological information, mainly for cleaning and normalization. For etymons, we keep both the processed forms and the original ones, for future reference. We provide below some processing rules along with motivations.

For extracted source languages:

- Grouping together different abbreviations for source languages used by different dictionaries (e.g., \textit{tc}, \textit{tur}, \textit{turc}, \textit{turk} all refer to Turkish).

- Conflating different periods of some languages (e.g., we group \textit{vlat}, \textit{mlat}, \textit{nlat} – Old, Medieval, Neo-Latin under Latin), while keeping separated languages such as Old Slavic vs Slavic or Ancient Greek vs Neo-Greek.

For extracted etymons:

- Removing some diacritical symbols that mark the stressed syllable or vowel length and are not regularly rendered in the source language (e.g., Italian \textit{ab`ate} becomes \textit{abate} after removing the diacritical mark of the stress; Latin \textit{abbatt`ere} becomes \textit{abbattere} after removing the diacritical mark of a short vowel, which shows that the stressed syllable is the antepenultimate).

- Replacing the rough breathing mark ‘ with the letter \textit{h} for Greek etymons. This diacritical mark is rendered, in the transcription from Ancient Greek into Latin, by the letter \textit{h}, and we apply the same transformation (e.g., the Greek etymon \textit{onomophonos} of the word \textit{omofon} (meaning \textit{homophonous}) becomes \textit{homophonos} after removing the stress mark and replacing the rough breathing mark).

- Removing endings for the oblique cases of Latin or Greek etymons (e.g., \textit{marmor, -oris} for \textit{marmur} (meaning \textit{marble}), Neo-Greek \textit{`aroma}, \textit{ar`omados} for \textit{aromat} (meaning \textit{aromatic}) or secondary forms provided (e.g., Latin \textit{adnotare}, \textit{annotare} for a \textit{adnota} (meaning to annotate), French \textit{ballerin}, \textit{ballerine} for \textit{balerin} (meaning \textit{ballet dancer})).

- Removing the asterisk symbol that marks untested etymons (e.g., the Latin etymon *\textit{conquerire} of a \textit{cuceri}, meaning \textit{to conquer}).

- Removing letters provided between round or square brackets. The former represent the spelling from the cultured language for Latin (e.g., \textit{invol(u)tas}, etymon of \textit{invol}, meaning \textit{abundant}), but Romanian inherited words do not originate from the cultured language. The latter have different meanings, such as reconstructing an intermediary form of the word (e.g., Latin \textit{ecceum-\[i\]loc}), but in any case the information is not relevant for this study.

- Filtering out proper names, since they are not relevant for this study.

Table 3: The number of Romanian words that originate from each source language. We report only the languages from which at least 100 words originated.

3 Quantitative Analysis

In Table 2 we report the number of Romanian words having zero, one or multiple etymologies identified automatically. 48,887 words out of a total of 94,244 words have at least one automatically
identified etymology and this set will constitute our data from now on. In Table 3 we report the number of Romanian words that originate from each source language and how many of these words are verbs, adjectives and nouns. In Figure 1 we illustrate the distribution of Romanian words of different etymology, by proportion mapping. The bigger the bullet, the more Romanian words originated from the language in that geographical region. Note that we do not dispose of dated etymologies and so we lack the diachronic dimension; thus, different languages or different evolution stages of the same language are represented on the same territory (e.g., the two circles from Italy represent Latin and Italian and the three circles located in present day Bulgaria correspond to Old Slavic, Slavic and Bulgarian).

We also compared the data we obtained with the information we knew concerning the fundamental lexical core from Sala et al. (1988), namely 7.5% French borrowings and 30% Latin inherited words. We easily notice not only an inverted ratio between the quantity of words of Latin origin and those originated from French, but also a hugely expanded proportion of French borrowings. About 38% of the whole lexicon and almost 73% of the words that have at least one etymology attested in the dictionaries have French origin (versus only 7.5% of the representative lexicon), while the quantity of words of Latin origin (most of them inherited) hardly reaches 9% of the whole lexicon and 19% of the words that have at least one etymology attested in the dictionaries (versus the proportion of 30% for the fundamental lexical core). The gap is explainable by the distinction between the basic, common lexical core (covering 80% of everyday speech) and the cultured lexicon and specialised terminology, developed in the last century by massively borrowing lexical items from French.

Sorting the borrowings of each language by parts of speech highlights the significant quantitative breach between the nominal parts (by far the majority) and the verbal ones. But, while the inherited lexicon shows a ratio of 1 verb to 6 nominal parts (noun+adjective), the borrowing process has considerably enriched the quantity of nominal parts of speech, in detriment of the verbal ones: e.g., the French borrowings encapsulate a ratio of 1 verb to 12 nominal parts, the English ones display a ratio of 1 verb to 48 nominal parts, and the Turkish loanwords enclose a correlation of 1 verb to 388 nominal parts. This situation allows a deeper insight into the language structure, showing that expressing an action, state or occurrence requires a higher degree of internalized lexicon or of acquaintance with the language: we can deduce, on the one hand, that the speakers are able to express their experiences by using a fairly small number of verbs, but need to constantly increase the amount of nouns to designate the new objects they observe or concepts they acquire; on the other hand, morphosyntactic restriction may also play a part: while a nominal part of speech is easily adaptable to the morphological system of Romanian, the complex verbal conjugation may impede its immediate adoption. Also, it seems that the more related the source language is to Romanian, the easier is the morphosyntactic adaptation of verbs, which might explain the above ratio order, French, English, Turkish.

By classifying the lexicon in parts of speech, we also notice a shortcoming in the Romanian lexicography, namely the inconsistency of lexicographers when establishing the period when a word of Slavic origin entered the Romanian language: from this categorization it results that only one verb was borrowed from Old Slavic, while more than 200 come from Slavic. It is, however, evident that many fundamental verbs of Slavic origin have penetrated during the period of early contact between the two communities, thus, originate from Old Slavic (e.g., a iubi (meaning to love), a citi (meaning to read), a gresi (meaning to make a mistake)). In this case, we only highlight a terminological misunderstanding.

In order to quantify the resemblance between Romanian words and their etymons, for different source languages, we compute the edit distance (Levenshtein, 1965) for \{word, etymon\} pairs, using the post-processed etymon form (see Section 2.2). The edit distance counts the minimum number of operations (insertion, deletion and substitution) required to transform one string into another. We use a normalized version of this metric, dividing the edit distance by the length of the
longest string. The obtained values are between 0 and 1; the lower the values, the closer the Romanian words are to their etymons. In Figure 2 we report the average edit distance between the Romanian words and their etymons, per language. Overall, Romanian words borrowed from English are closest to their etymons. For 990 out of 2,064 words with English etymology, the edit distance is 0, meaning that those Romanian words have not undergone any transformations when entering the language (e.g., marketing, management, avocado). For Latin, 633 out of 9,313 words are identical to their etymon (e.g., vultur, meaning vulture).

Figure 2: Average normalized edit distance between Romanian words and their etymons for the top 10 languages from Table 3.

4 Qualitative Analysis

4.1 Analysis of Lexicographical Errors

In order to evaluate our automatic method for extracting etymologies, we excerpt a sample of 1,000 words. We manually determine the etymologies of the words in the sample using the web interface of dexionline, we compare these results with the automatically obtained etymologies, and we report an accuracy of 99.2%.

The main error source is the recording of erroneous etymologies in the dictionaries. One of the most common errors is to consider the ultimate origin (either Latin or Ancient Greek) as the immediate etymology of a Romanian word, without taking into account its form and sometimes meaning, which point to a different source language. To take just an example, apotr´opaion meaning “magic remedy to ward off evil” is considered to be directly originated from Ancient Greek apôtro´paoion, but neither the form nor the meaning allows such supposition: on the one hand, it is not usual for a word borrowed as a proparoxytone (a word stressed on the ante-penultimate syllable) to become an oxytone (stressed on the ultimate syllable) in Romanian, on the other hand, the Greek word functioned as an adjective, apotrópaios, whose meaning tute-
lary / expiatory / abominable does not precisely match the Romanian significance. Nonetheless, if we take a look at the European modern languages, we can easily find the German lexeme Apotrop¨aum, meaning exactly “magic remedy to ward off evil”, as a term circumscribed to archaeology, both formally and semantically able to account for the Romanian word. Thus, it would be correct to indicate the German noun as the immediate origin of the Romanian word, and not the Ancient Greek adjective, with which it only has a distant connection.

A quite frequent error consists of almost automatically labelling a “cultural loanword” as French. For instance, the origin of Ro. helipot (meaning helipot) is attributed to a nonexistent French word “hélipot”. Similarly, certain dictionaries invent a French word acquisiteur (for acq´ereur) in order to explain Ro. achizitor (meaning acquirer). A similar example is that of Ro. national (meaning national), explained as a borrowing from Latin nationalis (to which the French word national is added, by virtue of the concept of multiple etymology). Nonetheless, the supposed Latin word nationalis is not documented in Latin, the concept being a modern one.

4.2 A Semantic Insight into the Romanian Lexicon’s Structure

In this section we provide an analysis of the etymo-
logical composition of the Romanian lexicon based on semantic fields.

We start by building a list of conceptual domains, based on the Romanian linguistic atlases (Puscaru, 1938–1942; Petrovici, 1956–1972), which provide a list of semantic fields that covers the vocabulary, containing as well the most usual terms belonging to each of these onomasiological fields. We select a subgroup of these, and merge a few together, resulting in a final list of 10 semantic fields. We then manually extract a selection of prototypical terms for each of the resulted groups, on average 36 terms per group. We employ these terms as seeds for automatically populating the semantic clusters, using semantic similarity metrics based on word embeddings, a standard method for measuring lexical semantic similarity in the field of computational
analysis of semantic change. In our study, we make use of word embeddings computed using the FastText algorithm, pre-trained on Wikipedia for the top six languages Romanian borrowed from. The vectors have 300 dimensions and were obtained using the skip-gram model described by Bojanowski et al. (2016) with default parameters. These embeddings have previously been used in studies on semantic similarity of cognate sets in Romance languages (Uban et al., 2019, 2021). To group the terms in our dataset into the different semantic fields, we apply a KNN classifier (k=7) trained on the pre-defined list of semantic groups and prototypical terms. We then retrieve for each semantic cluster the distribution of etymologies for the words it contains. In Table 4 we show the top languages found in the etymologies of words belonging to each cluster.

One can easily observe in Table 4 that in 9 out of 10 semantic domains the first 3 source languages are invariably French, Latin, and Italian, precisely in this order. In 6 out of 10 onomasiological fields, the fourth position is occupied by a Germanic language (either German or English), while in 2 cases it is the Greek language holding this position. In 8 out of 10 domains, at least one Slavic language is represented among the first 8 source languages. It is also noteworthy that the Slavic (probably Old Slavic, see the comment above in Section 3) is the third most represented language in the onomasiological field of animals, and the fourth in the domain of agriculture and fifth in personality / emotions. The Turkish language reaches its highest position (the sixth) in the semantic field of food and drink, which reflects the predominance of trade relations between the two communities. The constant presence of French and Italian (putting aside Latin, which is mostly the source for inherited, not borrowed words) as top source languages in the borrowing process, clearly shows that the genetic relations, on the one hand, and the cultural connections, on the other hand, prevail over the geographical contiguity in the selection of source languages for the lexical enrichment.

5 Conclusions

For historical, geographical and linguistic reasons, Romanian presents a complex lexicographic picture, especially in terms of etymology. While reliable etymological dictionaries for Romanian are still missing, we proposed a computer-assisted etymological analysis doubled by a linguistic manual verification and interpretation, using the available dictionaries via dexonline. The comparison between the obtained data and previous knowledge about the Romanian fundamental lexicon revealed an inverted proportion between French and Latin and a surprisingly high percentage of French borrowings. We visualized the Romanian etymologies per source language on a geographic map and we also minded their part of speech proportions and interpreted them. Error analysis showed that the automatic extraction was performed with high accuracy, while the remaining errors are due to erroneous etymologies from the dictionaries. Finally, we experimented with the etymological composition of the Romanian lexicon based on semantic fields. Starting from a list of conceptual domains, adapted from Romanian linguistic atlases, we automatically obtained 10 onomasiological fields containing Romanian words in our dataset and their etymologies. For each of these categories, we ordered the source languages and interpreted the results from a socio-cultural and historical point of view.

Ethics Statement

All our data are extracted from publicly available sources. There are no ethical issues in our work.
Acknowledgments
We would like to thank the reviewers for their helpful comments. All authors contributed equally to this work. This research is supported by a grant of the Ministry of Research, Innovation and Digitization, CNCS/CCCDI UEFISCDI, project number 108, COTOHILI, within PNCDI III.

Abstract
Edit-based text simplification systems have attained much attention in recent years due to their ability to produce simplification solutions that are interpretable, as well as requiring less training examples compared to traditional seq2seq systems. Edit-based systems learn edit operations at a word level, but it is well known that many of the operations performed when simplifying text are of a syntactic nature. In this paper we propose to add syntactic information into a well known edit-based system. We extend the system with a graph convolutional network module that mimics the dependency structure of the sentence, thus giving the model an explicit representation of syntax. We perform a series of experiments in English, Spanish and Italian, and report improvements of the state of the art in four out of five datasets. Further analysis shows that syntactic information is always beneficial, and suggest that syntax is more helpful in complex sentences.

1 Introduction
Automatic Text Simplification (ATS) aims to reduce the linguistic complexity of a text for a certain target audience. ATS is useful for people learning foreign languages, suffering cognitive disabilities, or with low literacy level. The area of application of ATS is however not restricted to humans, as it has also been used to improve automatic NLP tasks such as parsing (Chandrasekar et al., 1996a), summarization (Beigman Klebanov et al., 2004; Silveira and Branco, 2012), semantic role labeling (Vickrey and Koller, 2008; Woodsend and Lapata, 2017), information extraction (Evans and Orasan, 2019) and machine translation (Gerber and Hovy, 1998; Štajner and Popovic, 2016; Hasler et al., 2017), among others.

ATS is often cast as a machine translation task, where the system receives complex sentences as input, and produces sentences that are simpler yet maintaining the original meaning. While early ATS systems were rule-based, statistical or hybrid (Saggion, 2017), in the last years neural network based ATS approaches have also been proposed (Alva-Manchego et al., 2020). In particular, sequence-to-sequence (seq2seq) neural models (Sutskever et al., 2014; Nisioi et al., 2017; Zhang and Lapata, 2017a) have shown to obtain state-of-the-art results. Such systems are trained on parallel corpora comprising pairs of complex/simple sentences, and implicitly learn the simplification rewrites needed to convert complex sentences into simpler ones.

Neural seq2seq systems are usually black boxes that are trained on an end-to-end fashion. As a consequence, built models are usually very difficult to interpret, and offer little control or hints that explain why a particular input word sequence has been rephrased. Edit-based ATS systems try to overcome this limitation by learning the transformations required to convert complex sentences into their simpler counterparts. The set of transformations is limited and known beforehand, and usually comprise edit operations such as delete, removal or lexical substitution (Alva-Manchego et al., 2017; Dong et al., 2019; Kumar et al., 2020). Because the set of allowed operations is restricted, the search space is considerably reduced. As a consequence, edit-based models are usually sample efficient and require less training examples compared to traditional seq2seq systems (Mallinson et al., 2020; Omelianchuk et al., 2021).

Edit-based ATS systems learn edit transformations at a word level, but often those operations are applied to whole phrases. Besides, systems need to capture long range relations among words, such as syntactic and phrase structures. For example, in the English sentence presented in Table 1 there is a long subject “Dry air wrapping around the southern periphery of the cyclone” that causes the...
Dry air wrapping around the southern periphery of the cyclone eroded most of the deep convection by early on September 12. In this sense, the president of the National Hunting Office, Juan Antonio Sarasketa, assured that this regulation project makes it impossible to possess and use weapons, (…) the president of the National Hunting Office, Juan Antonio Sarasketa, assured that this regulation project makes it impossible to possess and use weapons, (…) the president of the National Hunting Office, Juan Antonio Sarasketa, assured that this regulation project makes it impossible to possess and use weapons, (…) the president of the National Hunting Office, Juan Antonio Sarasketa, assured that this regulation project makes it impossible to possess and use weapons, (…)

Table 1: Sentences with long sentences (English) or subordination clauses (Spanish) cause ATS to fail.

The contributions of this paper are the following:

- We present a method to integrate syntactic information into an edit-based seq2seq system.
- The results confirm our intuition that syntactic information is useful for ATS systems. The new system surpasses previous state of the art in four out of five datasets. We conduct an ablation study that shows the effect of removing the syntactic information from the system.

This paper is structured as follows: in Section 2 we present the work done with dependencies, graphs and recent ATS systems; in Section 3 we describe our approach, in Section 4 our experiments and in Section 5 the results, we conclude and outline the future work in Section 7.

2 Related Work

Sentence simplification (SS) aims to reduce a sentence’s reading complexity while preserving its meaning. Recently, systems based on neural networks are gaining attention in ATS. For more information about previous works in ATS the interested reader is referred to these works (Shardlow, 2014; Siddharthan, 2014; Saggion, 2017; Alva-Manchego et al., 2020; Sikka et al., 2020). In this section, we focus on work that are based on dependencies and on one of the recently developed techniques, which is based on editing to simplify the text.

Dependency based simplification has proven to be effective in rule based and statistical simplification to analyze the texts and induct rules in the rule-based and hybrid architectures of ATS systems (indeed, the first module was a parser and many works have relied on dependency parsers) (Chandrasekar et al., 1996b; Woodsend and Lapata, 2011; Siddharthan, 2011; Klerke and Søgaard, 2013; Aranzabe et al., 2013; Saggion et al., 2015) as well as to perform tree transformations together with statistical machine translation (Zhu et al., 2010).

However, in the last years neural approaches have gained interest in ATS and SS research. The most popular framework has been the seq2seq models, which mainly rely on RNN and transformer based architectures (Nisioi et al., 2017; Zhang and Lapata, 2017b). While the majority of ATS systems are supervised, some works have obtained good results using unsupervised approaches (Surya et al., 2019; Martin et al., 2020b).

One of the main drawback of the aforementioned approaches is the lack of interpretability, i.e., the extend to which a system can explain in a meaningful way why certain actions have been performed. Edit-based systems (Alva-Manchego et al., 2017; Dong
et al., 2019; Kumar et al., 2020) offer a solution to the interpretability problem, as they directly learn a sequence of edit operations that convert complex sentences into simpler ones. Alva-Manchego et al. (2017) present a machine translation system that predicts three explicit simplification operations (keep, replace and delete) in aligned pairs of complex-simple sentences. Dong et al. (2019) propose EditNTS, a neural programmer/interpreter that learns to generate edit operations (add, keep, and delete) in a sequential fashion. Kumar et al. (2020) design a scoring function that measures the quality of a candidate sentence based on the fluency, simplicity, and meaning preservation and generate the simplified candidate sentences by iteratively editing the given complex sentence. The operations they take into account are removal, extraction, reordering and substitution.

Syntactic information has been previously used in rule-based systems, for instance, as an indicator to identify the complexity of sentences (Evans and Orasan, 2018). On deep learning systems, graph convolutional networks (GCN) over dependency trees is a usual method that leverages syntactic information into the models, and captures long-range syntactic relations among words. GCNs generalize the convolution operation usually applied in images to arbitrary graphs, and allow to refine information associated to nodes according to the information in the neighbor nodes (Kipf and Welling, 2017). They have been successfully used in NLP tasks such as semantic role labelling (Marcheggiani and Titov, 2017), information extraction (Zhang et al., 2018) and aspect-based sentiment analysis (Wang et al., 2020). Contemporaneous to this work, Zhe Lin (2021) use semantic information in seq2seq systems by including in the graph of the source sentence the predicate-argument relations between content words in a sentence.

3 A Syntax-Aware ATS System

Our system is based on EditNTS, an edit-based system that has obtained state of the art results on many datasets. We start by briefly describing EditNTS. Then, we describe the graph convolutional network that leverages syntactic information derived from dependency trees. Finally, we describe how to integrate the syntactic module into EditNTS.

3.1 EditNTS

We start by briefly describing the EditNTS system, and refer the reader to Dong et al. (2019) for a more detailed description. Let $x = x_1, \ldots, x_{|x|}$ be a complex input sentence and $y = y_1, \ldots, y_{|y|}$ its simplified version. EditNTS learns to produce a series of edit operations $z = z_1, \ldots, z_N$ which, applied over the input sentence $x$, produces $y$. Each edit operation $z_i$ is one of $\{\text{ADD}(w), \text{KEEP}, \text{DELETE}\}$. EditNTS contains an encoder, decoder and interpreter modules, which are described as follows:

**Encoder**

The encoder transforms the input sequence $x$ into a sequence of output and hidden representations ($o_i$ and $h_i$):

$$o_i, h_i = \text{LSTM}(x_{1:i-1})$$  \hspace{1cm} (1)

where $x_i$ is the concatenation of the embedding of the word $x_i$ and the embedding corresponding to the POS tag of $x_i$.

**Decoder**

The decoder receives the input from the encoder, and predicts the next edit label $z_t$ for each timestep $t$. Internally, it contains two recurrent networks that represent the edit operations and the output words produced so far:

$$o_{t}^{\text{edit}} = \text{LSTM}(z_{1:t-1} \mid h_{|x|})$$

$$o_{t}^{y} = \text{LSTM}(y_{1:t-1} \mid h_{|x|})$$

where $z$ are the embeddings of the edit operations and $y$ are the output embeddings\(^1\). The decoder also uses an attention mechanism between the current edit operation and the input words. Let $O$ and $O^{\text{edit}}$ be the matrices whose rows are the output vectors for the encoder and edit recurrent networks, respectively\(^2\). The attention mechanism is defined as follows:

$$E = \text{softmax}(KO^{\text{edit}}O^T)$$

$$c_t = E_tO$$

where $K$ is a parameter learned by the model. The decoder predicts the next edit label $z_t$ using a sequence of linear layers and activation functions. The input of the linear layer $i_t$ is a concatenation

\(^1\)The embedding matrix is shared between the encoder and decoder.

\(^2\)That is, $O_t = o_t$ and $O_t^{\text{edit}} = o_t^{\text{edit}}$. Through the paper we use the notation $M_i$ to represent the $i$th row of matrix $M$.  

331
of the output representation of the input word currently edited $o_{ki}$, the output representation of the previously generated edit labels $o_{j}^{\text{edit}}$, the representation of the previous generated words $o_{j}$ and the attention vector $c_{i}$:

$$i_{t} = [o_{ki}; o_{j}^{\text{edit}}; o_{j}; c_{i}]$$

$$z_{t} = \text{softmax}(V^{t}(\tanh(Vh_{t})))$$

again, $V$ and $V'$ are parameters learned by the model.

**Interpreter**

The interpreter applies the predicted edit operation $z_{t}$ on current word $x_{ki}$ and produces a new word $y_{ji}$.

### 3.2 Graph Convolutional Network Module

To leverage syntactic information into EditNTS, we first compute the dependency tree of the complex sentence $x$, which is represented as an undirected graph. The nodes of the graph are the words in $x$, and the edges represent syntactic relations among them. The graph is represented as an adjacency matrix $A$, where $A_{ij} = 1$ if an edge between nodes $i$ and $j$ exist.

We then apply a series of graph convolutional operations over the syntactic graph using a Graph Convolutional Network module. The module contains a series of $L$ linear layers, each one applying a convolution operation over the graph:

$$h^{l+1} = \text{ReLU}(\tilde{D}^{\frac{1}{2}}AD^{\frac{1}{2}}h^{l}W^{(l)})$$

where ReLU is the linear rectifier activation function, $\tilde{A} = A + I_N$ is the adjacency graph with added self connections, $D_{ii} = \sum j A_{ij}$ is the degree matrix and $W^{(l)}$ is a layer specific parameter to be learned. $h^{0}$ is the input of the graph, a matrix that assigns an embedding to each vertex in the graph. At each level, the convolution operation aggregates the embeddings of neighbor nodes to produce new embeddings that implicitly encode the structure of the underlying graph.

### 3.3 Augmenting EditNTS with syntactic information

In our final system the GCN initial input $h^{0}$ is initialized with the encoder outputs $o_{t}$ of each word in the sentence, and the corresponding adjacency graph derived from the dependency tree. The output $h^{L}$ of the GCN module is then combined with the original $o_{t}$ vectors as a residual connection, which is then passed to the EditNTS decoder (see Figure 1).

### 4 Experiments

In this section we describe the experiments performed within this work. We start by describing the datasets used for training and testing the system, followed by the experimental setting, which includes a description of the metrics used to evaluate the models.

#### 4.1 Datasets and parameters

We experiment our approach on ATS datasets from three languages: English, Spanish and Italian. The datasets used for each language are the following:

<table>
<thead>
<tr>
<th>Dataset</th>
<th>Lang</th>
<th>Train</th>

<td>9.01</td>
</tr>
</tbody>
</table>

Table 3: Corpora statistics (train). Sentence length measures the number of tokens and the depth shows the depth of the dependency tree.
English We used two datasets for English, WikiLarge/TurkCorpus and Newsela. WikiLarge is one of the most used to train ATS systems and was built by automatically aligning sentences belonging to the same article in English Wikipedia and Simple English Wikipedia. We used the split provided by Zhang and Lapata (2017a) for training and development, with a total of 296,402 and 2,000 sentences, respectively. Following usual practice, we tested the models trained on WikiLarge using the TurkCorpus dataset (Xu et al., 2016), which contains eight manually generated reference simplifications for 359 sentences. Newsela consists of 1130 news articles that were rewritten four times at different complexity levels. We used the train/development/test splits from (Xu et al., 2015), containing 94,208/1129/1076 sentences respectively.

Spanish We used two datasets for Spanish, Simplext and Newsela-es. The Simplext corpus contains 200 news texts from different domains, that were manually simplified (Saggion et al., 2015). We use the splits provided by Martin et al. (2020b) with 574/143/693 sentences for training, development and test. Newsela-es is similar to its English counterpart, we used the splits from Palmero Aprosio et al. (2019) and comprises 50,301/2,794/2,795 sentences for train/dev/test.

Italian For Italian we use the documents provided by Palmero Aprosio et al. (2019), a corpus containing 32,210 complex-to-simple pairs sentences that were obtained by merging three available data sets: the SIMPITIKI corpus (Tonelli et al., 2016), the corpora Terence and Teacher (Brunato et al., 2015), and a subset of the PaCCESS-it corpus (Brunato et al., 2016).

Table 2 shows the size of each dataset, and in Table 3 we present the average and standard deviation of the sentence length and depth for each corpus, for both the complex and simple sentences. The sentence length measures the number of tokens of each sentence and the depth shows the maximum depth of the dependency trees.

4.2 Experimental settings

We tokenized and syntactically analyzed the documents with spacy\(^4\), using the large models for each particular language. All words were lowercased. In the case of Newsela, we follow (Xu et al., 2015) and replace all named entities with a placeholder that represents the entity type.

During training, a teacher forcing strategy is followed half of the times. When teacher forcing is followed, the decoder is provided with the gold edit labels and target token; when not, the decoder at each time step is fed with the output produced in the previous edit label and target token. Default hyperparameters from EditNTS are used, and no hyperparameter tuning was performed: a batch size of 64, a hidden dimension of 200 and a learning rate of $10^{-3}$. We used Adam optimizer and a decay factor of $10^{-6}$. The models are trained during 50 epochs, and the model that obtained the best SARI score in the corresponding development split is selected and tested.

Table 5: Example of a sentence from Turkcorpus, Newsela-ES and the Italian corpus.

Regarding evaluation, the following evaluation metrics are used:

- **SARI** is a common evaluation metric for ATS systems (Xu et al., 2016) that measures the number of ngrams that have been added/removed/kept by the simplification system.

- **BLUE**. Following usual practice, we also include the BLUE score (Papineni et al., 2002) between the complex and simple sentences. Although BLUE has been criticized as a measure to evaluate simplification systems (Sulem et al., 2018; Dong et al., 2019; Martin et al., 2020b), we use it here for completeness.

We compute the evaluation metrics using the EASSE package (Alva-Manchego et al., 2019). We do not report the readability score Flesch–Kincaid Grade Level (FKLG) (Kincaid et al., 1975) because it is a language dependent metric which is only valid for English.

### 4.3 Baselines

We use the Identity baseline that simply copies the complex sentence. Apart from this, we compare our syntax-aware system against the state-of-the-art on each language. For English, we consider the deep reinforcement based neural system DressLS (Zhang and Lapata, 2017a), the transformer based model DMASS-DCSS (Zhao et al., 2018) and BART+ACCESS (Martin et al., 2020b), which also includes special tags to perform controllable text generation. There are fewer systems to compare against in the Spanish and Italian datasets, as, like many other areas in NLP, ATS systems have been developed mostly for English. For Newsela-es and the Italian dataset, we compare ourselves Neural TS (Palmero Aprosio et al., 2019), an MT system based on an attention encoder-decoder model. Finally, for Simplext we include the unsupervised system in Martin et al. (2020b). In the datasets for English we also report the results of EditNTS (Dong et al., 2019) with no syntax.

### 5 Results

Table 4 shows the results of our syntax aware system (dubbed Edit+synt in the tables), and compares them with the best performing systems on the different datasets. We see that the syntax aware system obtains very good results overall, and improves state of the art SARI results in four out of five datasets. This is a remarkable result that stresses the importance of syntax in text simplification. The table shows that datasets with smaller training data are most benefited from our approach, and suggests that the combination of edit operations and syntactic information is able to generalize in low training data regimes.

It is worth noting that the results obtained by us when running EditNTS without syntax are different to those reported in (Dong et al., 2019), and that the gap is specially large in the Wikilarge/Turkcorpus dataset\(^5\). We attribute this difference to the fact that the reported results in the original paper are obtained using the model that performed best in the test split, whereas we performed model selection according to the development dataset (c.f Section 4.2). There is also a slight difference in the Newsela dataset, which we attribute to the use of different evaluation scripts.

\(^5\)The latter results are marked with † in the tables.
Table 6: Main results. No syntax stands for the original system, whereas Syntax uses syntactic information. The ∆ measures the difference between both systems.

6 Analysis

In this section we perform an analysis of the results. We start by analyzing examples of the outputs, followed by an ablation study. Finally, we analyze the effect of the sentence complexity in the simplification process.

6.1 Output analysis

In Table 5 we present three sentences, one for each language that we explain next. In the English sentence (from Wikilarge), we see that both systems have been able to carry out a sentence splitting, but in the second sentence of the edit system the subject (he) is missing, which makes the ungrammatical (note that in the reference sentence, the pronoun is not correct). In the Italian sentence (from PaCCSS-it,SIMPITIKI, Terence-Teacher), the edit system has deleted the subject and it is ungrammatical (it could be grammatical with a different word ordering). The sentence created by Edit+synt has changed the modality of the verb (è ‘it is’-> può essere ‘it can be’)) and deleted the attribute più interessante ‘more interesting’, and this affects the meaning of the sentence. All in all, our analysis suggests that there is still a large room for improvement in non-English simplification. For example, the Spanish example in Table 5 is not correct at grammatical level: there is a dequesismo, which is the misuse of the preposition de in front of the conjunction que when the preposition is not required like in this case by the verb decir. This is not grammatically correct but it can be understood without problems. Moreover, the dequesismo is a common mistake by many speakers, and it would be interesting to check the corpus to find out if there are non standard grammatical variations or misuses. However, the main problem of the sentence is related to lexical simplification. The verb se agrava (it worsens) has been replaced with se reduce (it reduces). This is a wrong simplification, but if the sentence was not comprehensible at grammar level, the meaning preservation and simplicity cannot be correctly evaluated.

6.2 Ablation study

Table 6 shows the results of the system using syntactic dependencies or not. We see that, in general, syntactic dependencies are helpful and lead to an improvement in SARI on all datasets. The gain in SARI is particularly large in the Newsela and Simplext datasets, which are the datasets with highest average sentence depths. These results suggest that syntactic information is particularly helpful when simplifying complex sentences. This trend does not hold if we compare the SARI gain with the average sentence length. We analyze this correlation further in the next section. Regarding BLEU, the table shows mixed results, with gains in all datasets except in Newsela and Newsela-es.

6.3 The effect of the sentence complexity

The results in the ablation study indicate a correlation between the sentence complexity and the performance gain obtained when using syntactic information, and now we analyze this correlation further. Figure 2 shows an analysis of length and depth per sentence that helps understanding this relationship. The x axes in the figures correspond to the sentence depth (left) and length (right), and the y axes show the average SARI gain, that is, the average of the differences between the Syntax and No syntax scores for all sentences with one particular depth or length. While the results vary among datasets, the left graph shows a general tendency where the gain of using syntax is greater on the deepest sentences. That is, sentences that have complex dependency trees are better simplified, according to SARI, when using syntactic information.

The graphs have been smoothed using the Exponential Moving Average (EMA) technique with a smoothness factor of 0.75 to flatten the peaks. While the smoothing process removes information from the graph, the loss is outweighed by the improved visibility.
This gain is particularly high on the Newsela, WikiLarge/TurkCorpus and Simplext datasets.

The right graph in Figure 2 shows no overall correlation with the sentence length and the SARI gain. This result suggests that the length of a sentence per-se is not a valid indicator of the syntactic complexity of the sentences.

7 Conclusion and Future Work

In this paper we show that syntactic information is a valid source of information for edit-based text simplification systems. We have presented a system that extends a well known edit-based system with explicit syntactic information derived from dependency trees, by virtue of graph convolutional networks. The results show that the dependency information is useful, obtaining state of the art results on four out of five datasets in different languages. Further analysis show that the syntactic information is always beneficial (sometimes by a large margin), and that the improvement is often correlated with the depth of the dependency tree.

In the future we want to analyze the inclusion of dependency syntax information into transformer based seq2seq systems. In particular, we want to analyze whether explicitly modeling syntactic information is still a valid approach when the transformer based ATS system is initialized with large language models such as BART (Lewis et al., 2020).

Abstract

To fully model human-like ability to ask questions, automatic question generation (QG) models must be able to produce multiple expressions of the same question with different levels of detail. Unfortunately, existing datasets available for learning QG do not include paraphrases or question variations affecting a model’s ability to learn this capability. We present FIRS, a dataset containing human-generated fact-infused rewrites of questions from the widely-used SQuAD dataset to address this limitation. Questions in FIRS were obtained by combining a given question with facts of entities referenced in the question. We study a double encoder-decoder model, Fact-Infused Question Generator (FIQG), for learning to generate fact-infused questions from a given question. Experimental results show that FIQG effectively incorporates information from facts to add more detail to a given question. To the best of our knowledge, ours is the first study to present fact-infusion as a novel form of question paraphrasing.

1 Introduction

Recently, automatic Question Generation (QG) is being addressed for generating natural language questions for a given input text passage. Viewed as the reverse of the well-studied question answering task (QA), QG has been applied in education and tutoring (Heilman and Smith, 2010; Lindberg et al., 2013), dialog systems and chatbots (Shum et al., 2018), as well as for improving QA systems (Duan et al., 2017; Tang et al., 2018).

Various deep learning models are being rapidly developed for QG (Talmor and Berant, 2018; Kim et al., 2019; Tuan et al., 2020; Pan et al., 2020; Su et al., 2020; Wang et al., 2020a). However, it is only recently that QG studies have started focusing on an important aspect of the human question generation process known as paraphrasing, or the ability to ask questions in diverse ways all expressing the same intent (Harrison and Walker, 2018; Wang et al., 2020b).

Paraphrasing ability has been identified as a necessary aspect of learning human-like language generation (Shum et al., 2018; Huang et al., 2020) and was previously studied in context of community QA (Liang et al., 2016; Kunneman et al., 2019; Hosking and Lapata, 2021). These works address the identification of synonymous and syntactic question variations such as (“What’s the weight of an elephant in kg?”; “How heavy is an elephant?”). In addition to synonymous variations, human beings are also adept at generating questions expressing the same intent with varying level of details. For example, consider a QA pair from the SQuAD dataset1 shown in Table 1. SQuAD is one of the widely-used datasets for training QG models and contains about 100K training instances made up of an answer context, the answer string, and a “correct” question (Rajpurkar et al., 2016). We show in Table 1, fact-infused rewrites (or alternatively, variations) for the SQuAD question: “In what year did IBM get its name?”. Except question 2 which is a synonymous variation, the other variations include additional details of the entity “IBM” obtained from Google’s Entity Search API.2

We argue that question variations that include more detail can provide a form of query expansion and are likely to benefit downstream applications. Indeed, it has been observed that content words and named-entities referenced in the question improve the answerability of a question (Nema and Khapra, 2018) and result in improved QA and reading comprehension performance through the addition of

In what year did IBM get its name?

The company originated in 1911 as the Computing-Tabulating-Recording Company (CTR) through the consolidation of The Tabulating Machine Company, the International Time Recording Company, the Computing Scale Company and the Bundy Manufacturing Company. CTR was renamed “International Business Machines” in 1924, a name which Thomas J. Watson first used for a CTR Canadian subsidiary. The initialism IBM followed. Securities analysts nicknamed the company Big Blue for its size and common use of the color in products, packaging and its logo.

2 Related Work

Models for question generation and question answering are being rapidly developed in current NLP research. We refer our reader to a survey by Pan et al. (2019) for an overview on challenges, existing approaches, as well as evaluation metrics for QG. Several QG models use LSTM-based encoder-decoder setups with attention and copy mechanisms (Zhou et al., 2018; Duan et al., 2017; Zhao et al., 2018; Kim et al., 2019). Recent works are focused on improving QG performance by incorporating external knowledge, semantic information, and reinforcement learning into this basic architecture (Nema et al., 2019; Pan et al., 2020; Wang et al., 2020a; Majumder et al., 2021). Other state-of-the-art QG frameworks include variational autoencoders, graph convolutional networks and transformers (Lee et al., 2020; Su et al., 2020; Kriangchaivech and Wangperawong, 2019).

Paraphrase generation is a related task for identifying semantically similar texts in applications such as retrieval and question answering, query re-formulation and dialog system applications (Liang et al., 2016; Zhao and Wang, 2010). Similar to QG, seq2seq models and encoder-decoder architectures are common in paraphrase generation works (Gupta et al., 2018) but other approaches for paraphrase generation include variational autoencoders and translation models (Wang et al., 2019; Li et al., 2018; Hosking and Lapata, 2021).

3 FIRS Dataset Creation

As highlighted in Section 1, existing datasets for QA/QG and paraphrase generation do not include question variations with details. To fill this gap, we collected a new dataset by integrating the questions in the widely-used Stanford Question Answering Dataset (SQuAD) with relevant facts obtained from Google’s Entity Search API as follows:

**Collecting candidate question-entity pairs:** We selected from SQuAD, questions that refer to named entities in either the (1) question or (2) answer texts. In Table 1, we showed an example where the relevant entity *IBM* is mentioned in the question text. For the second case, consider a question from the SQuAD dataset from a passage on *Computer Security*, namely, “What is the source of the quote?” with the corresponding answer string “Reuters”. Nowhere in the SQuAD answer passage for this question is a mention of what “Reuters” is but using its entity description from Google, example paraphrases created by our crowdworkers for this question include “What news agency is the source of the quote?” and “Which international news organization is the source of the quote?”. This example highlights how a vague “What is” question can be expanded through the addition of the answer type (“news agency”) detail.

We obtained the subset of 25,316 questions from the 100K questions in SQUAD which reference ‘tangible’ named-entity types such as people, places, and organizations. Entity types referring to concepts such as “quantity, percent etc” are not supported in currently-available knowledge resources. For example, for the *IBM* question in Table 1, it is difficult to obtain focused knowledge pertaining to the answer “1924” (of type “date”).

<table>
<thead>

<td>International Business Machines Corporation is an American multinational technology company headquartered in Armonk, New York, with operations in over 170 countries.</td>
</tr>
</tbody>
</table>

Table 2: Search Result for “IBM” on the Entity Search API

**Obtaining Entity Descriptions:** We performed entity searches through the Google Knowledge Graph Entity Search API (GES) using the entity names as query strings. Next, entity-type match rules and text similarity thresholds were applied based on the source SQuAD passage to identify the correct entity description from the search results. We were able to obtain descriptions for 62,473 entities referenced in SQuAD questions using the above process. Based on crowdsourced annotations (described next), the precision of our search and filtering is \( \sim 97\% \). An example search result from GES along with its different fields is shown for the query “IBM” in Table 2.

We note that compared to other resources such as DBpedia (Lehmann et al., 2015) and YAGO (Hofart et al., 2013), the coverage of entities and facts is several scales higher in GES. After manually examining hundreds of results, we found GES to be consistently superior and accurate for our purpose. The “detailed description” fields were used by our crowdworkers while creating the question paraphrases. A limitation however is that there is no official documentation on the resources and algorithms employed in GES and neither is the full-

---

6[https://en.wikipedia.org/wiki/Knowledge_Graph](https://en.wikipedia.org/wiki/Knowledge_Graph)
type hierarchy information directly available given its proprietary nature.7

Creating ground truth paraphrases: We randomly sampled a subset of about 1600 (question, entity) pairs collected from Steps 1 and 2 for obtaining human-generated question variations. We set up our task through the crowdsourcing platform Amazon Mechanical Turk (AMT) following similar dataset collection efforts (Rajpurkar et al., 2016; Yang et al., 2018; Harrison and Walker, 2018). Each question, along with the entity descriptions was examined by three crowdworkers. The answer passage with the answer highlighted was also provided for the workers to identify cases where the entity is not relevant.

We required the crowdworkers to have greater than 95% HIT approval rate, a minimum of 10,000 HITs, and be located in the United States. The workers were instructed to “Rewrite the original question in more details using information from the provided knowledge” and to “Ensure that the intent of the original question remains the same.” Several examples of good and bad rewrites along with detailed explanations were included as guidance. At least one and up to three different re-writings were collected for each question per crowdworker.

After pooling the results of the AMT task, filtering out duplicates and variations that do not include any word from the extra knowledge (such as rewrite#2 for IBM in Table 1), our dataset has an average of four fact-infused variations for each question and is summarized in Table 3. We refer to our dataset as FIRS for Fact-Infused Rewrites of SQuAD questions.

3.1 Analysis of FIRS

We analyzed the question rewrites in FIRS along two dimensions, namely, (i) Diversity and (ii) Details. That is, a fact-infused rewrite should retain the semantics of the base question (original question from SQuAD) in terms of its intent but have other words that add extra details of relevant entities. To characterize this aspect, we employ the Simple Approximate Bigram Kernel (SBAK) similarity to measure the pairwise similarity between two sentences. Dependency-tree based similarity measures that account for partial matches and type of dependency edges are known to better represent semantic similarity between two sentences compared to bag-of-words similarity functions (Ambati, 2008; Özateş et al., 2016).

In Table 4, the average values of pairwise similarities of the fact-infused question variations with each other are shown in the “Intra-Set” column and with the base question are shown in the third column. The high SBAK similarity is indicative of semantic or intent similarity between the base question and the variations. However, the Jaccard overlap scores between the word sets (computed without stopwords) is lower due to the additional words present in the rewrites.8

The percentage spread of the parts-of-speech tags for the words added in rewritten questions are shown in Table 4. Not surprisingly, about 37% of the newly-added words are proper nouns or nouns whereas about 33% of words refer to adpositions, adjectives, and determiners that are often assigned to words surrounding noun phrases.9 These assignments indicate that the extra words added in rewrites are often content words and therefore, can be expected to improve the answerability of questions (Nema and Khapra, 2018).

Additional Notes on Data Collection: We performed the following checks to meet the ethics, quality, and reliability considerations for our collected questions. As part of the AMT data collection process, the anonymity and privacy of the crowdworkers is already ensured. Furthermore, the settings for the HIT approval rates, and location of

---

7Further details of the search result filtering processes are provided in the Appendix (See Footnote 5).

8The formulae from Özateş et al., 2016 are included in the Appendix for reference.

9https://universaldependencies.org
the worker, described previously are set similar to previous QA/QG data collection efforts to ensure the English language skills of the data annotators. A remuneration of $0.20 per assignment was paid to each worker. A total of 75 workers helped in creating our dataset, with about 47% of the workers labeling less than 5 questions each.

We ensure quality of the collected question variations, by employing a set of rules based on the a) similarity with the original question, (b) similarity within the collected paraphrases, (c) presence of the answer token, and (d) length of the rewritten question versus the original question. About 3% of the collected data was filtered out with the above rules. Finally, at every step of data collection, we performed checks manually on random subsets of the collected data to ensure the reliability of the named-entity taggers, the entity descriptions filtered from GES results as well as the quality of the rewrites produced by the workers.

4 Generating Fact-Infused Questions

Definition: Given two input sequences of \(|n|\) base question words, \(Q^b = q_1, q_2 \ldots q_n\), and \(|m|\) words of a fact related to an entity, \(F = f_1, f_2 \ldots f_m\), the objective of fact-infused question generation is to generate an output sequence of \(|k|\) words, \(Q^p = p_1, p_2 \ldots p_k\), such that \(Q^p\) is a fact-infused rewrite of \(Q^b\). That is, \(Q^p\) includes specific details from \(F\) while maintaining the intent of \(Q^b\) and our goal is to find \(Q^p\) that maximizes the conditional likelihood:

\[
Q^p = \arg\max_{Q} \mathcal{P}(Q|Q^b, F)
\]

We follow standard question generation approaches and adopt an attention-based encoder-decoder architecture for estimating the probability function, \(\mathcal{P}\) (Bahdanau et al., 2015; Sutskever et al., 2014; Kim et al., 2019). The main components of our Fact-Infused Question Generator Network (FIQG) are depicted in the schematic diagram in Figure 1 and summarized below:

**Fact and Question Encoders**: We use separate encoders for representing the question and fact sequences. The encoders are one-layer bidirectional LSTMs that extract contextual features from the input question (or alternatively, fact) and represent them as hidden states of the forward and backward LSTMs. Let \(E^i(Q^b)\) and \(E^i(F)\) represent the feature-rich embeddings of our base question and fact, respectively (Zhou et al., 2018). Then,

\[
E^i(Q^b) = [E^i(q_1), \ldots, E^i(q_n)]
\]

\[
E^i(F) = [E^i(f_1), \ldots, E^i(f_m)]
\]

where \(E^i(w)\) refers to the input feature embedding for word \(w\). Using LSTM notations, the hidden state for the fact encoder is therefore given by

\[
o_t^F = [\overrightarrow{h}_t^F; \overleftarrow{h}_t^F]
\]

where \(\overrightarrow{h}_t^F\) and \(\overleftarrow{h}_t^F\) are the hidden vectors of the forward and backward LSTMs, respectively, at time \(t\) and \(;\) represents the concatenation operator. The hidden state for the question encoder can be similarly represented as

\[
o_t^Q = [\overrightarrow{h}_t^Q; \overleftarrow{h}_t^Q]
\]

Next, applying the attention mechanism (Bahdanau et al., 2015) for the question encoders over its hidden states, the attention weighted sum of the contextualized question can be written as

\[
g_t = \sum_{i=1}^{n} \alpha_{ti} o_t^{Q^b}
\]

\[
\alpha_{ti} = \frac{\exp(a_{ti})}{\sum_{k=1}^{n} \exp(a_{tk})}
\]

\[
a_{ti} = f(s_{t-1}, o_t^Q)
\]

where \(\alpha_{ti}\) represent the attention weights with parameters \(a_{ti}\) such that \(Y_t^{Q^b} = \{\alpha_{ti}\}_{i=1}^{n}\) is a probability distribution over the question words. The values of \(a_{ti}\) depend on the hidden state of the decoder at the previous timestep \(s_{t-1}\), and the hidden state of the question encoder:

\[
f(s_{t-1}, o_t^Q) = v_E^\top \tanh(WE[s_{t-1}; o_t^Q])
\]

![Figure 1: Fact-Infused Question Generator Network.](image-url)
where $v_E$ and $W_E$ are learnable parameters.

The attention weights and vectors for the fact encoder are calculated similarly. We use $\gamma_{it}$ to refer to the parameterized and normalized attention weights for the fact encoder and $Y^F_t = \{\gamma_{jt}\}_{j=1}^m$ is a probability distribution over the fact words. The context vector for the fact can be written as:

$$m_t = \sum_{i=1}^{m} \gamma_{it} o^F_{it}$$

**Decoder:** The decoder takes the hidden states from the question and fact encoders to generate the paraphrased sequence of words. Our decoder is a uni-directional LSTM network whose state and context vectors are represented by $s_t$ and $i_t$, respectively, such that:

- $i_t = [E^d(p_{t-1}); m_{t-1}; g_{t-1}]$
- $s_t = LSTM(i_t, s_{t-1})$
- $s_0 = \overrightarrow{R}_1^0$

Here $E^d$ refers to the embedding from the decoder for the paraphrase word, $p_{t-1}$. The current context and decoder state vectors are combined with the attention vector from the question encoder to obtain the readout state and subsequently the generative probability distribution over the vocabulary using a maxout layer (Goodfellow et al., 2013):

$$r_t = W_r s_t + U_r i_t + V_r g_{t-1}$$
$$Y^V_t = \text{softmax}(W_y \text{ maxout}(r_t))$$

The matrices $W_y$, $W_r$, $U_r$ and $V_r$ are all learned during training.

**Copy mechanism:** Recent works for QG handle rare words by employing a pointer network that enables both copying of the words from the input source (answer passage) and generation of words during the decoding process (Gulcehre et al., 2016; See et al., 2017). For question rewriting using facts, we extend this copy mechanism to enable copying from both the input fact words as well as the question words. The copy switch in our case is a softmax function given by

$$p = \text{softmax} \left( W_{copy} s_t + U_{copy} g_{t} + Z_{copy} m_t + b \right)$$

where the matrices $W_{copy} \in \mathbb{R}^{3 \times |s_t|}$, $U_{copy} \in \mathbb{R}^{3 \times |g_t|}$ and $Z_{copy} \in \mathbb{R}^{3 \times |m_t|}$ are learnable parameters and $b$ is the bias parameter.

During the decoding step, $p$ is sampled to (1) copy the words from the question, based on $Y^Q_t$, the normalized, attention weights from the question encoder, or, (2) copy words from the fact based on $Y^F_t$, the normalized, attention weights from the fact encoder, or (3) generate a new word, based on $Y^V_t$, the generative distribution on the vocabulary estimated during learning.

### 4.1 Baselines

Considering the novelty of our proposed task, we are limited in our choice of baselines for comparing with FIQG. However, we note that similar to our objective which involves the infusion of parts of an entity fact into a given base question along with possible re-writing of the “wh”-word (for example, “Where” to “Which <location>”), existing QG approaches involve the inclusion of parts of an answer passage into a generated question template using attention and copy mechanisms. Thus, a straightforward application of QG models for our task would involve retraining the model using input passages comprising of both the base question and the fact sentences.

We also highlight that existing paraphrase generation models operate on a source question and generate synonymous variations by substituting specific words with related words and syntactic variations by using other exemplar questions (Fu et al., 2019; Hosking and Lapata, 2021). Consequently, we find QG models more appropriate for fact-infusion and compare FIQG with the following state-of-the-art QG baselines:

1. **NQG**\(^{10}\) is one of the earliest neural seq2seq models proposed for QG using feature-rich input embeddings comprising of words, answer position, parts-of-speech, NER and case information (Zhou et al., 2018).

2. **SGDQG**\(^{11}\) is a recent model designed to generate complex questions that require reasoning on multiple pieces of information (for example, in the HotpotQA dataset). SGDQG uses semantic graph information constructed from NLP relations between words in the passages (Pan et al., 2020).

3. **GSAQG**\(^{12}\) uses maxout pointer mechanism

\(^{10}\)https://github.com/magic282/NQG

\(^{11}\)https://github.com/YuxiXie/SG-Deep-Question-Generation

\(^{12}\)https://github.com/seanie12/neural-question-generation
with gated self-attention network to handle long text inputs (Zhao et al., 2018).

4. RefNet$^{13}$ is a two decoder based model where a second decoder refines the output from the first decoder for generating more complete questions (Nema et al., 2019).

5. ASs2s$^{14}$ employs an answer-separated seq2seq approach along with a keyword-net and interrogative word identification to handle irrelevant words in generated questions (Kim et al., 2019).

We note that QG models are being widely investigated in current research and some recent innovative aspects in learning QG include the use of variational encoders, graph convolutional networks, and incorporation of global and semantic knowledge (Pan et al., 2020; Wang et al., 2020a; Su et al., 2020; Majumder et al., 2021). Keeping the novelty of our task and dataset in mind, we compare against state-of-the-art models that use components very similar to FIQG and defer the investigation of more recent QG research on FIRS for future.

5 Experiments and Results

Implementation: We implemented FIQG in Python.$^{15}$ The hidden state sizes for the two encoders and the decoder are set to 256, whereas the depth for the attention mechanism is set to 512. The readout size is 128 whereas vocabulary size is $\sim 20K$ words, and the target sequence length was set to 50. Dropout rates are set to 0.5 for the dense layers and 0.3 for the attention layers, respectively. A learning rate of 0.001 was used.

Feature-rich embeddings (Zhou et al., 2018) were used for input representations using word, parts-of-speech tags and indicator embeddings. Indicator features using the BIO representation are incorporated in QG models to indicate the answer span in a passage to focus the question around the answer. For our case, this aspect corresponds to the named-entity whose fact we are integrating into the question. However, to differentiate the two cases, namely, when the entity is part of the answer versus when the entity name is part of the question, we use an extended set of tags: \{BA, IA, BN, IN, O\}.

Fact Extraction: The entity descriptions obtained from Google are brief summaries comprising 1-3 long sentences. The crowdworkers however only use specific segments of these summaries or entity facts in their paraphrases. To model this aspect, we used MinIE$^{16}$ an unsupervised, domain-independent fact extraction tool on our entity descriptions and mapped a specific fact from the summary with each rewrite (Gashteovski et al., 2017). We provide an example in the Appendix (Footnote 5).

Evaluation: Following existing QG works, we use BLEU (Papineni et al., 2002), METEOR (Lavie and Denkowsk, 2009), and ROUGE-L (Lin, 2004) scores to characterize model performance. All three measures are based on calculating the $n$-gram overlap between human-generated “gold” references and machine-generated predictions.

All baseline models were set up using the configuration settings shared by the authors. As in existing QG studies, we uniformly use pretrained embeddings from GloVe$^{17}$ (Pennington et al., 2014) for word representations and tune all models using the BLEU$^-4$ score on the dev portion of the dataset. All experiments were performed on a single GPU on an Nvidia cluster and FIQG took approximately 2 hours to train.

5.1 Results and Observations

Fact-Infusion Performance: In Table 5, we summarize the performance of FIQG and the baseline models using the different evaluation measures. FIQG is able to significantly outperform all baselines on the test data. Even though the number of training instances available in FIRS is significantly smaller than datasets such as SQuAD, fact-infused rewriting can be expected to be easier than standard QG since it involves combining a fact with a base question along with potentially rewriting the $wh$-word in contrast with QG where models learn to generate questions for a given passage and an answer-span. Indeed on SQuAD, the state-of-the-art QG models obtain BLEU$^-4$ and METEOR scores about half of that obtained on FIRS by FIQG. As such, the BLEU scores of the modified QG baselines on FIRS are also reasonably high although we note that separately representing the question and fact sentences via the double encoder in FIQG results in superior performance over

$^{13}$https://github.com/PrekshaNema25/RefNet-QG
$^{14}$https://github.com/yanghoonkim/NQG_A5s2s
$^{15}$Python 3.7.7, NLTK 3.5, Stanza 1.0.1 libraries were used in feature extraction whereas the deep learning models were implemented in Tensorflow 2.3.0.

$^{16}$https://github.com/uma-pi1/minie
$^{17}$http://nlp.stanford.edu/data/glove.840B.300d.zip
the baselines. Indeed, statistically significant gains are seen on all evaluation measures except the METEOR score for which the performance is similar to that of RefNet.

Ablation Experiments: The results of our ablation experiments are also shown in Table 5. Not surprisingly, and as shown in other QG studies, initializing our word embeddings with pretrained embeddings results in improved question rewriting performance. Without initialization from GloVe vectors, we observe a significant drop in the scores. Similarly, indicator features are known to help QG by providing signals to the model on what parts of the passage the generation should be focused on. For our smaller sentences, excluding them yields a small drop in performance. Moreover, discriminating between the two cases (answer versus question entity) seems to help the model attain a minor improvement in performance over using a single set of indicators as shown in the ‘w/ Combined Indicator’ row of Table 5. Although as observed in Section 3.1, the extra “fact” words in rewrites are often nouns and words related to nouns, excluding POS tag information causes a small drop in the performance. Based on these results, we can attribute the overall performance of FIQG mostly to the network architecture coupled with appropriately initialized word embedding features.

Anecdotal observations: We show sample test predictions with FIQG in Table 6 for discussion. In the first example, a fact related to an entity mentioned in the question (“Martin Luther”) is being utilized whereas in the second example, the fact relates to “David Booth”, the answer entity. FIQG missed some words from the human-specified variation (“target”) in the first case and gets the tense wrong in the second example. However, we note that the fact extracted from the summary did not contain the extra initials whereas the tense is also specified incorrectly in the base question from SQuAD. Barring these minor aspects, the predictions are legitimate and complete and in the second example we also note the change in the wh-word.

6 Conclusions and Future Work

We presented FIRS, to the best of our knowledge, a first-of-its-kind dataset containing fact-infused vari-
ations of a subset of questions from SQuAD. We proposed a double encoder-decoder model FIQG, for learning to generate question variations through fact infusion. FIQG is able to significantly outperform extensions of standard QG models on FIRS.

In future, we would like to investigate the use of question variations on downstream tasks such as QA, reading comprehension, and interactive dialog (Tang et al., 2018; Ribeiro et al., 2019; Gao et al., 2020). Additionally, question variations available in FIRS can be used for learning diverse question generation, adversarial models for QA, and QG on multiple passages (Ren et al., 2018; Yang et al., 2018; Gan and Ng, 2019). We would like to explore these aspects as well as study novel learning methods such as variational auto-encoders and reinforcement learning for improving performance on the fact-infused question generation task (Misra et al., 2018; Li et al., 2018).

Abstract
A core task in information extraction is event detection that identifies event triggers in sentences that are typically classified into event types. In this study an event is considered as the unit to measure diversity and similarity in news articles in the framework of a news recommendation system. Current typology-based event detection approaches fail to handle the variety of events expressed in real-world situations. To overcome this, we aim to perform event salience classification and explore whether a transformer model is capable of classifying new information into less and more general prominence classes. After comparing a Support Vector Machine (SVM) baseline and our transformer-based classifier performances on several event span formats, we conceived multi-word event spans as syntactic clauses. Those are fed into our prominence classifier which is fine-tuned on pre-trained Dutch BERT word embeddings. On top of that we outperform a pipeline of a Conditional Random Field (CRF) approach to event-trigger word detection and the BERT-based classifier. To the best of our knowledge we present the first event extraction approach that combines an expert-based syntactic parser with a transformer-based classifier:

- Input sentences are first pre-processed using a rule-based syntactic parser in order to generate smaller syntactic clauses as multi-word event spans.
- In a second phase, event prominence classification is applied in order to express whether it is a main or background event, using a classifier which is fine-tuned on pre-trained Dutch BERT word embeddings.

We also motivate the use of syntactic clauses as event spans, by comparing baseline and target classifier performances on other multi-word event span formats. On top of that we outperform a pipeline of a CRF event-trigger word detection approach

1 https://www.ugent.be/mict/en/research/NewsDNA is an interdisciplinary research project at Ghent University that aims to outline a news recommendation algorithm driven by diversity of topics and events that occur in unfiltered news streams.

1 Introduction
Recently, news publishers have shifted from newspapers to digital means which provide news readers easy access to a wide range of news information. However, the challenge is to find the right content that also corresponds to the user’s personal interests. Therefore, many of today’s major media and news websites offer automated news recommendation and personalization (Das et al., 2007; Odić et al., 2013; Moreira et al., 2019; Feng et al., 2020). News personalization paradigms define good news recommendations in terms of similarity to the user’s previous reading behaviour. Hence, news articles are recommended based on proximity to other articles the user has read (Liu et al., 2010; Adnan et al., 2014). However, this contrasts with the normative concept of journalism that stimulates diversity of topics and events in unfiltered news streams (Pariser, 2011; Joris et al., 2019). In this study we consider the news event as a means to model both diversity and similarity in news articles in the context of a news recommendation system.

We present an event extraction approach that will be integrated in a news recommender for Dutch¹. As current typology-based event detection fails to handle the variety of events in real-world situations we applied event prominence classification. This allows us to detect unrestricted news events and to overcome the sparsity of a small training data set. Our event extraction approach combines an expert-based syntactic parser with a transformer-based classifier:

- Input sentences are first pre-processed using a rule-based syntactic parser in order to generate smaller syntactic clauses as multi-word event spans.
- In a second phase, event prominence classification is applied in order to express whether it is a main or background event, using a classifier which is fine-tuned on pre-trained Dutch BERT word embeddings.

We also motivate the use of syntactic clauses as event spans, by comparing baseline and target classifier performances on other multi-word event span formats. On top of that we outperform a pipeline of a CRF event-trigger word detection approach

¹https://www.ugent.be/mict/en/research/NewsDNA is an interdisciplinary research project at Ghent University that aims to outline a news recommendation algorithm driven by diversity of topics and events that occur in unfiltered news streams.
and our BERT-based classifier. Furthermore, our approach is positioned with respect to the state of the art in Section 2 and is outlined in Section 3. An overview of the data set is given in Section 4. Section 5 presents the results of experiments on the held-out test set followed by a results analysis and discussion, conclusion and outlook on future work.

2 Related Work

Knowledge-based approaches are still frequently used for event extraction. Such methods are based on ontologies (Frasincar et al., 2009; Schouten et al., 2010; Arendarenko and Kakkonen, 2012) or rule-sets (Valenzuela-Escárcega et al., 2015) which represent expert knowledge. Information is mined from corpora based on lexical, syntactic (Hearst, 1992, 1998) and semantic patterns or frames (Cunningham, 2002a,b; Xie et al., 2013; Borsje et al., 2010; Hogenboom et al., 2013).

As the manual creation of rule-sets and ontologies is difficult and time-consuming, data-driven event extraction approaches made their entrance. The ACE (Automatic Context Extraction) annotation standards\(^2\), ERE (Entities, Relations, Events) annotation standards (Song et al., 2015; Aguilar et al., 2014) and TAC-KBP (Text Analysis Conference Knowledge Base Population)\(^3\) workshops and competitions stimulated the creation of data sets labeled with entities and events, e.g. the ACE 2005 corpus (Walker et al., 2006). As a consequence, supervised methods became predominant but initially concentrated on fixed event types using single-word event spans (Mitamura et al., 2015a). As compensation for small event spans, sentence or cross-sentential context information was used. In Ji and Grishman (2008) and Hong et al. (2011) events were extracted through cross-document and cross-sentence inference, respectively. Liao and Grishman (2011) improved event extraction performances adding topic classification information.

As feature engineering approaches emerged, a larger scope than one-word event spans was targeted. Hand-designed sets of lexical, semantic or syntactic features were extracted and fed into classifiers, allowing the model to take more context into account (Patwardhan and Riloff, 2009). Event extraction tasks are typically applied in a pipeline architecture where event trigger word identification, argument and event classification are conceived as separate tasks (Ahn, 2006). Other than a pipeline architecture, multi-task architectures perform several subtasks simultaneously to benefit from their interdependencies. In Li et al. (2013) events were extracted incorporating features that capture dependencies of multiple triggers and arguments. Luan et al. (2019) and Wadden et al. (2019) extracted events combined with named entity and argument role prediction.

However, the choice of features is a manual and elaborate process that requires extensive linguistic domain expertise. More recently deep neural networks superseded methods that show a strong dependency on feature resources, although the latter ones are still not definitely outperformed. Jacobs et al. (2018) and Nugent et al. (2017) used lexical, syntactic features, word2vec (Mikolov et al., 2013), glove (Pennington et al., 2014) and fastText (Bojanowski et al., 2017) word embeddings. Better performances were reported for an SVM classifier compared to a Recurrent Neural Network (RNN). In contrast, Nguyen and Grishman (2015) demonstrated that Convolutional Neural Networks (CNN) significantly outperformed feature-based methods on the ACE 2005 task.

Meanwhile, contextual language models have proven successful in a transformer architecture (Vaswani et al., 2017) that fully benefits from the attention mechanism. It has been integrated in a range of NLP tasks using pre-trained contextual BERT (Bidirectional Encoder Representations from Transformers) word embeddings (Devlin et al., 2018), predominantly for English. Mao and Liu (2019) report encouraging results for an event factuality classifier using BERT. Piskorski et al. (2020) report SVM event classifications with Term Frequency-Inverse Document Frequency (TF-IDF) that are outperformed by a fine-tuned BERT event classifier. The results of these studies inspired us to combine an expert-based syntactic parser with a BERT-based language model classifier for Dutch in order to extract multi-word events.

3 Method

3.1 Event Extraction for News Recommendation

In this study, an event is considered as the unit to measure proximity to other articles the user has read for news recommendation. It can be defined as the smallest extent of text that expresses its occurrence.
(Song et al., 2015), or a change of state at a particular place and time (Mitamura et al., 2015b), and is identified by a word or phrase called event trigger, nugget, event span or mention. Event mentions can be single-word event triggers that are usually (main) verbs, nouns, adjectives and adverbs. Multi-word event triggers can be continuous when the event span consists of consecutive tokens and even complete sentences, or discontinuous when its participants, or argument roles are also involved (Doddington et al., 2004). As they are more challenging to predict, we initially performed event classification on event spans with a fixed and short length, i.e. 5 token windows with a verbal head only. In a second phase we targetted longer events with a variable length, i.e. annotated events and syntactic clauses (Sections 5.1 and 5.2). The event extraction process in this study consists of automatically assigning an event prominence label to continuous multi-word event spans from a held-out test set. For the Dutch input document (translated in English) in Figure 1, the Main event is about a promotion campaign activity; the Background event provides background information about the Main event. Our hypothesis is that our target transformer classifier model is capable of categorizing new information into more general prominence classes, fine-tuned on pre-trained BERT word embeddings.

### 3.2 Syntactic Pre-Processing and Extraction of 5 Token Windows

Multi-word event spans, in this study defined as syntactic clauses as output from raw sentences processed by the Alpino syntactic parser, are fed into our baseline and target event prominence classifiers. The complete process is depicted in Figure 2.

The Alpino parser’s knowledge-based part consists of a rule-based head driven phrase structure grammar (HPSG) and lexicon (100,000 entries). The integrated part-of-speech (POS) tagger reduces lexical ambiguity. The resulting dependency parse trees are disambiguated with a maximum entropy component (Van der Beek et al., 2002; Van Noord et al., 2006; Smessaert and Augustinus, 2010). An F-score of 91.14% was measured for 1,400 manually annotated sentences from the Twente News corpus (Ordelman et al., 2007).

For our experiments we applied a set of rules on the parser output in order to split sentences in the test set into separate main and subclauses. Subclauses in sentence medial position were not considered, but only in sentence initial and final position. In this way, the syntactic structure of our pre-processed test sentences is more similar to the clauses in the training set. For the Dutch sentence⁴ in row 1 of Table 1, the labels ssub (subclause), begin and end position are used to extract the relative subclause from the syntactic parser output in row 3. As a preparatory step event classification was first performed on fixed event spans with a short length. To that end main head verbs in a 5 token window context were extracted from the annotated events in our data, also by applying rules on the syntactic parser output.

We compared our syntax-driven event extraction approach with a CRF⁵ (Lafferty et al., 2001) model to event detection as outlined in Colruyt et al. (under review), combined with our target classifier. For an input sequence of lexical, word shape and syntactic features, the CRF predicts a target sequence in IOB format. Tokens starting an event mention are labelled as B, tokens inside the mention as I, and tokens outside the mention are labeled as O.

### 3.3 Baseline Classification Models

For a prominence classification of multi-word event spans, i.e. 5 token windows or syntactic clauses, into Main, Background and None event labels, an SVM classifier was trained as baseline model using the scikit-learn Python library. SVM performances were compared for Bag of Words (BOW) and TF-IDF count-based methods. Instead of deriving meaning from an entire corpus, word representations are constructed one sentence at a time, with a prediction-based method that predicts word identity given a sentence context. The model

---

⁴English translation: “Soldiers will be deployed in the Rocinha district, which includes about 70,000 inhabitants.”

learns that words occurring in similar sentence contexts are semantically related. This was applied by combining the SVM classifier with Dutch pre-trained word2vec word embeddings (Tulkens et al., 2016). The embeddings were pre-trained on the combined Dutch Roularta\textsuperscript{6}, Wikipedia\textsuperscript{7} and SoNaR corpora (Oostdijk et al., 2013) with a total of 54.8 million sentences and 803 million words.

### 3.4 Transformer-Based Target Classification Model

SVM baseline performances for event prominence classification were compared with a transformer-based (Section 2) classifier that relies entirely on the self-attention mechanism. It relates different positions of a single sequence in order to compute a representation of the sequence (Vaswani et al., 2017). For an input sequence $x = (x_1, ..., x_n)$ of $n$ elements, where $x_j \in \mathbb{R}^{d_z}$ each attention head in the self-attention sublayers calculates a sequence $z = (z_1, ..., z_n)$, where $z_i \in \mathbb{R}^{d_z}$. Each output element, $z_i$, is computed as weighted sum of linearly transformed input elements,

$$z_i = \sum_{j=1}^{n} \alpha_{ij} (x_j W^V)$$  \hspace{1cm} (1)

Each weight coefficient, $\alpha_{ij}$, is calculated with a softmax function,

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{n} \exp(e_{ik})}$$  \hspace{1cm} (2)

and $e_{ij}$ is computed with a function comparing two input elements,

$$e_{ij} = (x_i W^Q)(x_j W^K)^T \frac{1}{\sqrt{d_z}}$$  \hspace{1cm} (3)

where $W^Q, W^K$ and $W^V \in \mathbb{R}^{d_z \times d_z}$ are parameter indices that are unique per layer and attention head. The attention function maps vectors of queries $W^Q$ and key-value pairs $W^K$, $W^V$ to an output (Shaw et al., 2018).

BERT are unsupervised deep bidirectional word embeddings (Devlin et al., 2018) pre-trained on large corpora in the target language. Frequently, a smaller dataset is used for fine-tuning for the target NLP task. A replication study and evaluation of BERT resulted in RoBERTa (Liu et al., 2019) that is trained on more data, bigger batches and longer sequences. Bidirectional pre-training is realized with a masked language model (MLM). The MLM randomly masks input tokens in order to predict the original vocabulary relying on its left and right context. In addition to the MLM next sentence prediction (NSP) jointly pre-trains text-pair representations.

A Dutch BERT model, BERTje (de Vries et al., 2019) has been pre-trained on a dataset of 2.4 billion tokens from Wikipedia, Twente News Corpus (Oordelman et al., 2007), and SoNaR-500 corpora (Oostdijk et al., 2013). RobBERT (Delobelle et al., 2020), a RoBERTa based and larger model has

been pre-trained on 6.6 billion Dutch tokens from the OSCAR corpus (Suárez et al., 2019). Other than BERTje, RobBERT does not integrate NSP. Both models have an architecture of 12 transformer blocks (bidirectional layers) and 12 self-attention heads and a hidden size of 768.

4 Data

Our baseline and target event prominence classification models were trained on the EventDNA corpus. It comprises 1,771 Dutch news articles (Table 2, Documents), of which only the title and lead paragraph were kept, and is annotated with entities, news events and IPTC (International Press Telecommunications Council) Media Topic codes (Colruyt et al., under review). The annotation protocol was based on the ERE (Entities, Relations, Events) annotation standards (Song et al., 2015; Aguilar et al., 2014).

Entity spans can be assigned one out of four possible labels: person (PER), location (LOC), organization (ORG), and (MISC) for other entity values (Table 2, Entities). A sentence can comprise more than one event (with an average of 1.3 events per sentence). All relevant semantic information (with priority over syntactic information) is included in the event span that can contain entire, main or subclauses, or nominal expressions. Hence the event’s arguments can be included. An Event span is annotated with a prominence feature label: Main events bring new information and actually caused the reporter to write the article; Background events give context or background to the Main event; raw sentences without events are labeled as None events (Table 2, Events). Our motivation to apply prominence classification other than event type labeling is mainly driven by a prior analysis of the EventDNA corpus which revealed a high frequency (32%) of event types in a small data set (Table 2, Sentences) that cannot be classified into one of the event types specified in the EventDNA annotation protocol. Figure 1 presents an example of an event span labeled as Background event, preceded by a Main and None event. For more information about the EventDNA annotations we refer the reader to Colruyt et al. (2019).

For our experiments, both data sets with annotated events and 5 token windows with verbal head, extracted from the corpus, were randomized and split into 80% train, 10% development (DEV) and 10% held-out test data as shown in Table 3. The number of 5 token window instances in the training and test set is lower than the number of annotated events, as only events with a verbal head were extracted. Subsequently, performance comparisons between the models trained on those two data sets in Section 5.1 are not entirely fair. For that reason we provided a test set with only overlapping instances between the 5 token window instances and the annotated event instances for a fair comparison (Table 3, Annotated events2).

In order to verify the feasibility of our approach to classify events based on the test sentences, split into syntactic clauses, with the Alpino syntactic parser (Section 5.2), we counted the syntactic constituents in the training data annotated with events. Table 4 shows that the majority of the annotated events in the training set consist of a single verbal main-, subclause or infinitival construction. By splitting our test input sentences into syntactic clauses the syntactic structure of our pre-processed test sentences is more similar to the single verbal main-, subclause or infinitival construction (50.97%) and main clauses combined with other verbal constituents (13.57%) in the training set.

As the test sentences were split into syntactic clauses, the number of test instances (Syntactic clauses) in Table 3 exceeds the number of the original Raw test sentences. Hence, performance comparisons on the Raw sentences and Syntactic clauses for the syntax based event extraction experiments in Section 5.2 are not entirely fair. However, the test sets in Table 3, used for our experiments in section 5, are based on the same 10% held-out test data from the EventDNA corpus. We mapped the raw sentence and syntactic clause test set versions with the Annotated events in order to assign the event labels, and manually verified these. For raw sentences comprising several events, we randomly assigned one event prominence class. We also pro-

5 Experiments and Results

We trained and tested our SVM baseline event classifier and target BERT event classifier on 5 token windows and annotated events (Section 4). Then we fed the syntactic clauses from the syntactic parser into the baseline SVM and target BERT classifiers. Finally, we positioned our approach w.r.t. a pipeline of a CRF approach to event-trigger word detection and target prominence classifier (Section 5.2).

5.1 Event Extraction Based on 5 Token Windows and Gold-Standard Events

For training the SVM baseline event classification models (Section 3.3), parameters were optimized using the DEV set. The best results were obtained with an RBF kernel with cost $C = 20$, using the default scale value of the parameter $\gamma$, applying one-vs-rest classification. SVM performances are compared for BOW, TF-IDF, and pre-trained word2vec Dutch word embeddings. For fine-tuning the target BERTje and RobBERT prominence classifiers (Section 3.4), AdamW optimizer was used (Loshchilov and Hutter, 2017) with a learning rate of $1e{-5}$ and a batch size of 10 instances. The maximum sequence length is similar to 69 tokens, which is the maximum sequence token length of the annotated events in the training data. As we are interested in single sentence classification we added the special [CLS] (classification) token. Minimal loss was obtained after 3 epochs of training for BERTje and 4 epochs for RobBERT with a cross entropy loss function. Performances were evaluated using Recall (Rec.), Precision (Prec.) and F-score.

Surprisingly, the SVM baseline classifier with word2vec embeddings did not outperform the SVM TF-IDF and BOW models (Table 5). However, the study of Tulkens et al. (2016) also reported varying performances for the Dutch word2vec embeddings compared to BOW and TF-IDF. In general, better performances are exhibited for the models trained on the annotated events than for the 5 token windows. For both data sets the transformer models outperform the SVM classifiers with slightly superior performances for RobBERT on the 5 token windows and BERTje on the annotated events. For the latter model, Table 6 exhibits worst performances on the Background prominence class, compared to Main and None classes.

5.2 Syntax Based Event Extraction

As we defined our target multi-word event spans as syntactic clauses (Section 3.1), the raw sentences in the test set were pre-processed with the syntactic parser outlined in Section 3.2, before feeding the resulting clauses to the baseline SVM and target BERT classifiers as used in Section 5.1. Table 7 shows best performances for the BERTje classifier on syntactic clauses, that are very similar to syntactic clauses 2, the syntactic clauses that were aligned (Section 4) with the Raw sentences for a fair comparison.

We also compared our event extraction approach using the BERTje model that classifies multi-word event spans, conceived as syntactic clauses, with a pipeline consisting of a CRF for event-trigger word detection (Section 3.2) and our BERT-based classifier. The CRF model was trained for ten iterations on the annotated Main and Background events in the training set (Section 4) and tested on the raw sentences in the held-out test set (Table 3). Only

the resulting detected (67% F1-score) Main and Background events, without the None events, were fed into the transformer classifier. Table 8 exhibits significantly poorer prominence classification results on the CRF detected events compared to classification on the syntactic clauses (also without the None events).

6 Results Analysis and Discussion

Analysis of BERTje attention heatmaps indicated the feasibility of our event extraction approach combining a syntactic parser and a BERT classifier. The sentence “Then an adviser to the president was convicted because he lied” (Figure 3 - left) consists of a main clause “Then an adviser to the president was convicted” (middle) with a main event, and a subclause “because he lied” (right). Figure 3 (left) shows that most attention in the raw sentence is erroneously attributed to the past participle in the subclause, “gelogen” (lied). After splitting the sentence in its main and subclause, most attention is now correctly attributed to the verbs in the Main (middle) and Background (right) event. Although the BERTje classifier performances on the syntactic clauses are better, compared to the CRF detected events (Table 8), classification performances are still poorer compared to classification on the test set with annotated events (Table 5). As the training data has been annotated taking into account semantic information, with priority over syntactic information, the boundaries of the syntactic clauses generated by the Alpino parser, are frequently different from the boundaries of the annotated events which results in poorer performances. On top of that 35.44% of the EventDNA training data consists of non-verbal constituents (Table 4). These are mainly news article titles, but also noun phrases as part of a main clause that have been annotated as separate events. However, our rule-set on top of the syntactic parser, splits raw test sentences into separate main and subclauses (Section 3.2), but does not isolate nominal constituents. This also partially explains poorer performances on the syntactic clauses compared to the annotated test events. A possible solution for this bottleneck is combining the rule-set on top of the syntactic parser, with the BERTje self-attention mechanism. Tokens in the syntactic clause to which the highest attention values are attributed can be extracted, e.g. nominal constituents as part of a clause.

The transformer models outperform the SVM (Section 5) and benefit from the structure of language that is taught during pre-training. Certain self-attention heads exhibit linguistic notions of syntax and coreference. In line with the studies of Vig (2019), Vig et al. (2019) and Clark et al. (2019), coreference relations are situated in the middle and deeper layers of the self-attention blocks as depicted in Figure 4. For the sentence “She survived the bullet to her head”, coreference between the Dutch personal pronoun ze (she), on the right, and the possessive pronoun, on the left, haar (her) is depicted as connecting lines. Darker colors represent higher attention weights. In general

Table 6: BERTje classification performances (%) on annotated events per prominence class

Original Dutch sentence: “Ze overleefde de kogel door haar hoofd”
In spite of the advantages of using the transformer model, minimal loss was already obtained after only 3 epochs of training for BERTje (Section 5.1). The BERTje model pre-trained on a large corpus, allows a small dataset being used for fine-tuning on the event prominence classification task. However, applying data augmentation on the small NewsDNA dataset might increase training time during fine-tuning. Although the pre-trained BERTje model is large (2.4 billion tokens), it contains other data than news corpora, whereas our training set consists entirely of news. This raises the question whether it is not better to use a domain-specific pre-trained model consisting entirely of news corpora.

A bottleneck of classifying prominence labels only based on the sentence level, is the lack of context information. This has an impact mainly on the Background prominence class (Table 6). Semantic and syntactic information cues within a sentence can in some cases be sufficient to correctly predict a Background class. E.g. the conjunction “when” in “when she tried to convince the shooter” introduces a subclause with a noun “shooter”, which refers to a shooting or killing Main event outside the subclause that contains a Background event “convince”. However, frequently more context information is necessary in order to correctly pre-
dict the Background prominence label. As a next research step, for fine-tuning the transformer model, extra separator tokens [SEP] with previous and/or next annotated events can be inserted to the current training instances. This can provide the model more context to improve Background prominence class predictions. Furthermore, instead of using event prominence classes, more generalized event types can be generated, by mapping the original more specific event types in the NewsDNA data to broader event classes. This would decrease the need for more context information. However, the latter approach might not offer the complete solution to handle the variety of events expressed in real-world situations.

7 Conclusion and Future Work

This study shows that an event extraction approach of an expert-based syntactic parser in combination with a transformer-based classifier (BERTje) is feasible. The resulting model outperforms (62.95% F-score) a pipeline of a CRF approach to event trigger word detection and a BERT-based event classifier. We also demonstrated that a syntactic clause can be used as event span. Prominence classification is our answer to take into account a real-world situation where event types in held-out test data are frequently not covered because of training data scarcity. The BERTje model benefits from self-attention heads with linguistic notions such as syntax and coreference and outperformed (70.75% F-score) an SVM baseline classification model. A bottleneck of classifying prominence labels only based on the sentence level, is the lack of context. This has an impact mainly on the Background prominence class. Therefore further work includes exploring ways to provide more context information in the transformer model. It can be fine-tuned on training data where previous and following annotated events to the current single event instances are inserted. As a next step the BERTje self-attention mechanism will be leveraged to select the tokens in the syntactic clause with the highest attention values. This will allow e.g. the generation of nominal constituents on top of the clauses generated by the syntactic parser. Although the transformer model exhibits promising performances fine-tuned on a small dataset, data augmentation of the training set might optimize the fine-tuning and boost performances. Finally the classifier output will be fed into a news recommender system.

Abstract

Mental health is getting more and more attention recently, depression being a very common illness nowadays, but also other disorders like anxiety, obsessive-compulsive disorders, feeding disorders, autism, or attention-deficit/hyperactivity disorders. The huge amount of data from social media and the recent advances of deep learning models provide valuable means to automatically detecting mental disorders from plain text. In this article, we experiment with state-of-the-art methods on the SMHD mental health conditions dataset from Reddit (Cohan et al., 2018). Our contribution is threefold: using a dataset consisting of more illnesses than most studies, focusing on general text rather than mental health support groups and classification by posts rather than individuals or groups. For the automatic classification of the diseases, we employ three deep learning models: BERT, RoBERTa and XLNET. We double the baseline established by Cohan et al. (2018), on just a sample of their dataset. We improve the results obtained by Jiang et al. (2020) on post-level classification. The accuracy obtained by the eating disorder classifier is the highest due to the pregnant presence of discussions related to calories, diets, recipes etc., whereas depression had the lowest F1 score, probably because depression is more difficult to identify in linguistic acts.

1 Introduction

An analysis performed by Chisholm et al. (2016) estimates that approximately 10% of the world’s population is living with a mental illness. The Global Burden of Disease Study (2017) states that depression is a very common illness and there are more than 264 million people affected by it. At its worst, the illness can lead to suicide and it is the second highest cause of death for people between 15 and 29. Between 76% and 85% of the potentially diagnosed people, do not benefit from any treatment for their illness due to living in impoverished areas and not having access to mental care. It is difficult to discuss about digital solutions in the context of isolated areas with low data availability and limited access to professional help. Social stigma is another obstacle present regardless of age, gender or race, which makes early intervention difficult. Persons facing difficulties often avoid discussing their issues from various reasons. However, researchers working with Machine Learning algorithms can draw plenty of expertise from the unstructured data roaming the World Wide Web. The advent of social media platforms brings up an influx of large quantities of various types of unstructured textual data. The continuous advancements made in the field of Machine Learning enable the possibility to analyse such volumes of data efficiently. Experiments in this interdisciplinary domain managed to bring up useful input for mental health practitioners, socio-linguists, computer scientist and other researchers in the field. Pennebaker et al. (2015) perform one of the most influential quantitative studies, which reveals the way patterns of parts of speech, as labelled by LIWC founders, correlate with types of personalities and types of mental illnesses. The classes and the psychological dimensions mapped together served as a start for many projects including the prediction of Dark Triad personality traits by Sumner et al. (2012) and the risk of self-harm by Soldaini et al. (2018). Research in the area is conducted mainly on texts from mental health support groups, on just a few illnesses and some groups of individuals.

Our main research questions for this article are if and to what extent it is possible to detect and classify mental illnesses from general texts, if there...
are any differences between the difficulty of automatic detection and classification of different illnesses and, finally, if such a classification may rely on posts only. To this end, we experiment with state-of-the-art methods on Reddit, to improve previous results and provide new insights on mental illness discovery from general text. Reddit is a social media network hosting numerous communities where users join in order to participate in various discussions. Each community or “board”, the way it is called by Reddit users, has a subject on which people must post. We employed highly performant deep learning models such as the Transformers, introduced by Vaswani et al. in 2017, which also led to the creation of BERT by Devlin et al. in 2018, a pretrained model trained on expansive general datasets, in order to be later fine-tuned on more specific tasks. Vale et al., (2021) efficiently applied BERT for question answering. Topal et al., (2021) use it for text generation and Sun et al., (2020) use it for text classification. Thus, we identify a solid ground for efficient usage in mental illnesses detection and classification.

2 Related Work

NLP researchers have shown an increased interest in the area at the intersection of Machine Learning and Psychiatry in the last years. Social media is an indispensable resource for research. Yet, the particularities of the online setting rise a range of challenges. As there are not any standards established for using social data, practitioners from many fields pointed to the dangers of using such data without a clear framework. Olteanu et al., (2019) address the issue of “biases, methodological pitfalls, and ethical boundaries” - discussing the problems often left unaddressed by researchers working with this kind of data. Selbst et al. (2019) analyse not only the ethical dilemma revolving around this type of studies, but also their feasibility and the integration of the social component into the compound of a socio-technical system.

When it comes to detecting mental illnesses from social media data, we have many examples at hand, which often look at data coming from those Reddit communities, which are support groups for people struggling with an illness or another. Most articles look at a single illness in comparison to a control group: Vedula et al. (2017) and Tsugawa (2019) – depression, and Bimbaum et al. (2020) – schizophrenia. Our goal is to detect a wide range of mental illnesses using deep learning techniques, which seem like the best candidates for this task. Jiang et al. (2020) employ deep learning methods similar to ours, but we concentrate on obtaining better results by training the models on individual posts rather than posts grouped by users, which might not work as expected. For example, if a user produced few contributions or has a fresh account, they would probably have few posts available. On the other hand, some types of user are the observing type and rarely contribute to discussions. One aspect worth mentioning is the nature of the data used in many classification tasks. Texts containing explicit content and linguistic cues pertaining to the properties of a certain illness are often used. Kim et al. (2020) and Thorstad et al. (2019) perform automatic text classification by their author’s mental illnesses, with good results, on texts that specifically discussed these conditions on dedicated forums. Nevertheless, these classifications are of little help in finding risk population, when looking at general text, which does not include mental illness topics. Among the few researchers who report using datasets containing general discussions coming from people who self-reported their diagnosis in one of the support communities are Jiang et al. (2020) and Cohan et al. (2018).

The results are favorable and leave room for improvement. We believe it is important to experiment further for a better understanding of the ways in which mental illnesses can be detected in earlier stages and how even general discussions contain traces of how mental illnesses manifest themselves in language. In addition, this is a direction worthy of exploration because the persons asking for guidance represent a very small and idiosyncratic part of the population battling with mental illnesses, thus early mental illness detection from general text might be of a real help.

3 Data

We used the SMHD dataset introduced by Cohan et al. (2018). This dataset contains non-explicit texts: A Large-Scale Resource for Exploring Online Language Usage for Multiple Mental Health Conditions. They test some classification algorithms, but no deep learning. Also, employed LIWC categories for classification. These categories include standard linguistic dimensions – pro-nouns, articles, present tense, future tense; psychological processes – positive emotions,
negative emotions, anger, anxiety; personal concerns – work, achievements. The SMHD dataset contains texts extracted from Reddit’s general discussion communities grouped on users and illnesses. Individuals diagnosed with a mental illness were detected by searching for self-reports in the dedicated support groups. The dataset features multiple illnesses, which are present in the psychiatric taxonomy DSM-5 (American Psychiatric Association, 2013). As stated by the authors of the dataset, “Six conditions are top-level DSM-5 disorders: schizophrenia spectrum disorders (schizophrenia), bipolar disorders (bipolar), depressive disorders (depression), anxiety disorders (anxiety), obsessive-compulsive disorders (ocd) and feeding and eating disorders (eating). The three other conditions are one rank lower: post-traumatic stress disorder (ptsd) is classified under trauma- and stress-related disorders, and autism spectrum disorders (autism) and attention-deficit/hyperactivity disorder (adhd) under neurodevelopmental disorders”. The opposing group of users is the control one, whose members are selected based on having no posts in the support groups and at least 50 posts on Reddit. The complete dataset contains 20,406 diagnosed users and 335,952 control users. The texts do not contain any terms related to mental health, neither the diagnosed groups, nor the control ones. Our experiments will use just a selection of each group of illnesses to speed up the computation process. The models are not user centered and will learn from each individual post. Selecting data based on a fixed number of users was not suitable for our tasks due to the imbalance at the user level when it comes to the number of comments and posts available. Therefore, we selected randomly 50,000 posts for each group of users.

The numbers shown in tables 1 and 2 might reflect certain particularities about an illness, how the diagnosed users communicate in the online environment. This variation depends also on how the users engage, whether they create posts or comment on somebody else’s and on the format adopted by each community – if pictures are posted often, then the comments are on the shorter side, if story telling is the center of the community, people engage with the purpose of telling their opinion or a similar story, hence the lengthier texts.

The authors of the dataset conducted a linguistic analysis based on LIWC categories. Several differences were observed between the diagnosed groups and the control users. Pennebaker et al. (2015) and Ireland and Mehl (2014) underline that pronounced usage of first-person singular with most conditions is consistent with the theory that illness drives one towards self-focus. An interesting finding underlining the bias of the dataset towards the predominantly male demographic is the female references that point to discussions about relationships and love related issues with the bipolar, depression and anxiety groups.

Table 3: The number of tokens per group of illnesses and average number of tokens per person in a given group.

Reddit does not impose a very strict post limit hence we have diverse lengths. However, the deep learning models we used impose a limit for training. The SMHD has already undergone preprocessing, but we needed more cleaning. We remove any posts shorter than 4 tokens. Very short texts are often noise like thankful comments or very short approval phrases, which would confuse the model and do not contain significant meaning.
actions are pertaining to a class or another. Special characters and symbols are removed, and contractions are handled using a dictionary automatically translating them into the expanded forms. Table 3 shows the average number of tokens produced by users diagnosed with a certain illness and the average number of tokens a post from a user has. The next section will look at another data related problem, namely the ethics and biases of working with social media data.

4 Ethics and Biases

Reddit represents a social media application whose users are part of communities and engage in discussions. Each social media network represents a cluster of people who are defined by certain characteristics. The Hootsuite yearly report (2021) shows that more than 60% of the Reddit users are males aged 18 to 34. Accordingly, studies show that there is a tendency in males to display less emotionally charged input due to the social stigma in the offline world. Nadeau et al. (2016) find that men often avoid seeking professional help or talking about their problems. Concealing their emotional state in real life is a strategy in order to avoid prejudices and is not something specific for the female population. Ireland and Mehl’s (2014) research conducted in the psychology area proves that manifestations of negative emotions are muted across many settings and situations. Alternatively, Schoenebeck (2013) and Shelton et al. (2015) demonstrate that people tend to discuss personal things in anonymous spaces and share unpopular opinions. In this situation, Reddit represents a good source of data for a population, which is underrepresented in clinical studies. Anderson (2015) prove that some platforms might be more attractive for a demographic than others. Behavioral biases imply that users of a platform display a particular behavior, observable in how they interact with each other or what type of content they create. One such bias is the way in which users seek and share information. De Choudhury et al. (2014) discovered that users diagnosed with one illness behave differently in this aspect from the others. Nevertheless, we cannot claim that this is representative for all the individuals diagnosed with a mental illness. There are certain biases plaguing the studies based on social media, which should be at least mentioned for awareness. Here, we consider the population bias a positive fact, which enables studies targeting the young adult and adult males. However, this bias does not affect much our dataset, because the data collected comes from neutral communities where a variety of topics is discussed.

5 Discriminative Features

We run a Naïve Bayes Classifier in order to find out the most informative features from each category in our dataset. We used the classifier implemented in the scikit-learn library by Pedregosa, et al. (2011) to get a top of n most informative words by scores. Our experiment includes the 9 illnesses as labels, and the control group. The top n words can be seen in table 4. We notice that across the dataset, the top 8 words are mostly associated with the illness’s groups. The words belong to the category of meaning words as established by the LIWC taxonomy. Even if the texts come from general discussion boards with less restrictive discussion topics, we can see that the terms are related to the diagnosis. There are words pertaining to the group of emotion: “awkwardness”, “spiritual”, “psychotic”, “guilt”; love and sexuality: “attraction”, “sexuality”, “cis”, “trans”, “hormones”; terms related to illness and medication: “illness”, “doses”, “medication”, “therapy”, “pharmacist”, “relapse” and acronyms: “NC” (no contact), “AA” (Alcoholics Anonymous), HSV (Herpes Simplex Virus), STD (Sexually Transmitted Diseases), TRP (in this case it refers to a Reddit community called r/The Red Pill – a controversial Men’s Rights Activists (MRA) space which has now been removed). The idiosyncrasy of the network is seen in the occurrence of terms related to its own internal structure. Wide ranges of topics are discussed and that might differ in a clinician’s office, in face-to-face situations and where one’s identity is known. These distinctive features will help our classifiers to better distinguish the control users from the diagnosed ones because in some cases like in the depressed users and the ones suffering from anxiety the language is less distinctive.

6 Classification Methods

Identifying significant differences between our groups was the main drive for training classifiers. We trained 3 different models based on the Transformers architecture to see how each performs binary classification between a diagnosed group and a control one. We obtained state-of-the-
art results for text classification using BERT, RoBERTa and XLNET, as it follows.

BERT is a language representation model designed to pre-train deep bidirectional representations from unlabeled text by jointly conditioning on both the left and right context in all layers introduced by Devlin et al. (2018). BERT’s key technical innovation is applying the bidirectional training of Transformer, which is an advanced Long Short Term Memory Network (LSTM) to language modelling. The model uses the Transformer architecture to capture long distance dependencies within sentences. The pre-trained model contains a general knowledge of language and by giving it task-specific data we can obtain promising results. BERT uses a special tokenizer, which has a specific way of dealing with words outside its vocabulary. It accepts input in a required formatting: we have to add tokens marking the start and end of a sentence, pad and truncate sentences in order to have a uniform length. An attention mask is added in order to differentiate between the padding and the first type of tokens. The [CLS] token marks the beginning of a sentence and must be present for any sentence-level classification task. The [SEP] token separates one sentence from the next so the model can learn entailment. [CLS] and [SEP] tokens were used when the developers pretrained BERT, and we must preserve the same scheme for the model to work properly. The maximum sentence length supported by BERT is 512 tokens. Our experiment uses the Hugging Face Pytorch implementation.

Table 5: Hyperparameters for each model.

Our machine needed smaller batch sizes to be able to train the model, so we used 3. We established a learning rate (Adam ε) of 1e-5 for the AdamW loss function implemented by Loschilov and Hutter (2017). We trained the model for 3 epochs only, because we noticed overfitting starting with the 4th epoch.

The second method we used is XLNet, which is another method for pre-training language representations introduced by Yang et al. (2019). XLNet was meant to overcome the limitations imposed by BERT with its autoregressive model and does so by outperforming it on 20 tasks as shown by Yang et al. (2019). For this method, we have a different formatted input and there is no limit for the length of the input texts. However, the input arrays need to be of the same size. This is addressed by padding the inputs that do not meet the size of the longest sequence. Padding means simply adding 0s until the length is met. For this classifier we had to limit the length of sequences to 126 due to computational resources. The optimum batch size was 8. The loss function we used was AdamW with the same hyperparameters as for BERT. We trained this model for 4 epochs. With a training set of approximately 100000 texts, we get a number of 50000 training steps.

The last model we used, RoBERTa implemented by Liu et al. (2019), is Facebook AI’s training method and it promises to improve on BERT. The researchers involved in implementing RoBERTa prove that BERT was undertrained and there is still a long way to go in terms of design choices and the way in which the improvements are reported. We did not use the full size of our dataset due to its large size and subsequent long training times.

Finetuning RoBERTa implies loading the weights of the pretrained model, in our case, the RobertaForSequenceClassification model. We use a sequence length of 256 and a batch size of 8. The loss function used here is AdamW with Adam ε of 2e-5.

7 Results

We obtained the results using 50,000 posts for each group alike. The compound of 100,000 posts for each binary classifier was split in 80,000 for training and 20,000 for testing. We trained our models with different hyperparameters until we reached the optimum ones detailed in table 6. We manage to overrun the baseline established by Cohan et al. (2018) using Transformers-based models on just a sample of their dataset. Their best results lie at approximately 50% accuracy with 57% being the best result obtained using Supervised FastText on Bipolar Disorder, while ours lie at approximately 75%, with 81% the best result. We also improve the results obtained by Jiang et al. (2020) on post-level classification as seen in table 7 by a considerable margin. We compare the results obtained using BERT and calculate the difference between our results and the ones from Jiang et al. Higher results were obtained with XLNet and RoBERTa in some cases. The BERT model achieves the highest accuracy for an illness: schizophrenia, OCD, eating disorder, autism and anxiety. We notice that discriminative features play an important role in building a performant model. The accuracy obtained by the eating disorder classifier is the highest due to the pregnant presence of discussions related to calories, diets, recipes etc. (as seen in table 6), whereas for depression we obtained the lowest F1 score, probably because depression is not always identifiable in linguistic acts, cf. Ireland and Mehl (2014). It is often a matter of contextual factors that might drive a user to discuss their emotional state or any other.
Table 6: Results for BERT (B), XLNET (XL) and RoBERTa (R) classifiers. Best results are in bold for each illness.

8 Conclusions

Our automatic classification experiments used the Transformers-based models BERT, XLNet and RoBERTa on the SMHD dataset for the classification of 9 mental health illnesses. We manage to overrun Jiang et al. (2020) by approximately 0.10-0.15 on the single-post classification task and prove that individual posts yield satisfactory accuracy. We overrun Cohan et al. (2017) by 0.20-0.30 who did not employ any deep learning methods.

We used a Naïve Bayes Classifier to discover the most important features for each group of users. Our results add to the group of articles showing good prospects for this field. An encouraging finding is the sufficiency of focusing on general text rather than mental health support groups and classification by posts rather than individuals or groups. Another takeaway is the sufficiency of post-level classification and avenue to improve this approach in future work by paying attention to contextual cues such as time, events, entailment of posts or any other possible triggers that might help the earlier detection of a mental illness. Further experimentation with different setups and data that are more diverse is also required. This would benefit our research and increase the possibility of future integration of automated tools, which could assist clinicians in the earlier detection of mental health issues.

Table 7: Comparison of BERT classification results – Jiang et al. (2020), Cohan et al. (2017) and our model. We report the results obtained by our binary classifiers in comparison with the binary classifiers trained by them. Cohan et al. did not employ any deep learning methods at the time, so we picked the highest F1 scores obtained with SVMs, Logistic Regression, FastText and CNNs.

Abstract

Code-mixing (CM) is a frequently observed phenomenon that uses multiple languages in an utterance or sentence. There are no strict grammatical constraints observed in code-mixing, and it consists of non-standard variations of spelling. The linguistic complexity resulting from the above factors made the computational analysis of the code-mixed language a challenging task. Language identification (LI) and part of speech (POS) tagging are the fundamental steps that help analyze the structure of the code-mixed text. Often, the LI and POS tagging tasks are interdependent in the code-mixing scenario. We project the problem of dealing with multilingualism and grammatical structure while analyzing the code-mixed sentence as a joint learning task. In this paper, we jointly train and optimize language detection and part of speech tagging models in the code-mixed scenario. We used a Transformer with convolutional neural network architecture. We train a joint learning method by combining POS tagging and LI models on code-mixed social media text obtained from the ICON shared task.

1 Introduction

In bilingual and multilingual communities, code-mixing or code-switching occurs when a person alternates languages below the phrase level inside a sentence or an utterance. Code-mixing (CM) is generally observed in informal settings such as casual conversations or social media text.

Code-mixing is defined as mixing phrases, words, and morphemes of one language into another language (Myers-Scotton, 1997).

Language identification (LI) and part of speech (POS) tagging are the fundamental steps in processing any code-mixed sentence. LI deals with resolving the language ambiguity of each word in a code-mixed text. POS tagging involves assigning a part of the speech label for each word in a sentence based on its syntactic and semantic information. It helps analyze the grammatical structure of the sentence. Both Language Identification and POS tagging are sequence labeling tasks as they tag each word in a sentence by its corresponding language and POS tags, respectively.

While processing a monolingual text, the primary step to understand the sentence’s grammatical structure would be POS tagging. However, in the code-mixed scenario, we must consider multilingual phenomena, i.e., each word’s language while POS tagging. Similarly, POS tagging helps capture a better grammatical structure of the text. Moreover, identifying the grammatical structure can improve language identification. In the code-mixing scenario, two tasks go hand in hand. Thus, a joint learning model on POS tagging and LI will considerably enhance the code-mixed text analysis.

Recently the transformer models with transfer learning such as BERT (Devlin et al., 2018) achieved state-of-the-art accuracy in sequence classification tasks. An evaluation benchmark on code-mixed datasets - GLUECoS (Khanuja et al., 2020) stated that a modified version of BERT (Devlin et al., 2018) called mod-mBERT that was fine-tuned on synthetically generated code-switched data outperformed on all the code-mixed datasets.

Recently, BERT with ensemble models has shown improved performance on text classification tasks (Dowlagar and Mamidi, 2021; Safaya et al., 2020). To improve our tasks’ performance, we have used a convolutional model. The convolutional approach learns a compositional structure in the sequences more efficiently since the representations are built on hierarchy.

In the code-mixed social media text, the native words are often written in the Roman script. The introduction of such non-standard transliterations will add complications while processing the
text. It is necessary to deal with these complications as they might introduce errors in further processing steps. To tackle such problems, we back-transliterated the Roman words into their native script.

This paper presents a pre-trained transformer encoder with convolutional neural network architecture for POS tagging and language identification of Code-Mixed Social-Media text. The model uses sub-word level input representation to handle morphologically rich words.

Our contributions are as follows:

1. We pre-process the data to deal with variations in spelling and transliterations.
2. We propose a transfer learning-based approach to jointly model LI and POS tagging tasks, achieving state-of-the-art accuracy on the ICON 2016 shared task dataset.
3. We design a BERT with convolutional neural network architecture for LI and POS tagging tasks. Our analyses confirm it is a better alternative than the joint Bi-LSTM model.

The paper is organized as follows. Section 2 presents a survey of related works on language identification and POS tagging in a code-mixed social media text. Section 3 introduces the proposed approach of jointly modeling the language identification and the part-of-speech tagging task for code-mixed social media text. In Section 4, we present the experimental setup and performance of our joint model. Section 5 concludes the work.

2 Related Work

Since the last decade, LI and POS tagging for code-mixed text has been a topic of interest in the field of natural language processing (NLP).

CM language identification: (Aguilar and Solorio, 2019) used a large pre-trained model ELMo, and adapted it to code-switching settings to obtain contextually rich embeddings. The paper used a Bi-LSTM CRF for language identification. (Mave et al., 2018) compared different word-level language identification systems for code-switched Hindi-English data and a standard Spanish-English dataset and found that the CRF model works the best on the given datasets. (Gundapu and Mamidi, 2018) performed LI using CRF on Telugu-English CM data. (Barman et al., 2014; Solorio et al., 2014) used SVM and CRF for language identification on CM data. (Rijhwani et al., 2017) used HMM for language identification on seven languages.

CM POS tagging: (Bhattu et al., 2020a) addressed the problem of prediction of POS tags for OOV words in low resource languages using character-based word embedding as input features to a Bi-LSTM and CRF network. (Ball and Garrette, 2018) used a meta embedding approach for the part of speech tagging where the word is represented in both code-mixed languages. Thus, it maintains embeddings for each language and is processed appropriately at inference time without committing to one or the other language. It used a Bi-LSTM model for POS tagging. (Jamatia et al., 2015) presented POS tagging results on English-Hindi social media text using various ML and deterministic approaches, among which CRF gave the best results.

Joint Learning: The joint learning models have been studied for the code-switched LI and POS scenarios. (Soto and Hirschberg, 2018) proposed a joint learning approach for POS tagging and LI using recurrent neural networks. (Barman et al., 2016) used a factorial CRF for joint modeling of POS tagging and language identification.

To the best of our knowledge, a joint learning model with BERT and CNN architecture for language identification and POS tagging on code-mixed data is not yet analyzed.

3 Proposed Model

In this section, we briefly describe the BERT and convolutional models. We then introduce the proposed joint model for POS tagging and LI of CM social media text. The architecture of the proposed model is given in figure 1.
3.1 Pre-processing

This section presents the steps performed for transliterating the code switched data to its respective languages.

The given code-mixed dataset portrays the real-time scenario of variations in script changes. Pre-processing is necessary on the text. During pre-processing,

1. To resolve the transliteration variations resulting from script change, we back-transliterated the script to the native language. Our code-mixed datasets have the matrix and embedded languages, where the embedded language is mostly English. Firstly, we used the NLTK\(^1\) English word corpus to detect if the word is in English or not. We used google trans API\(^2\) to detect the word’s language id. Later, we back transliterated the non-English word to its native script using a deep transliteration engine\(^3\).

3.2 Background - BERT

Bi-directional Encoder Representations with Transformers (BERT) (Devlin et al., 2018) is a transformer encoder stack trained on the large corpora. BERT uses a transformer architecture (Vaswani et al., 2017). The transformer architecture consists of a series of multi-headed attention, point-wise feed-forward layers with layer normalization to learn contextual relations between words (or sub-words) in a text. In our approach, we used a small version of the pre-trained multilingual BERT model called bert-base-multilingual-cased obtained from the transformers library. The pre-trained multilingual BERT models are trained on a large multilingual Wikipedia and book corpus. They capture a better semantic representation of words in a text. As the pre-trained model is trained on generic corpora, we need to fine-tune the model for our tasks. During fine-tuning, the pre-trained BERT model parameters are updated.

3.3 Convolutional Model

The convolutional neural network (CNN) model is made of convolutional layers. In short, a convolutional layer uses filters. These filters have a width for processing text. If a filter has a width of 3, then it can see three consecutive tokens. It has many filters, and these filters will slide across the sequence, from beginning to the end, looking at all three consecutive tokens at a time. These filters will learn to extract a different feature from the text. This feature extraction will then be used by the model - potentially as input to another convolutional layer.

Similar to the BERT model, the convolutional model has a positional embedding layer to remember the sequence. The token and positional embeddings are element-wise summed together to get a vector containing information about the token and its position within the sequence. It is followed by a linear layer that transforms the embedding vector into a vector with the required hidden dimension size. The next step is to pass this hidden vector into convolutional blocks. In convolutional blocks, the input sequence is padding such that the length of the input sequence and output sequence should be equal. A Special activation function called gated linear units (GLU) (Dauphin et al., 2017) is used after convolutions. The GLUs have gating mechanisms (similar to Bi-LSTMs (Hochreiter and Schmidhuber, 1997)) contained within the activation function. After passing through the GLU activation, each token’s hidden dimension size is the same as it was when it entered the convolutional blocks. Finally, residual connections are applied to solve the vanishing gradients problem, and linear transformations are done to match the dimensions. This process is repeated for $N$ convolutional blocks.

CNN model is formulated as,

$$ h^l_i = v^l \left( \sum_{k=0}^{l-1} h^{l-1}_{i-k/2}, \ldots, h^{l-1}_{i+k/2} \right) + b^l_w + h^{l-1}_i $$

(1)

Where $h^l_i$ is the output of the $i^{th}$ sequence in $l^{th}$ block. $v^l$ is the GLU activation function. $\left[ h^{l-1}_{i-k/2}, \ldots, h^{l-1}_{i+k/2} \right]$ are convolutional transformations of previous layer. $W^l$ and $b^l_w$ are learnable parameters and $h^{l-1}_i$ is the residual output from the previous layer.

After performing the convolutions, Finally, we compute a distribution over the $T$ possible LI or POS tags by transforming the top convolutional encoder output $h^L$ via a linear layer with weights $W_{s_2}$ and bias $b_{s_2}$.

$$ y^l_{i} = \text{softmax} \left( W_{s_2} h^L_i + b_{s_2} \right) $$

(2)

$$ O^l_{i} = \text{argmax} \left( y^l_{i} \right) $$

(3)
3.4 Joint Learning Framework

In sequence tagging, we have to learn a function \( f : x \rightarrow y \) that maps an input sequence \( x \) to the corresponding label sequence \( y \). We want to find the best label sequence \( y \) given an input sequence \( x \) that maximizes the probability (\( p \)) of the sequence given the label.

\[
\hat{y} = \arg\max_y p(y|x)
\]

In the multilingual code-mixed scenario, if the POS tagging and LI tasks are trained together, joint learning will help the model learn better data representation, improving the tagging accuracy. Thus, we propose a joint training model. The LI and POS tagging tasks can be viewed as conditionally independent in the joint learning scenario, given the transformer encoder parameter values. To jointly train the POS tagging and LI models, the objective is formulated as,

\[
p(y_{\text{lang}}, y_{\text{pos}}|x) = \prod_{t=1}^{T} p(y_{\text{lang}}|x,E)p(y_{\text{pos}}|x,E)
\]

Where \( p(y_{\text{lang}}, y_{\text{pos}}|x) \) is the conditional probability of learning the joint task given the input word sequence, and \( E \) stands for encoder parameter values.

The negative logarithm of the above equation gives us the loss function:

\[
L = -\log \prod_{t=1}^{T} p(y_{\text{lang}}|x,E)p(y_{\text{pos}}|x,E)
\]

\[
= -\log \prod_{t=1}^{T} p(y_{\text{lang}}|x,E) - \log \prod_{t=1}^{T} p(y_{\text{pos}}|x,E)
\]

Which can be further written as

\[
L = L_{\text{lang}} + L_{\text{pos}} \tag{4}
\]

If we apply a joint loss function for both the models, we can learn a better POS tagging and LI model for the CM scenario.

4 Experiments

This section evaluates the above method with the individual POS tagging and language identification models on the CM dataset.

Table 1: A example of language and POS tagged Hindi-English code-mixed sentence obtained from the corpus. Where "hi" refers to the Hindi language and "en" reference to the English language.

4.1 Dataset

The dataset used for the LI and POS tagging task on the CM language is obtained from the ICON shared task 4. The CM social media text consists of 3 languages (Bengali, Hindi, and Telugu with mixed English words). The sentences are in roman script. Each word is labeled with its corresponding language label and POS tag. The total number of CM sentences in this dataset is 9212. Two types of POS tagging schemas are used in the dataset. One is a coarse-grained (CR) tagset that used google’s universal POS tag-set (Petrov et al., 2011) and the other is fine-grained tagset (FI) with an extended tag-list related to social media text (Gimpel et al., 2010; Owoputi et al., 2013). We have used both POS tagsets in our experiments. The initial dataset contained errors in tagsets, which were addressed in the article (Bhattu et al., 2020b). We have used the revised tagset in our paper obtained from (Bhattu et al., 2020b). An tagged Hindi-English sentence is given in the table 1.

4.2 Baselines

We compared the performance of our model with the related works on the CM data. The acronym “(I)” refers to the individual model, and “(J)” refers to the joint model.

**CRF (I):** A CRF model is used for language identification on the CM data. The features set defined in (Gundapu and Mamidi, 2018) is used while training the CRF model.

**FCRF (J):** A factorial CRF model with joint learning (Barman et al., 2016) for LI and POS tasks.

**Bi-LSTM CRF (I):** This is the most commonly used model for the LI and POS tasks. It uses Bi-

LSTM and CRF consecutively for POS tagging the CM text (Aguilar and Solorio, 2019; Bhattu et al., 2020a).

**Bi-LSTM CRF (J):** A Bi-LSTM CRF model that is trained for the task of joint learning (Soto and Hirschberg, 2018).

**BERT (I):** Pre-trained multilingual BERT (Devlin et al., 2018) is used for the given LI and POS tasks.

**BERT (J):** A joint BERT model (Chen et al., 2019) is used for CM language identification and POS tagging.

### 4.3 Implementation

We implement the proposed model as follows. The input text is pre-processed. The pre-processed text is given to the BERT model. The BERT encodes the input text. The encoded input is given to the convolutional model. The encoded output is given to the 2 multi-layer perceptron models (MLP), each one for the two tasks LI and POS tagging. Then we aggregate the loss of the two models. The loss is then propagated backward, and the model optimizes to minimize the losses of both the NN models.

The proposed model is trained using Adam optimizer with cross-entropy loss obtained from the joint model. The hyperparameters are: Optimization ($\alpha$) = 0.001, dropout probability is 0.25. The number of epochs used is 10. All the deep learning models are implemented in python 3.6 using the PyTorch and the Torchtext libraries. We used the NVIDIA RTX 2070 graphics card with an 8GB GPU memory. We have used python-crfsuite\(^5\) and pytorch-crf\(^6\) for the CRF model, and the BERT model is obtained from the transformers\(^7\) library.

### 4.4 Performance

We compared our model with all the baselines and the results are tabulated in tables 2, 3 and 4. The proposed model has shown an improvement in the language identification and the POS tagging tasks compared to the baseline models (CRF and Bi-LSTM CRF). Using joint learning, The joint model has seen a further improvement when compared to the individual models.

Even the BERT model has proved better than the other models because of its state-of-the-art transformer architecture. We have observed that the transformer architecture helped the model to learn the tags that have a low frequency and gave better recall for the low-frequency tags. We observed the same in our convolutional seq2seq model.

Our model, the BERT with the convolutional seq2seq architecture, formed a meta-learning approach on the code-mixed text. The BERT model learned the better representation of the data. The kernels used in the convolutional seq2seq model helped the model consider the previous tagged information while predicting the current tag. We had observed that the suffixes are classified correctly when our approach was used.

For Language Identification, we have seen a considerable difference in joint learning and POS tagging when compared to the CRF model on the Telugu-English dataset. We have observed that most of the misclassified te(Telugu-word) and en(English-word) are correctly classified with joint learning. Even the acro(acronym) words which were of low frequency, were better identified with our approach. Some mixed words, i.e., with intra level code-mixing, are present in the data. These have undergone sub-word tokenization and were unidentifiable by the BERT model. As the CNN model uses the filter of size 3, the previous two tokens will be considered while predicting the tag of the current token. The CNN model and the pre-processing step helped the model to detect the mixed words correctly, which further improved the performance of our model.

In fine-grained and coarse-grained POS tagging, the major shift in joint-learning and individual task learning is observed in the baseline CRF model on the Bengali-English coarse-grained dataset. We have observed that the incorrect tagging of $G_N$ as $G_V$ or vice versa has decreased when joint learning is used for the POS tagging scenario.

We have also observed that our approach performed better in tagging $G_N$ and $G_V$ words when compared to the CRF and Bi-LSTM CRF models. It resulted in improved accuracy. It is due to its state-of-the-art multi-headed attention feature used in this model.

In the code-mixing scenario, the word’s POS tag depends on the following factors: how the word is used in the CM sentence, its multilingual feature, and its context. With the help of joint learning, which considered the grammatical structure and multilingual nature of the word, the incorrect classification problem of tagging $G_N$ as $G_V$ and
vice-versa is reduced.

We have observed low macro-F1 scores in our tagging models. It is due to the presence of distinct tags with low frequency and was insufficient to be trained by the existing models. These tags compromised the F1 score on the given data.

The experiments conducted on various models show that the joint learning model achieves improved POS tagging and LI in the code mixed scenario.

5 Conclusion

In this paper, we presented the joint BERT with the CNN model for POS tagging and LI. The joint learning model allowed the POS tagging and LI to be conditioned on each other to achieve better processing of code-mixed text. We tested our model with individual tasks. The results prove that our model achieves better metrics when compared to individual models. Such relations can effectively achieve better sentence-level semantic representa-

tion due to such diverse learning scope.

Recently meta embedding representations that include both the pre-trained embeddings and domain-specific fine-tuned embeddings are achieving great results in the field of NLP. The joint learning with meta embeddings is left as future scope.

Abstract

Previous research has used linguistic features to show that translations exhibit traces of source language interference and that phylogenetic trees between languages can be reconstructed from the results of translations into the same language. Recent research has shown that instances of translationese (source language interference) can even be detected in embedding spaces, comparing embedding spaces of original language data with embedding spaces resulting from translations into the same language, using a simple Eigenvector-based divergence from isomorphism measure. To date, it remains an open question whether alternative graph-isomorphism measures can produce better results. In this paper, we (i) explore Gromov-Hausdorff distance, (ii) present a novel spectral version of the Eigenvector-based method, and (iii) evaluate all approaches against a broad linguistic typological database (URIEL). We show that language distances resulting from our spectral isomorphism approaches can reproduce genetic trees on a par with previous work without requiring any explicit linguistic information and that the results can be extended to non-Indo-European languages. Finally, we show that the methods are robust under a variety of modeling conditions.

1 Introduction

The study of cross-linguistic variation has been a key focus of linguistics for genetic or typological classification of languages. Historical comparative linguistic methods determine genetic relationships between languages using concept lists of words with a common origin in multiple languages that share similar meaning and pronunciation (Swadesh, 1952; Dyen et al., 1992). Linguistic typology studies how distinct languages are, and what generalizations can be made regarding cross-linguistic variation on different levels of linguistic analysis and representations (Trask, 2000). Comrie (1989), for example, studies language variance in terms of their functional processes, whereas Cysouw (2013) measures language distance using structural features. More recent research indicates that semantic similarity between languages can serve as a quantitative means to determine cross-linguistic variation across languages. Seminal work of Eger et al. (2016) provides evidence that semantic alignment between languages can be explained by geographical factors. Likewise, Thompson et al. (2018) find that differences correlate with cultural distances among societies speaking the languages.

Conversely, it has also been shown that language differences are so profound that the structure of a language is approximately preserved even when translated into another language. This is often referred to as source language interference (Toury, 2012). Rabinovich et al. (2017) show that source languages of translations into the same target language can be clustered solely based on interference phenomena in the translations in the target language using simple linguistic features and that these clusters correspond with genetic distance. In a similar vein, Bjerva et al. (2019) find that comparable results can be established by clustering neural language model (NLM) based vectors using raw words, part-of-speech (POS) tags, phrase-structure or dependency-based input sequence representations of the data, showing that the distances between these learned language representations are more reflective of syntactic (structural) similarity rather than genetic relationship. Chowdhury et al. (2020) show that source language interference is even evident in simple word, POS, synset and semantic tag based embedding spaces computed from originally authored and data translated into the same target language. They use a graph-based Eigenvector (EV) divergence from iso-
morphism distance measure (Søgaard et al., 2018), originally used for bilingual dictionary induction, to capture divergence from isomorphism between monolingual original and translation embedding spaces. With this, they quantify distances between the source languages of the translations and predict phylogenetic trees, and analyse the correlation between isomorphism measure based distances and genetic relations in language families.

However, to date, (i) alternative graph-based distance metrics have not yet been explored for embedding-based approaches to detect translationese; (ii) it is not clear how word-embedding based approaches fare under different data settings including a) varying the number of most frequent words considered in the graphs, b) different corpus sizes and c) different word embedding architectures; (iii) it is not clear how the previous approaches (using either linguistic feature vectors, NLM based feature vectors, or divergence from isomorphism graph-based distance between embedding spaces) compare on the same data against the commonly used gold standard phylogenetic tree of Serva and Petroni (2008) (SP08); (iv) it is not clear how function words would affect graph-based distances; (v) evaluation of the graph- and embedding-space approach against the broader URIEL typological data base (Littell et al., 2017) has not been carried out; and (vi) it is not clear if the scope of this research can be expanded to include non-Indo-European languages.

In this paper, we show (i) that Gromov-Hausdorff (GH) distance can be used as a distance metric to quantify divergence from isomorphism between simple embedding spaces in monolingual settings and develop a novel Spectral Graph-based (SGM) distance measure, extending the original EV-based approach; (ii) that graph- and embedding-based distances are fairly robust under different data settings and that they are not sensitive to skip-gram or CBOW-based embeddings; (iii) divergence from isomorphism graph-based measures using embeddings can reproduce genetic trees on a pair with linguistic feature vector and NLM based approaches (Rabinovich et al., 2017; Bjerva et al., 2019); (iv) that function words and concept lists are still relevant within this general approach; (v) that graph- and embedding space-based distance metrics correlate not only with genetic features but also with geographical and syntactic ones (Littell et al., 2017); and (vi) that this research can be extended to translations from non-Indo-European languages.

The rest of the paper is organised as follows. We review related work in Section 2. Section 3 introduces the concept of graph isomorphism and our SGM measure, together with EV and GH. We describe the experimental setting in Section 4. In Section 5, we report results on the isomorphism metrics, infer language family relationships and correlate them with linguistic benchmarks. We describe robustness experiments in Section 6 and compare to previous work in Section 7. Finally, we extend our analysis to non-Indo-European source languages in Section 8 and summarize and draw conclusions in Section 9.

2 Related Work

Representational distance between two languages refers to how different one language or language variety is from another. Several analyses (Malaviya et al., 2017; Onecevay et al., 2020) have attempted to disentangle the typological factors that influence language representational distance. Rabinovich et al. (2017) clustered languages based on linguistically inspired features of their translations into the same target language and show that syntactic footprints of the source language in the translations can be used to estimate phylogenetic similarities between their source languages. They use agglomerative clustering with variance minimization (Ward Jr, 1963) as linkage procedure and compare their generated trees (P) to the pruned gold-tree (g) (SP08) of Serva and Petroni (2008). Their comparison metric is the sum of squared deviations between each language pair’s gold-tree distance and corresponding distance in their computed tree DP:

\[ \text{Dist}(P, g) = \sum_{i,j} (D_P(l_i, l_j) - D_g(l_i, l_j))^2 \] (1)

It is worth noting that the use of SP08 as a gold standard has also been questioned in the literature. Fortson IV (2011) observes that the SP08 approximation is only suited for a small subset of languages and that it fails to explain finer-grained inconsistencies in the Indo-European language family.

Bjerva et al. (2019) expand the work of Rabinovich et al. (2017) in their NLM- and sequence-based approach and argue that representational distance between languages can be better explained by structural relatedness than by language genetics. Chowdhury et al. (2020) use departures from
isomorphism based on the EV measure (Søgaard et al., 2018) on simple embeddings to infer genealogical distances. They compare different embedding spaces (word, POS, synset or semantic tags) constructed from translations into a single target language and the target language in terms of how similar their corresponding nearest neighborhood graphs are by analyzing their eigenvalues.

The similarity between languages can also be measured using the (dis)similarities between their discrete linguistic properties. Such properties are typically handcrafted and collected in typological databases such as URIEL (Littell et al., 2017) which lists a large inventory of properties for 8000 languages of various typological characteristics, such as overlap in syntactic features, or proximity along phoneme features (Cysouw, 2013). URIEL is a compilation of a variety of linguistic resources including the World Atlas of Language Structure, WALS (Dryer, 2009), PHOIBLE (Moran et al., 2014), Ethnologue (Lewis et al., 2015), and Glotolog (Nordhoff and Hammarström, 2011). Based on linguistic feature vectors, URIEL provides precomputed distance statistics between any language pairs stored in the database in terms of various metrics including genetic, geographical, syntactic, phonological, and phonetic inventory distances.

In this work, we follow the approach of Rabinovich et al. (2017) and evaluate our geometrical measures against the phylogenetic benchmark SP08. We compute the branching length directly from SP08, assuming it reflects the actual proportions. Additionally, we follow He et al. (2019) to compare our generated trees against the average of three precomputed measures of language distance, namely genetic, geographic, and syntactic distances based on the URIEL database.

3 Graph Isomorphism

We define the distance between languages based on word usage and the notion of isomorphism. An isomorphism \( f \) between two metric spaces \((\mathcal{X}, d_\mathcal{X})\) and \((\mathcal{Y}, d_\mathcal{Y})\), where \( \mathcal{X} \) and \( \mathcal{Y} \) are two sets of words in two languages and \( d_\mathcal{X} \) and \( d_\mathcal{Y} \) are the metric distances, is a function \( f : \mathcal{X} \mapsto \mathcal{Y} \) that is a distance preserving transformation i.e.: for all pairs of points \( x_1 \) and \( x_2 \) in \( \mathcal{X} \) such that, \( d_\mathcal{Y}(f(x_1), f(x_2)) = d_\mathcal{X}(x_1, x_2) \).

For a vocabulary \( V = v_0, v_1, ..., v_n \) in language \( \ell \), we define its graph as \( G(V, E, w) \), where \( V \) denotes the set of vertices corresponding to the vocabulary words; \( E = e_0, e_1, ..., e_m \) is a set of edges; and every pair \( \{v_i, v_j\} \) has a non-negative edge weight \( w_{ij} \) associated with it. Our approach starts with mapping words \( v_\ell^i \) in language \( \ell \) onto points \( v_\ell^i \) using distributional semantics methods. Each language is then represented with its own graph \( G_\ell^i \). After mapping words onto points \( v_\ell^i \) as vectors, the distance between words is defined as the distance between their vectors. We quantify the similarity between languages \( \ell_1 \) and \( \ell_2 \) through a distance function between their graphs \( d(G_\ell^1, G_\ell^2) \). In what follows we make the concept mentioned above more concrete.

3.1 Gromov-Hausdorff (GH) Distance

The first measure we use to quantify the similarity between languages is the Gromov-Hausdorff distance (GH) proposed by Patra et al. (2019).

Given two metric spaces \((\mathcal{X}, d_\mathcal{X})\) and \((\mathcal{Y}, d_\mathcal{Y})\), we start with the Hausdorff distance, defined as:

\[
d_{H}(\mathcal{X}, \mathcal{Y}) = \max \left\{ \sup_{x \in \mathcal{X}} d(x, \mathcal{Y}), \sup_{y \in \mathcal{Y}} d(y, \mathcal{X}) \right\}
\]

where \( d(a, \mathcal{B}) = \inf_{b \in \mathcal{B}} ||a - b||_2 \) is the distance of point \( a \) in \( \mathcal{A} \) from set \( \mathcal{B} \). Informally, it is the largest distance needed to travel from a point in \( \mathcal{A} \) to a point in \( \mathcal{B} \).

However, the Hausdorff distance is easily affected by isometric transformations. The GH distance which is the infimum of the Hausdorff distances under all possible isometric transformations is a more robust measure. By contrast, the GH distance reduces the distance over the isometric transforms \( f \) and \( g \) between \( \mathcal{X} \) and \( \mathcal{Y} \) as follows:

\[
d_{GH}(\mathcal{X}, \mathcal{Y}) = \inf_{f,g} d_{H}(f(\mathcal{X}), g(\mathcal{Y}))
\]

The computation of Hausdorff distance is NP-hard, and hence we follow Patra et al. (2019) and compute the Bottleneck distances (Chazal et al., 2009) which are considered to be reasonable lower-bounds.

3.2 Spectral Graph-based Matching (SGM)

Our second measure is based on the graph-based Eigenvector similarity method. Søgaard et al. (2018) used this similarity to measure the distance between two embedding matrices corresponding to two languages \( \ell_1 \) and \( \ell_2 \), via their Laplacian matrices, \( L \). They argue that the Laplacian eigenvalues are good compact representations for the
graph Laplacian, and that their comparison can consequently capture the degree of isomorphism. Although similar in spirit to their approach, our method to build the underlying graphs \((G_{\ell}^1\text{ and } G_{\ell}^2)\) differs. We use the same idea to model differences between two embedding spaces \(X\) and \(Y\) for the single target language translations from different source languages, as proposed by (Søgaard et al., 2018) but our method to build the underlying graphs \((G_{\ell}^1\text{ and } G_{\ell}^2)\) differs from their approach. While they extract the nearest neighbors by computing the cosine similarity of the cross-lingual word pairs, we take inspiration from the Isomap algorithm of Tenenbaum et al. (2000) and build a weighted connected graph over the data points to capture better neighborhood relations. Weights \(w_{ij}\) correspond to the distance between points \(i\) and \(j\) in the input space \((X, d_X(i, j))\). We connect each point only to its \(K\) nearest neighbors to consider more geometrical information on the interaction between all vectors within the initial space to improve the graph characterization of the spaces. The value \(K=6\) is chosen to have similar edge density for all graphs. We estimate the geodesic distances between vertices (points) in the input space using shortest-path distances obtained with Dijkstra’s algorithm (Dijkstra et al., 1959) on the constructed graph to minimize the sum of the weights of their constituent edges. The subsequent distance matrix represents the basis for our graphs. From this point onwards, the computation of the Laplacian matrices and the final measure \(\Delta\) is as in Søgaard et al. (2018), where

\[
\Delta = \sum_{i=1}^{k} (\lambda_{1i} - \lambda_{2i})^2. \tag{4}
\]

First for \(L_1\), we find the smallest \(k\) in Equation 4 such that the sum of its \(k\) largest eigenvalues \(\sum_{i=1}^{k} \lambda_{1i}\) is at least 90% of the sum of all its eigenvalues. Similarly, we find another \(k\) for \(L_2\), and take the smallest of these two, such that, \(k = \min(k_1, k_2)\). The graph similarity metric returns a value in the half-open interval \([0, \infty)\), where values closer to zero indicate better isometry. We compare our SGM metric with the metric of Søgaard et al. (2018) (referred to as EV) in Section 5.

4 Experimental Setting

In this section, we provide information on the data, and the vector spaces used for computing deviation of isomorphism. Since we quantify language similarity based on the degree of isomorphism in monolingual spaces, we independently train monolingual word embeddings for the target language and translations into that target language.

4.1 Data

We use the same setup as Rabinovich et al. (2017), Bjerva et al. (2019) and Chowdhury et al. (2020), and use the comparable portion of Europarl (Koehn, 2005) with translations from 21 European Union languages into English to minimize the impact of domain difference. The tokens per language vary, ranging from 67k tokens for Maltese to 7.2M for German. We refer to the multiple translations into English as \(L_j\)’s, where \(j=1,2,...,n\); and to originally written text in English as \(L_o\).

We select the subset of translations from 16 languages covering four families: Romance (French (fr), Italian (it), Spanish (es), Romanian (ro), Portuguese (pt)), Germanic (Dutch (nl), German (de), Swedish (sv), Danish (da), Slavic (Czech (cs), Slovak (sk), Slovenian (sl), Polish (pl), Bulgarian (bg)) and Baltic (Latvian (lv) and Lithuanian (li)) into English and English original (en) text.

For these 17 datasets, we define two settings, the full data condition and the small data condition to investigate the effect of data settings on our methods. The former makes use of the complete Europarl edition available for a language (recall that data size differs widely); for the latter, we randomly extract \(m\) sentences, where \(m\) corresponds to the lower-bound data-size of our translationese data, i.e., the size of the Latvian corpus (118,525 words). We shuffle and randomly subsample \(m\) sentences with the same seed for all target-side language data. We report results for the full data setting and use the small data for robustness checks and comparisons with existing literature.

4.2 Vector Spaces

Our data are original English \((L_o)\) or translations from language \(j\) into English \((L_j)\). For each data set we induce separate monolingual embeddings in the full and small data conditions, from their respective tokenised (Koehn et al., 2007) and lower-cased data using fastText (Bojanowski et al., 2017).

We train 300 dimensional embeddings with words with more than 5 occurrences in the data. We use skip-gram with negative sampling (Mikolov et al., 2013) with standard hyper-parameters (character \(n\)-grams of sizes 3 to 6, and a learning rate of...
Afterwards, embeddings are mean centered and unit normalised. For comparison purposes, we also create vector spaces using the CBOW algorithm and standard hyper-parameters.

5 Results and Evaluation

We analyze the behaviour of the different distance measures: the Gromov-Hausdorff distance (GH) and the two Eigenvector similarity-based ones (SGM and EV). We apply them to (i) infer language families, (ii) reconstruct phylogenetic trees, and finally (iii) perform correlation analysis against two benchmarks (SP08 and URIEL).

5.1 Language Distance Measures

First, we perform an experiment to determine how distant the vector spaces created from $L_o$ and $L_j$’s are. We compute each metric over the top-$n$ most frequent common words in our data, where $n \in \{1000, 1500, 2500, 3500\}$ to explore the behaviour of the measures with different graph sizes. Notice that having the same number of components (vertices and edges) is a condition for isomorphism.

Results with the normalised distances are displayed in Figure 1. The behaviour for the metrics varies with respect to the number of the most frequent top-$n$ datapoints considered. SGM is the most stable measure across all configurations, showing most variance for 1000 points. EV shows larger variability in distinguishing language similarity, while GH results are relatively stable with respect to larger datapoints (2500 and 3500 points). These variations are due to the different nature of the metrics. GH calculates the distance between the spaces only on the subset of $n$ words, while SGM weights the nearest neighbors of a word which could lie outside the top-$n$ to build the initial graph. Thus SGM considers more context for each point and thus needs less datapoints to successfully describe the space. As expected, results with EV and SGM are closer to each other than to GH because they follow a similar methodology, except that SGM retains more context than EV.

We observe that, in all plots, the differences between original English and translations from Germanic, followed by Romance languages are the lowest, indicating that vector spaces of these languages are closer to each other in terms of semantic embedding space based isomorphism measures. However, isomorphism weakens consistently with increased linguistic distances of Baltic and Slavic families irrespective of the method used, providing evidence that language distance in semantic space is higher for etymologically distant language pairs. Additionally, we observe some outliers varying from measure to measure. GH puts ro far from the other Romance languages and da and sv are placed relatively far from other Germanic relatives.
On the other hand, SGM (and to lesser extent EV) locates pl close to en.

5.2 Reconstructing Language Phylogeny

Figure 2 shows evidence that deviations from isomorphism between semantic spaces computed from $L_j$'s into a common target language (en) and originally authored text ($L_o$) in en reflect linguistic notions of distance between the source languages and the source language families of the translations. This is evidence for an important aspect of translationese, namely source language interference, in semantic space. Below we further investigate whether the distance in semantic space signal can be used to infer phylogenetic trees.

In our predicted trees, Figure 2, we observe trends that indicate groupings based on morphological or other typological properties. We identify some well known language–language relationships in all three trees showing high similarity between English and other Germanic languages, with some divergences —for example, sv is located far away from its other Germanic counterparts under GH reconstructions and pl is always misplaced into the Germanic-Romance language group, despite its Slavic origin. The influence of geographical factors such as language contact or structural interactions (Balkan Sprachbund) can also explain some of the interesting divergences. Overall, the trees exhibit coarse-grained language family contour traces, i.e., Baltic and Slavic languages are close together, while Germanic and Romance form another group in most of the cases.

Our simple embedding-based results provide evidence that translationese is reflected in semantic spaces and that without reliance on fine-grained linguistic knowledge, differences in semantic embeddings space are powerful enough to detect important language differences related to linguistic typology in semantic spaces, corroborating previous results of Chowdhury et al. (2020). This further reconfirms in word embedding based semantic space earlier findings of Rabinovich et al. (2017), Bjerva et al. (2019) which used manual feature engineering or NLMs with a focus on morphologic and syntactic structure.

5.3 Correlation with Typology, Geography and Phylogeny Benchmarks

Above we observed how predicted trees not only show genetic effects, but also other characteristics that might be due to the geographic proximity and not to just to phylogenetic evolution. In this section, we compare our language classification predictions, Figure 2, against linguistic benchmarks. We estimate Kendall correlations between our generated trees and SP08 (representing genetic similarities), and our trees and the averaged URIEL features introduced in Section 2 (representing other rich typological similarities beside genetic ones). The Kendall correlation between the two benchmarks SP08 and the selection of URIEL features is 0.56 reflecting the different nature of the two benchmarks. Although the genealogical distance is common in both, the source for this kind of information is different.

Our results, summarised in the top rows of Table 1, show that correlations between predicted trees and URIEL are higher than with SP08, demonstrating that other factors besides genetics are reflected in the semantic spaces. SGM reproduces the genetic SP08 benchmark better than EV and GH, while GH clearly correlates better with structural URIEL features, followed by SGM and EV. This corroborates NLM-based findings of Bjerva et al. (2019) in our semantic word embedding based spaces: the differences and similarities between languages and language representations go beyond genetic (dis)similarities. Further, we find that while correlations are better under full data conditions, they exhibit a similar behaviour in simulated small-data scenarios, suggesting that our graph-based approaches are effective in a variety of data settings.

6 Robustness Analysis

After showing that exploiting departures from isomorphism between spaces can be used to predict relations between languages, we analyze the impact of various modeling assumptions and different training conditions that might have an effect in skewing the results.

6.1 Data Size Effects

Large differences in data sizes between high and low-resource languages have played a pivotal role in the performance of monolingual embeddings (Vulić et al., 2020; Sahlgren and Lenci, 2016). In our work, to some extent this is already minimized

---

by taking only the most frequent \( n \) words to estimate the distances between embedding spaces, but still the quality of even these embeddings might differ. To examine the impact of the data size for our experiments, we use the embeddings obtained under the small data condition (see Section 4) and compare the results in the bottom rows of Table 1.

The results show that SGM correlates best with SP08 under all training conditions (number of datapoints and corpus size), but the correlation decreases with respect to URIEL features. GH shows good correlation in some instances (1500 and 2500 datapoints) for both SP08 and URIEL, while EV, shows no consistent correlation. For EV, we consider frequent words and mutual nearest neighbors, thus in the small data condition, it has even less access to contexts. Our spectral graph-based measure SGM, which is inspired by the ideas of node representation in contemporary geometric and manifold learning (Cayton, 2005), provides more intuitive understanding of linguistic distances than what is offered in Chowdhury et al. (2020) under varied data settings.

6.2 Word Embedding Effects

Köh (2015) showed that different methods to obtain word embeddings (CCA, skip-gram, CBOW, GloVe, etc.) behave similarly when capturing syntactic and morphological information. We check that this is also the case with our distance methods by comparing the performance obtained with skip-gram and CBOW architectures, and observe small variations with similar global trends. To give an example, correlation results for SGM under the full data condition with CBOW and skip-gram vary only in the ±0.05 range.

We also performed experiments with lower dimensions (50,100,200) which may lead to reduced expressivity, but, very interestingly, we obtained similar performance as we did with 300 dimensions. For example, on 100-dimensional monolingual word embeddings, the differences are: GH (±0.077), SGM (±0.013), and EV (±0.088).

7 Comparison with Previous Approaches

7.1 Leaf-Node Tree Distances

In order to compare our results with previous work, we calculate tree distances using the leaf-node distance in Equation 1 previously defined in Rabinovich et al. (2017), and compare with the best results on SP08 in Rabinovich et al. (2017) and Bjerva et al. (2019). We report our results in the small and the large data conditions for 1500 most frequent datapoints obtained with different metrics in Table 2. All distances are normalized to a zero-one scale.\(^3\)

\(^3\)Notice that the results of Table 1 and Table 2 cannot be directly compared as Table 2 is computed after summing over all possible pairs of the leaves (languages), while Table 1 shows the association with benchmarks (SP08 and URIEL) keeping only originally authored English as its source. Table 1 follows Chowdhury et al. (2020) to correlate the results with the benchmarks and Table 2 compares the findings to Rabinovich et al. (2017); Bjerva et al. (2019).

\(^4\)Although an overall correlation similarity analysis based on confusion matrices would be more optimal, we perform...
According to the mean distance, our simple embedding and graph-based approaches, especially GH can reproduce genetic trees on a par with previous work without requiring any explicit linguistic information.

Unlike previous methods which rely on surface-level features of the source language, our graph-based isomorphism analysis is unsupervised and still is able to detect important language differences related to linguistic distances. Of all the methods, GH is the closest to SP08, followed by SGM and EV in the full data settings while the trend for SGM-EV is reversed under the small data condition.

7.2 Function and Content Words

To control topical skew, we investigate whether our approaches of departure from isomorphism works on non-lexical representations. To this end, we first focus on function words which introduce and identify key discourse referents and represent relationships between entities but are considered to be not well-modeled by distributional semantics (Bernardi et al., 2015). We use the list of function words defined in Koppel and Ordan (2011) to construct the language distance measure of Section 5.1 in Figure 3(a). In this case, the number of data points is 468, well below the minimum number of points used with content words (1000).

The performance of all three methods show similar trends as in Figure 1. The figure demonstrates that function words are able to capture departures of isomorphism in a similar way as the complete set of words, indicating that source languages carry over grammatical constructs into the translation product, corroborating in simple embedding space prior findings of Rabinovich et al. (2017) and Bjerva et al. (2019) with function words.

Additionally, we explore the much smaller cog-
nate collection of Swadesh word lists (Swadesh, 1952) to capture the relatedness between languages in Table 1 and the language distance computed from their embeddings is shown in Figure 3(b). As this concept-aligned resource ensures a consistent set of word-lists across all our languages, thereby enhancing comparability, these findings are particularly important. The results in Table 1 show that the large context (6 neighbors) exploited by SGM estimations exceeds other isomorphism methods, while highlighting the limitations of EV in low-data regimes with limited access to contexts.

8 Analysis for non-Indo-European Source Languages

Previous research (Rabinovich et al., 2017; Bjerva et al., 2019; Chowdhury et al., 2020) focused on investigating translationese and source language interference for European language families. Here we extend this work, for the first time, to the best of our knowledge, to translations from non-Indo-European languages into English. We explore the language distance measures of Section 5.1 on the UN corpus (Tolochinsky et al., 2018) which consists of translations covering typologically different languages such as Arabic (ar) and Chinese (zh), as well as Indo-European languages (i.e., Russian (ru), Spanish (es) and French (fr)). The embedding spaces are created in the same manner as for Europarl dataset.

We show results with 1500 words in Figure 4 and observe the following trends: compared with translations from ar and zh, the difference between original English and translations from fr and es tend to be smaller, the distance to zh is the largest, and that within the European language family distances is mostly \( fr < es < ru \). This is in line with our previous results in Figure 1 on the same-domain monolingual Europarl data under different data settings. However, despite these general trends, GH and EV measured distance scores are similar for es, ar and ru, while EV has fr more distant to en than es, ru and ar. This is something that would need to be further explored in future work. Of all measures, SGM, which captures more context from the interaction between data-points and their neighborhoods, accords best with linguistic expectations about language (dis)similarities.

9 Conclusion

In this paper we contribute to the ongoing line of research in computational typology, exploring the potential of translations into a single target language that retains the traces of the source languages to reflect the distances between them. Specifically, we propose an alternative graph-based distance measure to explore (dis)similarities between languages. Our results show that simple graph- and embedding-based distance based methods perform on a par with the best results achieved by previous approaches based on linguistic features in detecting source language interference in translations. We compare Gromov-Hausdorff and our novel Spectral Graph based approach with the original Eigenvector-based divergence from isomorphism measure (EV) against URIEL and SP08, show that our alternative graph isomorphism measures outperform EV and, for the first time, expand translationese research to non-Indo-European languages. We perform robustness tests to verify that our methods are stable under a variety of modeling conditions.

In future work, we aim to leverage our estimated similarities to better explain transfer behavior (local information spreading from one language to the other) in downstream applications such as machine translation.

Abstract

Large transformer models, such as BERT, achieve state-of-the-art results in machine reading comprehension (MRC) for open-domain question answering (QA). However, transformers have a high computational cost for inference which makes them hard to apply to online QA systems for applications like voice assistants. To reduce computational cost and latency, we propose decoupling the transformer MRC model into input-component and cross-component. The decoupling allows for part of the representation computation to be performed offline and cached for online use. To retain the decoupled transformer accuracy, we devised a knowledge distillation objective from a standard transformer model. Moreover, we introduce learned representation compression layers which help reduce by four times the storage requirement for the cache. In experiments on the SQUAD 2.0 dataset, a decoupled transformer reduces the computational cost and latency of open-domain MRC by 30-40% with only 1.2 points worse F1-score compared to a standard transformer.

1 Introduction

Open-domain question answering (QA) aims to answer questions from a collection of text passages. It is an important and challenging task with application to several domains such as web search and voice assistants. The most popular architecture for open-domain QA is retriever-reader (Chen et al., 2017). Given a question, the retriever uses an information retrieval (IR) system over a collection of passages to return top-K results that are most likely to contain an answer. Then, the reader uses a machine reading comprehension (MRC) model on each of the top-K results to find an answer. In the end, the top-K MRC answers are ranked to produce a final answer.

For both the retriever and the reader, large transformer models such as BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019) and ELECTRA (Clark et al., 2020) achieve state-of-the-art results. A disadvantage of large transformer models is the high computational cost for inference which makes them hard to apply to online runtime systems, e.g. voice-assistants. Transformers’ computational cost comes from three major factors. Firstly, the size of the feed-forward layers which project to an intermediate higher dimension and projects back to the original dimension. Secondly, the multi-head self-attention has quadratic computational complexity in the sequence length. Thirdly, the total number of layers.

Dense passage retrieval (DPR) (Karpukhin et al., 2020) is a retriever model which uses a transformer question encoder and transformer passage encoder to capture semantic similarity. The question and passage encoders are trained such that passages that are likely to contain an answer have a large embedding dot product with the question embedding. The embeddings for the passages are generated offline and indexed for efficient distributed KNN search (Johnson et al., 2017), and only the embedding for the question is generated at runtime. Since questions are usually short, the retriever runtime inference computational cost is low.

MRC reader models process the top-K passages returned by the retriever to get an answer. In transformer-based MRC models, each passage is encoded together with the question using a CLS and separator characters [CLS] Question [SEP] Passage. The encoding is followed by a prediction head which determines the answer span. If there is no answer, the model result is a zero-length span on the CLS token. The joint encoding of the document and the question produces rich interaction features but it increases the sequence length, and thus the computational coast. Since the
MRC model inference is executed at runtime on long sequences of a question and passages, MRC is the main computational bottleneck in retriever-reader QA.

There have been several ideas to reduce the runtime inference of transformer models, such as precision reduction via quantization (Zafrir et al., 2019; Shen et al., 2020), knowledge distilling to a smaller architecture (Sanh et al., 2019; Jiao et al., 2019), and approximate multi-head attention for reducing the quadratic complexity (Wang et al., 2020; Beltagy et al., 2020). In this paper, we take an orthogonal approach, decoupling the transformer encoding for multiple inputs to improve efficiency, which can be combined with the aforementioned techniques. The motivation for the decoupled transformer is that in open-domain QA the passages are known in advance and part of the passage computation can be performed offline and stored. Then, online at the runtime the question computation can be performed only once and combined with the stored state from passages with cross-attention.

We use the decoupled transformer to reduce the computational cost of open-domain MRC by 30-40% with only 1.2 points worse than the F1-score on the SQUAD 2.0 benchmark.

Our contributions are as follows:

• We propose and evaluate a novel decoupled transformer approach for MRC in open-domain QA to reduce runtime inference cost. Our approach uses a knowledge distillation (KD) objective to bridge the gap between a standard transformer and decoupled transformer.

• We conduct experiments to understand how much cross-attention between inputs is needed in MRC and other natural language processing (NLP) tasks like paraphrasing identification and natural language inference.

• We devise an accurate representation compression approach to reduce the storage requirement for decoupled transformer offline state. The compression provides a four-fold reduction in the index storage requirement for large corpora such as Wikipedia, from 3.4 TB to 858 GB.

2 Related Work

DC-BERT (Zhang et al., 2020) is a decoupled transformer that has dual BERT models. An online BERT encodes the question and an offline BERT pre-encodes all the passages and stores their encodings. Conceptually, DC-BERT goals and architecture of combining local and global context are similar to our work with the following major differences:

• We apply decoupled transformers to MRC and DC-BERT is designed and evaluated for the retrieval passage ranking. With the recent introduction of DPR, passage ranking as explored in DC-BERT is less important, so MRC becomes the primary bottleneck.

• We investigate how much cross-attention is needed for MRC and other NLP tasks.

• We introduce compression and decompression layers to reduce representation storage requirements.

Another model where the query and the passage are encoded independently using a transformer is ColBERT (Khattab and Zaharia, 2020). The main modeling applications for ColBERT are retrieval and passage ranking. After encoding the query and the passage independently, late interactions are introduced using an efficient sum of maximum similarity computations. ColBERT representations are used for retrieval, so it combines the strengths of DPR and DC-BERT. However, the efficient late interactions in ColBERT do not have enough representation power for complex tasks like MRC.

3 Decoupled Transformer

In the decoupled transformer, Figure 1, we split the transformer model \( M \) into two components.

1. Input-component \( M_{\text{input}} \) (the lower \( N \) layers) which processes the inputs independently and produces a representation. The representation for the inputs that are known in advance, i.e. the passages, is stored and used without computation.

2. Cross-component \( M_{\text{cross}} \) (the higher \( M \) layers) which processes the inputs jointly (after concatenation) and produces the final output.

3.1 Workflow

The workflow is depicted in Figure 2. Offline, we run the input-component \( M_{\text{input}} \) on each passage from the collection of passages and store the representation in the search index. Moreover, we compress the stored passage representation to reduce
Figure 1: On the left, standard transformer model for MRC. On the right, decoupled transformer model with input-component and cross-component.

3.2 Benefits

The decoupled transformer reduces per question transformer complexity in lower $N$ layers from $O(N_p(L_q + L_p)^2)$ to $O(L_q^2 + N_pL_p^2)$ where $N_p$ denotes the number of top-K passages per question, $L_q$ and $L_p$ denote the average number of tokens of each question and passage.

At runtime, the computation for the lower $N$ layers for the passage is eliminated because it is performed once offline and reused. Moreover, the computation for the lower $N$ layers for the question is done only once for the top-K retrieved passages, and not repeated, as opposed to the normal transformer which uses all layers on both the question and the top-K retrieved passages.

3.3 Initialization

To build a decoupled transformer model, we start from a standard transformer such as BERT, RoBERTa, ELECTRA model which is fine-tuned on a target dataset such as SQUAD 2.0. Then, we create the decoupled transformer model by splitting the encoder layers into input and cross components which are initialized with the fine-tuned MRC model weights. In addition to the standard transformer weights, we create a global position embedding and segment embedding layers at the start of the cross-component and initialize them to the same weight as the local position and segment embedding from the input-component. The global position and segment embedding re-encode the tokens for the new position in the concate-
nated question-document encoding sequence. The segment embedding differentiates whether the encoded token is from the question or document.

### 3.4 Training Objective

During decoupled transformer training, we aim to preserve the standard transformer model accuracy. To achieve that, we propose a knowledge distillation (KD) (Hinton et al., 2015) objective from the standard transformer to decoupled transformer which helps preserve the original representation.

The objective function is the sum of four terms:

\[
L = (1 - \lambda)CE(y, \text{target}) \\
+ \lambda KL(\text{logits}/T, \text{teacher-logits}/T) \\
+ \sigma MSE(\text{represent}_n, \text{teacher-represent}_n) \\
+ \sigma MSE(\text{attention}_n, \text{teacher-attention}_n)
\]

1. A standard cross-entropy (CE) loss with the prediction \(y\) and hard targets from ground truth labels.
2. KD loss based on Kullback–Leibler (KL) divergence with logits from the teacher standard transformer model. We scale the targets with the same temperature \(T\) for both the teacher and student.
3. The mean square error (MSE) between the decoupled model final layer representation with the original model final layer representation.
4. The MSE between the decoupled model final layer multi-head self-attention output with the standard model final layer multi-head self-attention output.

The parameter \(\lambda\) determines the relative contribution of CE and KL losses. And, \(\sigma\) is a weight for the MSE losses.

The MSE losses on the final layer representation and the final layer self-attention are similar to TinyBERT (Jiao et al., 2019) approach to smaller model distillation. Unlike TinyBERT, we only apply the MSE losses only on the last layer. The motivation for the MSE losses is that we are aiming to make the representation at the end of the decoupled transformer to match the representation of the standard transformer.

### 4 Representation Compression

In open-domain QA the collection of passages are known in advance. So, with decoupled transformer, we run the input-component \(M_{\text{input}}\) on each passage offline and store the passage representation in the index. For a large corpus, the representation storage can be a significant amount. In the case of QA over Wikipedia, the storage requirement is around 3.4TB given around 32 million passages, averaging 150 tokens per passage, and 768 token dimensions for the BERT-base model with 16-bit precision.

To reduce the storage requirements for the passage representation of the decoupled transformer, we introduce a compression layer at the end of the input-component and a decompression layer at the start of the cross-component, see Figure 2. The compression layer is a linear projection from the original dimension to a compression dimension. The decompression layer is a linear projection from the compression dimension to the original dimension. These layers are similar to an autoencoder with a bottleneck.

### 4.1 Training Procedure

To train the compression and decompression layers we start from a decoupled transformer model. Then, we perform training in two phases:

- **Phase 1.** We train the randomly initialized compression and decompression layers to reconstruct the input-component output representation without updating the decoupled transformer model itself.
- **Phase 2.** We train the compression and decompression layers together with the decoupled transformer jointly. This means the cross-component receives the decompressed representation.

The intuition behind the two-phase approach is that since compression and decompression layers are randomly initialized, it is beneficial to first train the compression and decompression layers independent from the decoupled transformer to get near-optimal weights. Then, train the cross-component of the model to understand the slightly different decompressed representation.

### 5 Experiments and Results

#### 5.1 Datasets

We evaluate the decoupled transformer on SQUAD 2.0 (Rajpurkar et al., 2018) which is a popular MRC dataset over Wikipedia articles. In addition
to MRC, we evaluate models on the datasets below to understand how many cross-components layers are needed for tasks of different complexity and dataset size.

- **QQP** (Chen et al., 2018) and **MRPC** (Dolan and Brockett, 2005) datasets for paraphrasing identification. The task is given two sentences, recognizing if they are paraphrases or not.
- **MNLI** (Williams et al., 2018) dataset for natural language inference datasets. The task is given two sentences the “premise” and the “hypothesis”, to determine if the hypothesis entails, contradicts, or is neutral given the premise.

### 5.2 Setup

#### Models

We use ROaD-base (ElFadeel and Peshterliev, 2021) for the MRC experiments on SQUAD 2.0. ROaD is an ELECTRA model pretrained and distilled using multi-task learning. For the experiments on QQP, MRPC, and MNLI we use ELECTRA-base. All models are implemented in PyTorch and optimized using Adam (Kingma and Ba, 2014).

#### Hyperparameters

Table 2 shows the hyperparameters that we use for fine-tuning the standard transformer and training the decoupled transformer. We searched different values for the temperature $T$, and the weights $\lambda$ and $\sigma$. For $\lambda$, we experimented with 0.5, 0.7, 0.9, 0.95 values and we found that for decoupled transformer training a large $\lambda$ that biases towards the KL divergence objective work best. For $\sigma$, we experimented with 0.25, 0.5, 0.75, 1.0 values and we found that smaller values work better because otherwise the KL divergence objective is given less weight which leads to worse models.

#### Hardware

We perform the experiments and benchmarks on Nvidia Titan RTX with tensor cores GPU and AMD Ryzen Threadripper 3960X - 24 cores CPU.

### 5.3 Decoupled Transformer

First, we perform a set of experiments on a decoupled transformer without compression. For each experiment, we denote the decoupled transformer split configuration as $x$-$y$, where $x$ is the number of input-component layers, and $y$ is the number of cross-component layers.

Table 1 shows the performance and FLOPs starting from the baseline standard transformer model to decoupled transformer with extreme 11-1 split. We observe that tasks with a large dataset (QQP, SQUAD, MNLI contain over 100K samples each) have similar behavior with a noticeable drop when moving from decoupled transformer 5-7 split to 6-6 split, and another big drop when the number of cross-component layers becomes less than 3. While in MRPC, a small dataset with around 5K sample, the drop of performance was significant.

Table 1: Decoupled transformer results with variable number of input-component and cross-component layers. Baseline is a standard transformer model. The $x$-$y$ columns indicate the number of input-component and cross-component layers. We use F1 score for SQUAD 2.0 and accuracy for QQP, MNLI, and MRPC. There is a consistent trend for performance to degrade as we increase the number of input-component layers and decrease the number of cross-component layers. FLOPs is floating point operations for inference as a measure of computational cost.
and bigger than the other large datasets even with the decoupled transformer with 1-11 split.

With every layer, we moved from the cross-component to the input-component, the FLOPs decreased by about 8% and performance dropped by a small amount until the number of input-component layers equals to or bigger than the cross-component layers. The results show that choosing the right setting is application-specific and the best option depends on the particular performance and latency trade-offs.

For the following experiments, we use the 5-7 split because it provides the best trade-offs between accuracy and FLOPs across the evaluated datasets.

Table 3: Decoupled transformer ablation study for SQUAD 2.0 MRC decoupled transformer with 5-7 split. We remove one row at a time except for the last row where we add MSE losses to all layers and not just the final layer.

### Ablations

We perform an ablation study to understand the effect of the different modeling techniques on the decoupled transformer performance. Table 3 shows the results. First, we remove the SQUAD 2.0 pretraining and start with regular ELECTRA-base which reduces F1 significantly by 2.5 points. Then, we tried keeping the position and segment embeddings in the cross-component frozen which hurt F1 as expected. If we remove the distillation KL objective, F1 degrades significantly by 2.7 points. On the other hand, removing the MSE losses on the representation and attention does not cause a significant reduction in F1. However, adding MSE losses on all layers actually causes a reduction in F1 because the CE and KL objectives receive less weight.

### 5.4 Compression

To evaluate compression, we conducted experiments on a decoupled transformer with 5-7 split using the MRC model for SQUAD 2.0. Our goal is to understand how much impact different levels of compression have on the storage requirement and model performance.

Table 4 compares the results with five different levels of compression. We observed the performance degradation is minimal for 2x, 3x and 4x compression, and then it starts to degrade significantly. At 4x compression, the required storage for open-domain QA over Wikipedia with the previous assumptions is 3.4 TB which could be reduced to 858 GB.

**Ablations.** We evaluate the effectiveness of the two-stage training of the compression and decompression layers. Table 5 shows the results. First, we remove the training of the compression independent from the model fine-tuning which causes a significant 6.6 F1 score reduction. Second, we remove the joint training of compression and MRC layers which cause 1.6 F1 score drops. Overall, both stages are necessary for training effective compression layers.

### 5.5 Inference Performance

In addition to FLOPs computational cost analysis, we run inference benchmarks on GPU and CPU. For the benchmarks, we use FP16 PyTorch models without TorchScript. We test in two settings: long and short inputs. Long inputs are 64 words for the question and 448 words for the passage. Short inputs are 16 words for the question and 150 words for the passage. For each setting, we perform four runs and take the average time.
Table 5: Compression ablation study for MRC SQUAD 2.0 model with 5-7 split. We remove either training compression independent of the model or joint training.

Table 6 shows the benchmark results. For CPU the results are close to our FLOPs analysis, and for GPU the we get lower runtime reduction due to the GPU parallelism.

Table 6: Decoupled transformer inference performance. Baseline is a standard transformer MRC model. Long and short indicate the input length, and the times are in milliseconds. Diff is the difference with the baseline.

Table 7: Decoupled transformer with DeBERTa-base and ROaD-base on SQUAD 2.0 model. EM is exact match accuracy. FLOPs is floating point operations for inference as a measure of computational cost.

5.6 Results

Table 7 compares the decoupled ROaD-base 5-7 split model with 4x compression with the ROaD-base model and DeBERTa-base model on SQUAD 2.0 MRC task. The DeBERTa model introduces additional positional embeddings that increase the computational cost by 20%. Still, the decoupled ROaD model achieves comparable accuracy with DeBERTa while requiring two times fewer FLOPs.

6 Conclusion and Future Work

We presented the decoupled transformer model for reducing runtime latency of MRC models in open-domain QA. The decoupling allows for part of the representation computation to be performed offline and cached for online use. To bridge the accuracy gap between a standard transformer and decoupled transformer, we devised knowledge distillation objectives for both model logits and features. Moreover, we introduced a representation compression approach that allows for a four-times reduction in representation storage requirements for open-domain QA without significant loss of accuracy. We use the decoupled transformer to reduce the computational cost of open-domain MRC by 30-40% with only 1.2 points worse than the F1-score on the SQUAD 2.0 benchmark.

In the future, we are planning to extend the decoupled model with a DPR objective. The goal is for the input-component to also produce DPR-like embeddings suitable for similarity search. This way, we can have a single model that acts as both retrieval and reader.

Abstract
Modern deep learning models for natural language processing rely heavily on large amounts of annotated texts. However, obtaining such texts may be difficult when they contain personal or confidential information, for example, in health or legal domains. In this work, we propose a method of de-identifying free-form text documents by carefully redacting sensitive data in them. We show that our method preserves data utility for text classification, sequence labeling, and question answering tasks.

1 Introduction
Data privacy has become an important topic recently, and new regulations that govern the processing and usage of consumer personal data arise every year. We use the term sensitive data to define all information that contains personal data or other potentially compromising data that can lead to the re-identification of individuals or organizations. With the advent of machine learning, privacy and compliant data governance have become even more important.

Free-form text documents often contain sensitive data. For example, legal documents contain full information about individuals or organizations, dialogues contain references to different people and possibly information that can lead to their identification, such as addresses or job positions. NLP applications such as text classification or question answering require annotated data, and as Feyisetan et al. (2019) argues, the privacy cost of annotating texts must be considered when developing new applications.

Anonymization, or de-identification, is viewed as one of the ways to make working with non-public datasets both safer and more compliant. It is also important to preserve utility in de-identified data for further usages, e.g. machine learning or analytics. Traditional approaches like $k$-anonymity (Sweeney, 2002) were shown to be ineffective when applied to high-dimensional media (Aggarwal, 2005) for example, free-form texts. Moreover, unlike structured data present in relational databases, anonymization of unstructured text documents poses additional challenges, because locations of textual spans which constitute sensitive data must be inferred at runtime.

Previous work either focused on preventing the model from memorizing data (Kerrigan et al., 2020) or considered only the text classification task. In this paper, we aim to solve the challenges of preserving both privacy and utility in free-form text documents with respect to different NLP tasks. We propose a simple “find-and-replace” method for automatically de-identifying documents and evaluate the utility of the de-identified data with respect to different downstream tasks, namely named entity recognition, question answering and text classification. To the best of our knowledge, this is the first work that evaluates the utility of the de-identified data for sequence labeling and reading comprehension tasks.

Specifically, our contributions are as follows:
1. We develop and evaluate the deep-learning-based method for de-identifying text documents.
2. We conduct series of experiments and show that our method mostly preserves utility for different NLP tasks: NER, QA, and text classification.
3. We investigate how our method impacts the end task performance for different model architectures.

2 Background
2.1 Preserving Privacy In Texts
There are several research directions in privacy in NLP. One research direction covers generating synthetic training data, thus abandoning original
data completely. Krishna et al. (2021) shows that this approach performs well for text classification and protects against membership inference attacks. However, in narrow domains such as legal contracts, maintaining internal coherency is important for information retrieval tasks, but generating long coherent texts is still a challenging NLP task (Tan et al., 2021).

Another area of research focuses on adding noise during training to prevent models from memorizing their training data. For example, Kerrigan et al. (2020) add noise to gradients during training to prevent large generative models from "memorizing" training data. However, NLP applications like NER or QA are powered by large amounts of annotated training data and data annotation happens before model training. This means that more people, including annotators, should have access to private data, which adds additional scrutiny to the dataset development process (Feyisetan et al., 2019).

The third branch of privacy research can be viewed as a form of noise added to the original data. The system that adds this noise must satisfy the requirement, stated in Dwork (2006):

Anything that can be learned about a respondent from the statistical database should be learnable without access to the database.

While this assumption is not achievable in practice, because we have to extract some value from the database, several methods were proposed to satisfy more relaxed privacy guarantees, e.g. $(\varepsilon, \delta)$ differential privacy (Geng and Viswanath, 2013).

Finally, a practical approach for texts de-identification via targeting named entities was proposed. In this approach, the auxiliary NER model is trained to recognize sensitive spans in the document that are further redacted. Stubbs et al. (2015); Marimon et al. (2019) organized challenges to develop the best de-identification system for English or Spanish medical texts, however, they did not explore the utility of anonymized data.

Our method falls into the latter research direction, however, we treat text de-identification as an auxiliary part of our work, focusing on measuring utility in the de-identified data.

### 2.2 Measuring Utility In The De-Identified Data

Rahman et al. (2018) show that models trained via privacy-preserving methods may poorly generalize to the original data. This means that data utility is reduced during the de-identification procedure.

Several approaches to measure utility in de-identified data were proposed. For example, Sánchez et al. (2014) follow the information-theoretic approach to ensure that de-identified entities do not exhibit any information that would help the attacker to de-identify data, even when the attacker has access to large amounts of open information from the Internet. Another approach is to measure utility as the quality of models trained on the downstream tasks on the de-identified data (Xu et al., 2020a). While the latter approach gives an intuitive and practical definition of utility, it is not clear how utility estimates depend on the end task, data, and model architecture. We adopt the latter approach and investigate impact of task, data and model choice in the section 4.

### 3 Proposed Method

We aim to develop a method that performs fine-grained substitutions of text spans comprising sensitive information. Contexts of sensitive data are kept intact and therefore our method preserves as much original text as possible.

#### 3.1 Extracting Sensitive Information

Searching for sensitive information, such as names or IDs of individuals, can be difficult in free-form texts. We formulate it as a named entity recognition (NER) task (Mamede et al., 2016), for which various methods were proposed. For example, IDs and other numerical information may be found by regular expressions, while medical diagnoses may be looked up in dictionaries. However, as Yadav and Bethard (2018) suggest, deep learning methods mostly outperform gazetteer-based or feature-based

models, and we opt for the neural-network-based approach.

Traditionally (Tjong Kim Sang and De Meulder, 2003), the performance of NER models is evaluated by micro-averaged f1-measure over extracted spans. Several datasets (Stubbs et al. (2015), Garat and Wonsever (2019)) exist to evaluate de-identification models, however, they do not provide annotations that would enable measuring utility in the de-identified data.

### 3.2 Replacing Sensitive Information

Several ways of replacing sensitive information were proposed in the literature (Carrell et al., 2020; Jiang et al., 2019). We study two methods:

1. **Sanitization** strategy redacts the sensitive information and replaces it with the token describing the label of the replaced entity, e.g. replace “John Smith” with generic label PERSON, “Organization inc.” with generic label ORGANIZATION.

2. **Pseudonymization** replaces real entities with synthetically generated but semantically and grammatically sound values. Pseudonymization is often used in practice when releasing private data for research or third parties (Stubbs et al., 2015). Table 2 provides an example of pseudonymization strategy for SberQuAD dataset.

<table>

<td>Чем заболел Колико в Сельниково?</td>
</tr>
<tr>
<td><strong>Answer:</strong> лихорадкой</td>
<td>лихорадкой</td>
</tr>
</tbody>
</table>

Table 2: Consistent pseudonymization for paragraph and question for SberQuad sample and its English translation. All mentions of Байрон (Byron) (highlighted with dashed underline) are pseudonymized consistently. In addition, all mentions of Миссолонги (Missolongi) are also anonymized consistently.

To implement Sanitization strategy, we need only the label of the entity the token corresponds to, which is available from NER model prediction at inference time. However, such replacement erases coreference links throughout the document, which may be important for the downstream task. In section 4 we provide results and show when this strategy impairs the performance on the downstream tasks.

Pseudonymization strategy is more difficult to implement because tokens of different entity types should be replaced differently. For example, a sequence of random digits comprises a number, but sequence of random characters does not always comprise a valid person or organization name. We generate synthetic values for Pseudonymization strategy as follows:

1. For numerical spans, e.g. numbers, IDs, and dates, we generate random numbers of the same length.

2. For textual spans, e.g. names, addresses, we use lookup from dictionaries. We make a random selection from the dictionary independently for every word in the span.

For tasks that require reasoning over input text, like question answering (Rajpurkar et al., 2016), train instances should maintain internal coherency: inconsistent changes in context and question would leave the question unanswerable. To solve this problem, Pseudonymization strategy maintains a mapping between original and pseudonymized values during its work, which allows coherent replacements of entities values. During anonymization of the datasets, each dataset instance is processed independently, meaning that mentions of the same person in different instances will be anonymized differently. We do not add
any coreference information in Sanitization strategy.

### 3.3 Re-Identification Risks

Our de-identification system relies on the NER model. Deleger et al. (2013) show that even double manual de-identification is not perfect, so de-identification errors will inevitably occur. Such errors may lead to re-identification of the de-identified subject, for example, when not all of their mentions were de-identified. Scaiano et al. (2016) propose to use all-or-nothing recall to evaluate de-identification models, because if even one mention of the person within the document was not de-identified, adversary may be able to re-identify the person. For example, if document has 10 mentions of the person, of which 9 were anonymized, then all-or-nothing recall is 0, while regular recall is 0.9. We measure all-or-nothing recall in our experiments. Meystre et al. (2014); Scaiano et al. (2016) argue that re-identification risks are further reduced for Pseudonymization strategy compared to Sanitization: when encountering specific names in the pseudonymized document, it is difficult to tell whether they were left intact by an imperfect anonymizer system or they are the result of pseudonymization.

### 4 Experiments

#### 4.1 Experimental Protocol

Let $S$ be our anonymization strategy (for example, sanitization or pseudonymization) and $D_{target} = (T_{target}, V_{target})$ be the target dataset for which we train model on a downstream task. Target dataset is split into train and validation sets named as $T$ and $V$. Let $M$ be the model trained on $T_{target}$. Our goal is to evaluate how $M$’s performance on $V_{target}$ depends on the dataset $M$ is trained on: original $T_{target}$ or de-identified $T’_{target}$. Inspired by this goal, we design the following experimental protocol:

1. Anonymize $T_{target}$, $V_{target}$ and obtain $T’_{target} = S(T_{target})$, $V’_{target} = S(V_{target})$
2. Train model on original data: $M = M(T_{target})$, get validation metrics $M(V_{target})$
3. Train model on de-identified data: $M’ = M(T’_{target})$, get validation metrics for both original and de-identified data: $M’(V’_{target})$, $M’(V_{target})$
4. Compare results of models: $\Delta = M’(V_{target}) - M(V_{target})$

We repeat this experiment for every strategy $S$ and compare results for each strategy with the baseline that was trained on the original data. Our anonymization procedure may yield distribution shift which may result in imperfect generalization to the original validation set and therefore in negative values of $\Delta$. $\Delta \geq 0$ means that data utility was completely preserved. We repeat each experiment 3 times and report mean and variance for $M’(V_{target})$ across them in Table 3.1.

#### 4.2 NER Models For Extracting Sensitive Data

For experiments on publicly available data, we use Collection3 corpus created by Mozharova and Loukachevitch (2016) to develop our anonymizer system. This corpus has the same annotation schema as FactRuEval and is approximately 7 times larger. We train vanilla BERT-based NER
model on Collection3 corpus and obtain the micro f1 measure 0.931. To measure re-identification risks, we manually review 200 randomly chosen documents from anonymized SberQuAD train set and find that all-or-nothing recall is 0.93.

For NER model for in-house data de-identification, we use an in-house corpus of 3040 documents with 426 272 annotated entities. This corpus has annotation schema similar to Ontonotes dataset (Weischedel et al., 2011). We train BERT-CRF model on this corpus using 90-10 train-test split, evaluate the model using micro f1-measure over spans and get the value of 0.93. We performed an additional evaluation to see how well our model finds sensitive data. We asked domain experts to manually annotate sensitive information in 30 legal documents of various types and then checked our system’s output against these annotations. We found that of 1030 entities, 1009 were anonymized, resulting in 0.98 recall and 0.95 all-or-nothing recall.

4.3 Downstream Tasks And Models

To show that our method transfers across tasks and domains, we use different NLP tasks and datasets:

**FactRuEval** (Starostin et al., 2016) is a NER dataset developed to evaluate fact extraction from Russian news articles. It is annotated similarly to Tjong Kim Sang and De Meulder (2003) and has PER, LOC, ORG entities.

**RuReBus** (Ivanin et al., 2020) is another NER dataset consisting of state documents and reports. It has more diverse annotation schema then FactRuEval. It is annotated with custom annotation schema that includes entities like METRICS, ACTIVITY, QUALITATIVE. Unlike FactRuEval, most of the classes in this dataset are not considered as sensitive data, except for INSTITUTION class, which is similar to ORG class in FactRuEval.

**SberQuAD** (Efimov et al., 2020) is Russian extractive question answering dataset similar to SQuAD (Rajpurkar et al., 2016). It has 9,080 unique paragraphs and 50,364 questions, about 20% of answers and about 72% of paragraphs contain named entities that should be anonymized, e.g., people, locations, or organizations. Unlike Rajpurkar et al. (2016), SberQuAD does not have unanswerable questions.

For the text classification task, an internal dataset of 5,000 texts annotated with 13 different classes was used. Data instances are segments of legal documents and classes represent types of these segments.

We use train-dev splits provided by the authors for all publicly available datasets. For text classification and NER tasks, we use micro averaged f1 measure. For SberQuAD, we use f1 measure as in the SQuAD dataset.

Comparative statistics of all datasets are shown in Table 1.

For NER datasets, we use simple BERT for token classification as described in Devlin et al. (2019). For SberQuAD, we use the same architecture as Devlin et al. (2019) used for SQuAD. For the in-house text classification dataset, BERT performed on par with gradient boosting (Ke et al., 2017) on top of tf-idf vectorization, and we choose boosting for its simplicity. It is also interesting to investigate how our anonymization methods affect end task performance for different vectorization methods.

4.4 Utility Tests

As described in subsection 4.1, we measure the utility of anonymized data as the performance drop between models trained on original and anonymized datasets. All experiments were implemented with AllenNLP (Gardner et al., 2018) framework. We present our results in Table 3.1.

In all experiments, baseline models trained on original data achieved performance close to currently reported state-of-the-art results. We note that in all experiments anonymization impairs end task performance, although results vary depending on the task and dataset.

Experiments on RuReBus dataset showed only a slight performance drop, however, all models achieve relatively low scores compared to the FactRuEval dataset. We attribute low scores to the inconsistent annotations in the RuReBus dataset. We attribute the low difference between performance on pseudonymized and sanitized data to the annotation schema: most entities in the schema are not considered sensitive information. However, for entity INSTITUTION, which is close to ORG entity, performance drop is significant: from 0.436 f1-measure in original data to 0.348 in sanitized data.

Similarly, in text classification task performance changes are also small compared to SberQUAD and FactRuEval tasks. This can be explained by the nature of the task: Xu et al. (2020b); Marivate and Sefara (2020) show that text classi-

</tbody>
</table>

The factification task is robust to different kinds of noise, including word substitution, which is close to our anonymization procedure.

Results on SberQuAD dataset confirm our hypothesis that consistent anonymization is important for question answering: difference between pseudonymized and sanitized data is higher than in previous experiments. About 28% of the dataset was kept intact by anonymization and therefore performance drop for anonymized instances will be even larger.

The largest difference in performance between models trained on sanitized and pseudonymized data is in FactRuEval dataset. This difference can be attributed to the annotation schema and nature of the task: Bernier-Colborne and Langlais (2020) showed that NER models rely more on entity text and less on the entity context. This intuition explains performance drop for models trained on sanitized data: they have not seen any real entities during training and can find entities based only on the context during the evaluation on the original data. However, models trained on pseudonymized data are able to generalize from synthetic entities to real ones.

Our experiments suggest that task, data and annotation schema impact downstream task model sensitivity to data anonymization.

### 4.5 Impact Of The Downstream Model Architecture

In lieu of the current NLP state, we perform most of our experiments using BERT-based models. However, we also explore how anonymization impacts end task performance for different model architectures. We choose FactRuEval dataset for this experiment because in prior experiments we showed that it is more sensitive to data anonymization. We use three popular NER architectures:

**BERT-FC** is a vanilla BERT for token classification model (Devlin et al., 2019), both pre-trained layers and projection layer are fine-tuned during training. We use *RuBERT* initialization trained by Kuratov and Arkhipov (2019) in all experiments because it performed the best on the original data in all experiments.

**BERT-BiLSTM** is an architecture with the 2-layer bidirectional LSTM applied on top of BERT embeddings. During training, BERT parameters are frozen and only LSTM layers are tuned. We use the same *RuBERT* initialization.

**w2v-CNN-BiLSTM** is a popular architecture that uses fixed word embeddings together with character embeddings to encode each token and BiLSTM on top of them to encode context. We use word embeddings trained by Grave et al. (2018) and keep them frozen during training due to the small size of the training corpus.

We provide results in Table 4. As in subsection 4.4, pseudonymization enjoys lower performance drops for all architectures. We notice that performance drops for BERT-based models are lower. This can be explained by the number of OOV words that generates our pseudonymization procedure: synthetic names or addresses are randomly sampled from the large dictionaries, so they are mostly not present in the embeddings table even for large pre-trained word embeddings. We calculated that only 38% of all names and 15% of all surnames from our dictionaries are present in the pre-trained embeddings. Our results support the claim made by Hendrycks et al. (2020), who showed that pre-trained transformers are more robust to distribution shifts.

### 5 Suggestions To Practitioners

Our experiments highlight several characteristics of anonymization procedure, downstream task and
model architecture that should be taken into account when using anonymized data for training NLP models. Our suggestions are as follows:

1. Noise-robust downstream tasks are also robust to anonymization.

2. Downstream tasks that do not require reasoning over named entities are robust to anonymization.

3. Downstream tasks that require reasoning over named entities also require coherent pseudonymization to maintain data consistency.

4. Pseudonymization works better than sanitization, although it is more difficult to develop.

5. Transformer-based models generalize the best between original and anonymized data.

6 Conclusions And Future Work

In this work, we consider the practical side of anonymizing unstructured documents while simultaneously preserving their utility for different downstream tasks. New policies regarding personal data make privacy research a more important topic over the years. We anticipate that in the near future de-identification of sensitive data before training will become a necessity. We hope our work will pave the way for investigating broader impact and limitations of free-form text anonymization.

We demonstrate that pseudonymization mostly preserves data utility for different extractive NLP tasks. We show it is possible to achieve close results with the model trained only on the de-identified data. However, it is not yet clear whether our results transfer to generative tasks and more complex settings, for example, scenarios with multiple languages like machine translation or multilingual datasets. We believe this is the promising research direction.

Abstract

This paper presents the preliminary results of an ongoing project that analyzes the growing body of scientific research published around the COVID-19 pandemic. In this research, a general-purpose semantic model is used to double annotate a batch of 500 sentences that were manually selected from the CORD-19 corpus. Afterwards, a baseline text-mining pipeline is designed and evaluated via a large batch of 100,959 sentences. We present a qualitative analysis of the most interesting facts automatically extracted and highlight possible future lines of development. The preliminary results show that general-purpose semantic models are a useful tool for discovering fine-grained knowledge in large corpora of scientific documents.

1 Introduction

The COVID-19 pandemic that affected almost every country at the beginning of 2020 has provoked a massive increase in scientific papers related to biomedical sciences (Velavan and Meyer, 2020). The scientific community’s effort to fight the spread of the virus is evident in the record number of research papers about COVID-19 that have been submitted to conferences, journals and preprint services. Several academic publishers joined the effort by providing free access to research in related areas that could be useful to scientists and academics. The amount of information produced during this period greatly surpassed the ability of human researchers to stay up-to-date, which in turn spawned an increased interest in the application of computational techniques to automatically organize, normalize and link the existing information.

A recent initiative is the COVID-19 Open Research Dataset (CORD-19), published by the Allen Institute for AI (Lo et al., 2020), which makes available a large corpus of scientific papers on COVID-19 and related topics. At the moment of writing, it contains 76,674 scientific articles. The corpus has been used as part of a Kaggle challenge¹, which focused mainly on unsupervised tasks related to organizing and categorizing the different aspects of the whole COVID-19 situation. Based on these resources, computational tools, e.g., SciSight (Hope et al., 2020), SciFact (Wadden et al., 2020), and similar (Bras et al., 2020), have been created to enable the interactive visualization and exploration of the scientific literature and the discovery of connections between the available methods, symptoms, interventions, etc.

Unsupervised approaches are a natural strategy for dealing with large, unlabeled corpora, while supervised approaches have the caveat of requiring training examples to be manually annotated, but can provide precise answers to specific questions given enough supervised data. For example, identifying domain-specific entities such as symptoms, medication and treatments, and semantic relations between them. Learning to recognize this type of information in natural language, even academic language, is a challenging task, given the large number of varieties in which the same semantic fact can be stated. In this context, different annotation models have been designed to capture the semantic meaning in different domains and levels of discourse. Token-level annotation models, such as AMR (Banarescu et al., 2013), capture fine-grained semantic relations between elements in a natural language sentence, independently of domain, which means that only general-purpose relations can be recognized. In contrast, domain-specific annotation models can capture more detailed relations, such as .
Phylogenetic studies have shown that 2019-nCoV and SARS-CoV belong to the subgenus Sarbecovirus, but they are distantly related, with a sequence identity of 79.6% at the whole-genome level. However, SARS-CoV, using the same receptor, was not detected in skeletal muscle by post-mortem examination.

In conclusion, SARS-CoV is the closest related virus to 2019-nCoV for which a significant number of epitopes has been defined in humans (and other species), and that also causes human disease with lethal outcomes.

The main objective of this research is to build a manually annotated corpus that can be used to train knowledge discovery systems for analyzing the COVID-19 research. For this purpose, we apply the SAT+R annotation model to English sentences in the CORD-19 corpus, manually annotating a small training set that can bootstrap a text-mining process for the entire corpus. The main contributions of this research are:

- The manual annotation of 500 sentences hand-picked from the CORD-19 corpus with the SAT+R annotation model, using a volunteer crowd-based approach with 2 versions of each annotation made by different non-expert annotators.
- The implementation and evaluation of a baseline text-mining pipeline trained on the manually annotated sentences.
- The application of the text-mining pipeline to the full CORD-19 corpus with an analysis of the most relevant concepts and relations discovered.
- All the relevant data to replicate and continue this research, including the source code and annotated corpus in BRAT Standoff format (Stenetorp et al., 2012), are available online for the research community.

The remainder of this paper is organized as follows. Section 2 introduces the SAT+R annotation model and presents the manually annotated corpus, its statistics and quality metrics, and details about the annotation process. Section 3 presents and evaluates a baseline machine learning pipeline to automatically annotate the raw text in the CORD-19 corpus. Section 4 describes the most relevant concepts and relations automatically extracted from the a larger fraction of CORD-19 corpus. Finally, Section 5 discusses the findings and lessons learned during this research and highlights possible lines of development, and Section 6 presents the conclusions.

2 Corpus Description

This section introduces the CORD-ANN corpus, an ongoing linguistic resource which contains semantically annotated sentences extracted from COVID-related research papers in the CORD-19 corpus. The corpus is constructed following the SAT+R annotation model (Piad-Morffis et al., 2019a), which is based around Concepts linked by Actions, and additional ontological and teleological relations, such as is-a, part-of, etc.

Table 1: Summary statistics for the CORD-ANN corpus.

as is-a, has-property, causes, entails, among others. During an initial annotation trial it was identified that Predicates, one of the semantic types defined in SAT+R, produced a large degree of disagreement among annotators while providing little additional information, and for this reason this element is not considered. Figure 1 shows three real sentences annotated with a variety of the semantic elements defined in the SAT+R annotation model.

Table 1 shows the total number of annotated elements. The annotated corpus has 500 sentences manually selected from the CORD-19 corpus. Each sentence was manually annotated by 2 different annotators who where not allowed to share their annotations. Table 1 shows a fine-grained description of the corpus annotations. A total of 10, 201 entities and 9, 444 relations were annotated, averaging 10.20 entities and 9.44 relations per sentence.

A manual pre-selection process was carried out to choose the sentences that contain the most relevant content. The annotation process is realized in batches of 5 sentences, given the linguistic complexity of the academic language of the corpus and the fact that the annotators are not native English speakers. That being said, the majority of the annotators were undergraduate student or graduate students of different university degrees with at least a B2 English level. The annotation procedure was adapted from the methodology proposed by Piad-Morffis et al. (2019a). The tool used for annotation is BRAT (Stenetorp et al., 2012) given the simplicity of its user interface. Configuration files and related infrastructure are published in the project repository.

The annotators were recruited through social media and most are from the academic institutions to which the authors are affiliated. A total of 21 different annotators were involved in the corpus creation, although several more showed some degree of interest but didn’t complete any annotation batch. The degree of involvement varied widely, since two annotators account for approximately half of the corpus (51 and 48 batches respectively) while 9 annotators submitted only one batch. An annotation guide with several examples was published online, and the first batch from every annotator was cross-checked by the authors to provide feedback. Afterwards, a continuous annotation campaign was managed through social media, with regular periods in which the annotators joined in an online forum to ask for clarifications or share their suggestions.

The annotation process was carried out from March 28th until June 9th, when the first 500 sentences were completed. At the moment of writing, the annotation campaign has been temporarily halted in order to analyze the partial results obtained and decide the best course of action for the continuity of this research.

Table 2 shows the agreement score between each pair of annotations for each type of semantic element. The metrics reported are precision, recall and $F_1$ computed as a micro-average between every pair of sentences doubly annotated. Since the $F_1$ metric is symmetric with respect to precision and recall, these are taken with respect to an arbitrary first annotator for each sentence. Overall, the agreement for entities is higher than for relations. The most difficult semantic relations to annotate, in terms of agreement, are entails, causes and has-part, while the easiest are the teleological relations subject and target, followed by the ontological relations is-a and has-property.
3 Baseline Text-Mining Pipeline

This section presents a simple machine learning pipeline for the automatic annotation of entities and relations in raw sentences from the CORD-19 corpus following the annotation model described in Section 2. This pipeline is trained on the 1,000 manually annotated sentences (i.e., the two versions of each annotated sentence), and executed on the remaining of the CORD-19 corpus. A high-level overview of the pipeline, shown in Figure 2, is composed of the following steps:

1. Sentences are tokenized and syntactic and morphological features are extracted from each token (using the spaCy\textsuperscript{4} library).

2. The annotated entities are converted from BRAT’s Standoff format to a BILOUV encoding (i.e., \textit{Begin}, \textit{Inside}, \textit{Last}, \textit{Out}, \textit{Unit} and \textit{Overlap}).

3. A CRF model $M_E$ is trained on the token features to predict the BILOUV encoding.

4. Each relation pair is converted to a set of aggregated features, and negative relation pairs are randomly sampled.

5. A linear model (logistic regression) $M_R$ is trained on relation pairs to predict the 10 Relation classes in Table 1 plus and additional NONE relation label.

6. The entity model $M_E$ is executed on unlabeled sentences and the result is converted from BILOUV encoding to BRAT’s Standoff format.

7. The relation model $M_R$ is executed on the pairs of entities predicted in the previous step.

For the entity model $M_E$, the syntactic and morphological features include lemma, coarse and fine-grained part-of-speech, dependency labels, general-purpose entity labels (e.g., PERSON, LOCATION, etc.), word shape, and several flags for specific patterns such as emails, numbers, and URLs. For the relation model $M_R$, the aggregated features correspond to the features of the tokens that comprise the two entities that participate in the relation, as well as the features of all the tokens in the smallest sub-tree of the dependency tree that contains both entities.

The ultimate purpose of these models is to automatically extract relevant knowledge from the unlabeled pool of sentences. Taking into account the complexity of this natural language comprehension task, there is always a trade-off between extracting as much knowledge as possible (i.e., maximizing recall) versus extracting knowledge as accurately as possible (i.e., maximizing precision). However, this trade-off can be explicitly controlled by measuring a degree of uncertainty $\sigma$ in the models’ predictions, and only outputting the elements (i.e., entities and relations) whose uncertainty is below a given threshold $\sigma^*$. For the entity model $M_E$, the raw marginal probabilities provided by the CRF

Figure 3: Maximum precision achieved for different semantic elements given a specific uncertainty threshold. Only results with recall above 0.1 are considered.

To better understand the trade-off between precision and recall, Figure 3 shows the precision obtained at different uncertainty thresholds for each annotation element. However, since a very high precision can be achieved with an arbitrarily low recall, we only consider annotations for which the average recall is above 0.1 at the given threshold level. This guarantees that at least a 10% of the potential number of those semantic elements would be extracted from the unlabeled collection.

4 Preliminary Insights in Knowledge Discovery

This section presents a qualitative analysis of a knowledge discovery process that can be performed using machine learning models trained on this type of annotated data. For this purpose, the remaining sentences of the CORD-19 corpus that were not used during the annotation process were fed to the machine learning models $M_E$ and $M_R$ and all pre-

Table 7: Most common instances for the relations is-a and has-property.

dicted entities and relations were stored. Table 5 presents the total number of sentences processed as well as entities and relations extracted. Given the relatively low performance of the machine learning models, a simple post-processing was introduced to remove the most obvious sources of errors, such as numbers and mathematical symbols, that were incorrectly detected as entities. As expected, the distribution of extracted elements closely follows the distribution of annotations in the training set (see Table 1).

The 20 most common entities extracted are summarized in Table 6. Unsurprisingly, they correspond to common concepts in the medical literature related to epidemics, treatments, biological entities, as well as some COVID-specific entities and locations. Similarly, Table 7 shows the most common instances of the relations is-a and has-property, which are the most basic ontological relations. As expected, they correspond mostly to known relations in the medical domain and specifically in the COVID-related literature.

Finally, Figure 4 shows a cherry-picked graph of relations built around the concept COVID-19. This graph was constructed by sampling the most common relations that involve this concept, manually eliminating irrelevant tuples, such as in-context, and compacting very similar relations (in terms of lemma) into the same nodes. The graph shows interesting relations, such as known symptoms (grouped under the causes relation) and a number of properties that are reported among the biomedical literature in the CORD-19 corpus.

5 Discussion and Future Work

This section discusses two important insights that arise from this ongoing research. First, we analyze the quantity and quality of the extracted knowledge, in an attempt to validate the approach and estimate the impact of its components. Second, we discuss some lessons learned during the annotation process in the hope that future research can further improve on our work.

Arguably, two of the most relevant annotation patterns for the purpose of knowledge discovery are ontological relations such as is-a and has-property, and the Subject-Action-Target triplets via the target and subject relations. The fact that these 4 relations have a relatively high number of instances extracted is promising. In contrast, the relations en-
tails and causes show a significantly lower number of instances, as well as a lower performance. These relations are important from the point of view of knowledge discovery since they could directly link symptoms and treatments with evidences. However, more work is necessary to achieve a reasonable level of performance in their extraction.

The machine learning models presented in this work were designed as an initial baseline. In a practical scenario more powerful models would be deployed. Possible strategies include using a separate CRF model for each entity class, and using a hierarchical model for the relation extraction step. Another possible strategy is to repurpose existing models deployed in similar tasks. According to the 2020 edition of the eHealth-KD Challenge, the top performing deep learning models in this task achieve $F_1$ values of 0.82 and 0.63 in entity and relation extraction, respectively (Piad-Morffis et al., 2020). Since they are also built on the SAT+R annotation model, their adaptation to the corpus used in this research is straightforward. However, it should be considered that the reduced number of training examples in our corpus presents a significant challenge for any machine learning model, which motivates the use of transfer learning techniques. In this sense, additional annotated corpora with SAT+R, such as the one presented in Piad-Morffis et al. (2020) can be used to bootstrap such a system.

Moving forward towards a fully-fledged ontology learning process still requires a significant effort after the annotation and model training. Particularly, since each entity can be potentially represented in the text in different forms, a normalization step would be necessary to group all mentions of similar entities under a single concept. At the moment of writing we are developing approaches for automatic normalization of entity mentions based on Wikidata, but the results are still not available. Furthermore, in this work we have not taken into account the prediction confidence beyond its use as a threshold. Weighting the number of mentions of each entity and relation with their respective
confidence could provide an additional metric to determine what to include in the knowledge graph.

One surprising and positive conclusion of our research is that crowd-based annotation efforts like this one, even with complex cognitive tasks involving deep semantics, are feasible. The annotators that participated voluntarily in this research were motivated by purely altruistic reasons, since there was no monetary incentive. We argue that, even if the COVID-19 pandemic played a large role in this motivation, in general people can be motivated for this kind of work because of the positive social impact of the research. Regarding annotation quality, there is a non-trivial amount of initial tutoring and feedback necessary, but once an annotator acquires a certain level of expertise, these efforts begin to pay-off since the experienced annotator becomes a potential tutor for new recruits.

To improve the annotation process, two considerations are possible. First, the annotators can be automatically evaluated on a small trial set with automatic feedback. This way, a minimum level of initial expertise is guaranteed. Afterwards, it is interesting to apply active learning strategies (Settles, 2009) to automatically select which sentences to annotate. In addition to standard active learning approaches, where a classifier-based uncertainty or informativeness measure is used, in this context the inter-annotator agreement could be directly used to re-sample sentences for which the agreement is low, so that the more complex sentences receive more annotations.

6 Conclusion

This paper presents the preliminary results of ongoing research. The majority of current research in the CORD-19 corpus uses unsupervised or semi-supervised approaches for knowledge discovery. We propose a supervised approach for extracting semantic relations and concepts in scientific articles using the CORD-19 corpus. For this purpose we annotated 500 sentences using a general purpose semantic model. We propose a baseline text-mining pipeline, trained on this data and executed on 100,959 additional sentences of the CORD-19 corpus, for automatically extracting relevant knowledge. This approach allows the discovery of relevant facts mentioned in research papers with fine-grained semantics, including causality, compositionality, and contextual dependencies. The annotated corpus and baseline implementation can be used as a starting point for developing more powerful knowledge discovery systems that can automatically analyze the growing body of scientific research related to the COVID-19 epidemic and similar future scenarios.

Acknowledgments

Funding: This research has been supported by a Carolina Foundation grant in agreement with University of Alicante and University of Havana. Moreover, the research has been partially funded by the University of Alicante and the University of Havana, the Generalitat Valenciana (Conselleria d’Educació, Investigació, Cultura i Export) and the Spanish Government through the projects LIVING-LANG (RTI2018-094653-B-C22), INTEGER (RTI2018-094649-B-I00) and SIIA (PROMETEO/2018/089, PROMETEU/2018/089). Additionally, it has been backed by the work of both COST Actions: CA19134 – Distributed Knowledge Graphs and CA19142 – Leading Platform for European Citizens, Industries, Academia and Policymakers in Media Accessibility.

This research was possible thanks to the voluntary effort of several annotators, including: Abel Molina Sánchez, Alejandro Klever Clemente, Daniel Alejandro Cárdenas Cabrera, Daniel Valdés Pérez, Gabriela Bárbara Martínez Giraldo, Gabriela Fernández Ménade, Houcemeddine Turki, Inti Antonio Blanco González, We sincerely thank all of the above and the remaining anonymous annotators. Finally, we would like to thank the anonymous reviewers. Their helpful comments have been considered in the current version of this paper.

Abstract

Adaptive Machine Translation purports to dynamically include user feedback to improve translation quality. In a post-editing scenario, user corrections of machine translation output are thus continuously incorporated into translation models, reducing or eliminating repetitive error editing and increasing the usefulness of automated translation. In neural machine translation, this goal may be achieved via online learning approaches, where network parameters are updated based on each new sample. This type of adaptation typically requires higher learning rates, which can affect the quality of the models over time. Alternatively, less aggressive online learning setups may preserve model stability, at the cost of reduced adaptation to user-generated corrections.

In this work, we evaluate different online learning configurations over time, measuring their impact on user-generated samples, as well as separate in-domain and out-of-domain datasets. Results in two different domains indicate that mixed approaches combining online learning with periodic batch fine-tuning might be needed to balance the benefits of online learning with model stability.

1 Introduction

Machine Translation (MT) quality has increased significantly in recent years, notably with the advent of modern Neural Machine Translation (NMT) approaches (Bahdanau et al., 2015; Vaswani et al., 2017). Despite this progress, machine translated output requires post-editing in many cases, a process which is made more taxing when the same errors are repeated by MT systems segment after segment.

To tackle this issue, adaptive approaches to machine translation aim to incorporate user feedback, oftentimes in post-editing scenarios (Turchi et al., 2017), although on-the-fly adaptation is also relevant for interactive machine translation (Peris et al., 2017). In NMT, responsive model adaptation can be achieved via online learning approaches, where network parameters are updated based on each new sample of user-edited data. To perform this type of adaption from single data points, higher optimiser learning rates (LR) are typically required, which can affect the quality of the models over time. Alternatively, less aggressive online learning setups may preserve model stability, at the cost of reduced adaptation to user-generated corrections.

In this work, we study the evolution of online learning over time in a post-editing scenario, to determine optimal configurations in terms of both adaptation to continuous user input and model stability. For this purpose, we examine the behaviour of four different gradient-descent optimisers in two different domains, with varying learning rates, and evaluate their behaviour as the number of samples increases over time.

To measure system responsiveness to user input over time, we evaluate online learning on dynamically increasing sets of samples formed by simulated user corrections. To determine model stability as online learning is performed, we also measure the quality of the MT models on static test sets pertaining to the domain at hand and on out-of-domain datasets, as additional measures of model evolution over time via online learning. Additionally, we compare the best online learning variants to models trained via batch fine-tuning on accumulated user data.

To our knowledge, this type of evaluation has not been previously explored and our results can support further work on online learning for NMT, as well as help practitioners in the field determine optimal configurations to design responsive and balanced adaptive MT systems.
2 Related Work

Most studies of online learning for machine translation have taken place in the context of Statistical Machine Translation (SMT) (Brown et al., 1990; Koehn, 2010). Several methods have thus been proposed to adapt phrase tables and language models of SMT models, in post-editing, interactive or streaming scenarios (Hardt and Elming, 2010; Ortiz-Martínez et al., 2010; Levenberg et al., 2010; Bertoldi et al., 2014). Evaluations of user productivity in adaptive SMT have notably shown a significant overall reduction of effort in post-editing scenarios (Bentivogli et al., 2015).

In Neural Machine Translation, comparatively fewer studies have been dedicated to online learning approaches. Turchi et al. (2017) explore different strategies based on a posteriori integration of human post-edits, a priori adaptation by tuning to similar sentences in the training data, and a combination of both, showing substantial improvements over static models. Peris et al. (2017) compared SMT and NMT models in interactive MT scenarios, demonstrating significant improvements in effort reduction with the latter over strong phrase-based systems. In Peris and Casacuberta (2019), online training of NMT models is evaluated under both post-editing and interactive scenarios. Similarly to the present work, they compared different optimisers with varying learning rates on datasets covering five different domains and different scenarios, assuming availability or lack of in-domain data prior to online learning. We complement their work in the present study by measuring the precise evolution of online learning over time and comparing it to batch fine-tuning at different time steps.1

Several user-centric studies have also demonstrated the usefulness of online learning for NMT, via analyses of user effort in static and adaptive environments (Karimova et al., 2018; Simianer et al., 2019; Domingo et al., 2019, 2020).

3 Experimental Setup

In this section, we describe in turn the core components of our experiments, namely the selected corpora, the training modalities of the different types of NMT models, and the selected optimisers.

3.1 Corpora

We first selected four datasets to train a generic model based on out-of-domain data.2 To mimic a typical multi-domain generic model, we selected the following corpora: Europarl (Koehn, 2005), MultiUN (Eisele and Chen, 2010), OpenSubs (Lison and Tiedemann, 2016) and CC-Align (El-Kishky et al., 2020). Each of the four corpora was downsampled to the first 1M parallel sentences and the resulting datasets merged into a unique parallel corpus (Generic), from which development and test sets were extracted via uniform sampling.

As a basis for online learning, we selected two separate domain-specific datasets. In both cases, we used publicly available datasets and followed a similar methodology: the available test sets were used as is, to measure in-domain model stability over time, and are referred to as static in-domain test sets; the first 100K of the training sets were selected to simulate user post-editing, with the reference translations taken to be the post-edited version of the translated source segments, following standard practices in experimental protocols to evaluate MT adaptation and online learning (Ortiz-Martínez, 2016; Peris and Casacuberta, 2019). We refer to these datasets as dynamic in-domain, which are used to both perform incremental training and test the models in an online learning scenario. Dynamic ID datasets are further split in gradually increasing subsets of order $10^n$, with $n \in \{0, 1, 2, 3, 4, 5\}$, starting from the first sentence.

As our first in-domain (ID) test case, we selected the TED corpus (Cettolo et al., 2012), using tst2015 as development set, tst2016 as test set and the first 100K pairs of the 2016 training set as dynamic ID set for this domain.3 As this corpus consists of first-person presentations on varied scientific or technological topics, it is markedly different from the datasets selected to train the generic domain.

We chose NewsCommentary v16 as our second in-domain dataset, in the concatenated version available on OPUS, using the first 100K pairs as online training data, the next 1522 pairs as development data, and the last 3000 as test set. This corpus consists of third-person news commentary and is thus relatively closer to the generic corpora in terms of topics and style.

1Peris and Casacuberta (2019) also include a scenario where online learning is applied over models first trained via batch fine-tuning on in-domain data, a setup which differs from our experiments.

2Unless otherwise specified, all datasets are those available on the OPUS repository (Tiedemann, 2012), as of April 2021.

3We used the version of the corpus available here: https://wit3.fbk.eu/2016-01-d

417
All corpora were tokenised and truecased with Moses scripts (Koehn, 2005) and words segmented via joint Byte Pair Encoding (Sennrich et al., 2016), using 30K merge operations. Statistics of the prepared corpora are summarised in Table 1.

### 3.2 Models

All translation models were based on the Transformer-base architecture (Vaswani et al., 2017) and built with the MarianNMT toolkit (Junczys-Dowmunt et al., 2018). The models consist of 6-layer encoders and decoders, feed-forward networks of 2048 units, embeddings vectors of dimension 512 and 8 attention heads. The dropout rate between layers is 0.1 and embeddings for the source, target and output layers were tied.

For the generic static models, we used the Adam optimiser (Kingma and Ba, 2015) with $\alpha = 0.0003$, $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$. The learning rate was set to increase linearly for the first 16,000 training steps and decrease thereafter proportionally to the inverse square root of the corresponding step. We set the working memory to 6000MB and with a mini-batch set to automatically fit the specified memory. The validation data were evaluated every 3,500 steps and patience was set to 10.

For the online models, trained on the dynamic ID sets, the models were updated incrementally, with batches of one source-reference pair and a single update of the network based on the sample at hand. Each version of the model resulting from an update as described was taken as the basis for the next online update. We selected four representative optimisers, described in the next section.

To measure the impact of domain variation, all models were trained for translation from English to Spanish. Evaluation was performed on the BLEU metric (Papineni et al., 2002), computed with the sacreBLEU toolkit (Post, 2018).6

### 3.3 Optimisers

Stochastic gradient descent (SGD) (Robbins and Monro, 1951) is one of the most common methods to estimate the parameters of a network, given the gradient of an error function, as it computes estimates on a per-sample basis. In NMT, SGD usually takes the form of mini-batch SGD, where the gradient is computed as the average gradient of the samples in a mini-batch; we use SGD as a shortcut for mini-batch SGD in what follows.

Several optimisations have been proposed to address some limitations of SGD, in particular methods that include a parameter-level update of the learning rate. Among these approaches, Adagrad (Duchi et al., 2011) uses past gradients for each parameter to compute parameter-level updates. Adadelta (Zeiler, 2012) extends it by mainly restricting the accumulation of past gradients to a fixed window size, an approach independently proposed as the basis of the RMSProp optimiser. Another popular alternative is Adam (op. cit), which includes bias-corrected estimates of the 1st and 2nd moment, and is the default optimiser to train Transformer models in toolkits such as MarianNMT.

As indicated in Section 2, previous studies in online learning for NMT have compared the aforementioned parameter update methods, reaching different conclusions. Thus, Turchi et al. (2017) concluded that vanilla SGD was the optimal optimiser overall in their experiments, where the learning rate was fixed to 0.001 for all optimisers, whereas Peris and Casacuberta (2019) reached the conclusion that Adadelta, and to a lesser degree, SGD, were optimal after selecting the learning rate for each optimiser separately via grid-search on development sets. To gain further insights on optimal configurations for online learning, we selected four of the main optimisers, namely SGD, Adam, Adagrad and RMSProp, and measured the impact of different learning rates at different points in time, as described in the next section.7

---

6Adadelta can also be computed with a second type of estimate, using past updates instead of Lasso regularisation. To limit our experiments to the main optimiser variants, we only considered the first update rule in Adadelta and refer to it as RMSProp, to avoid confusion over which version of the Adadelta updates is used.

7The implementation of RMSProp in MarianNMT is our own; all others are based on the toolkit default implementation.
To evaluate the impact of online learning over time, we first evaluate the models against the references of the dynamic in-domain training set after $10^n$ online learning updates with each of the selected optimisers, with $n \in \{0, 1, 2, 3, 4, 5\}$.

### 4.1 Impact of Learning Rate

An important component of parameter update is the learning rate, which determines the amplitude of the updates. For online learning, a critical choice needs to be made between aggressive and conservative updates, based on high or low learning rates, respectively. The former may provide rapid adaptation, at the risk of deteriorating the network from overfitting to the samples, whereas the latter may delay or dilute the expected model adaptation, thus reducing the positive impact of online learning.

To measure both extremes, we selected the best learning rates for each optimiser according to the BLEU scores obtained on the dynamic datasets on the first (best@1) and last samples (best@100K), for each of the two selected domains. To determine an optimal learning rate for the first update, we randomly sampled 100 sentences and computed the BLEU score with all learning rates variants on the dynamic ID set, selecting the learning rate with the best average BLEU. This was meant to limit the impact of the characteristics of the first sentence in these datasets, which might not be representative of the data distribution. For the last update, all data points were considered to determine the best BLEU scores and associated learning rate.

Figure 1 and Figure 2 show the evolution of the optimisers for TED and NewsCommentary, respectively. We also include the evolution of the baseline generic models and models trained via batch fine-tuning over the available data (1 and 100K samples
Figure 3: BLEU scores as a function of number of samples and learning rates on the TED corpus

Figure 4: BLEU scores as a function of number of samples and learning rates on the NewsCommentary corpus
for figures (a) and (b), respectively); in the latter case, the optimiser is the one used to train the baselines, namely Adam, with the learning rate and moment inherited from the last baseline update.

Adam displayed a more erratic behaviour than the other optimisers, with sharp degradation after 10K updates when selecting a conservative learning rate, and after 100 with the more aggressive LR. Except for TED with the best \(0.1\) LR, where all optimisers started with maximal adaptation on the first update, Adagrad performed worse initially but eventually converged with SGD and RMSProp, while also obtaining the highest scores between 10 and 10K samples on TED with its most conservative LR, and between 10 and 1000 on NewsCommentary. SGD and RMSProp behave similarly with a more stable behaviour, except on NewsCommentary where RMSProp performed markedly better with a conservative LR. It is also worth noting that the best LRs, whether aggressive or conservative, differ in most cases depending on the domain. Although this might be expected considering that the selected domains differ in terms of proximity to the generic data, as previously noted, these differences illustrate the delicate task of determining optimal online learning setups across the board.

The baseline evolved as expected, with lower scores than models benefitting from in-domain data. For batch fine-tuning, the evolution featured increasing scores as more data are available, eventually converging with the best optimiser variants. Overall, all variants of online learning tended towards degraded performance as the number of samples and subsequent updates increased, particularly with high learning rates. This is not unexpected given the overfitting associated with network adaptation over minimal samples, but both SGD and RMSProp appeared beneficial at least up to the 100K mark on the dynamic in-domain sets. We will examine the behaviour of all models on the static and out-of-domain test sets in Section 5.

4.2 Optimal Optimiser Setup

So far we have examined the behaviour of the different optimisers over time with the best LR at the two extremes, i.e. for 1 and 100K samples. To determine whether other learning rates might be optimal at other time steps, we computed BLEU scores on the dynamic in-domain set as a function of both learning rates and number of samples. Figure 3 and Figure 4 show the results on TED and NewsCommentary, respectively.

With Adam, other learning rates are more stable over time than the best performing one selected on the basis of a single (averaged) sample, with higher scores and less erratic behaviour, in particular on NewsCommentary. Nonetheless, even these more balanced learning rates achieve poorer scores than the other three optimisers overall, for both initial and final updates.

For Adagrad, other values than the ones based on the extremes performed better for some intermediate sample subsets on the TED dataset, but the more aggressive LR was optimal overall on NewsCommentary, achieving better scores than all other optimisers as the number of samples increased.

RMSProp also achieved an overall better distribution of scores when selecting the most aggressive LR on TED. On NewsCommentary, the selected best LR for the initial sample \( (0.1) \) was not the optimal choice, although it performed closely to the optimal \(0.05\). Note that both LRs achieve an identical score on the first sample, but on the average score obtained on the 100 randomly selected sentences used to to select the most aggressive LR, the previously selected LR of \(0.1\) was markedly better.

Similarly, for SGD on NewsCommentary, the best LR option over the averaged 100 unique samples \( (0.1) \) performed slightly worse overall than an LR of \(0.05\) as the number of samples increased; on TED, the most aggressive SGD LR performed better than the alternatives, except when the number of samples reached the 100K mark.

Although these results show that selecting an optimal learning rate for either optimiser is bound to be less than optimal at a given point in time, both SGD and RMSProp with an LR of \(0.05\) appear to be reasonable choices that provide overall benefits on the two selected datasets. Interestingly, this value differs from the optimal ones established for SGD in separate experiments by Turchi et al. (2017) and Peris and Casacuberta (2019) (see Section 3.3), showing that LR selection for online learning might be dependent on domains and datasets.

5 Model Stability Over Time

As described in the previous sections, online learning can support post-editing by adapting to user corrections incrementally. This is obtained via relatively aggressive learning rates that enable updates to be significant on the basis of unique training
Figure 5 shows the results for TED and NewsCommentary at the 100K mark, when selecting the best learning rate for each optimiser based on the best BLEU scores for the initial updates, which, as a reminder, were computed over random samples of 100 sentences. On TED, batch fine-tuning outperformed all variants of online learning on the in-domain datasets, both static and dynamic, although only slightly over Adagrad on the static ID test set. On NewsCommentary, Adagrad outperformed all variants on the dynamic ID dataset, while also being only slightly under batch fine-tuning on the static ID test set. However, as described in previous sections, this optimiser also performed significantly worse than SGD and RMSProp for initial updates, thus being less beneficial for initial stages of online learning. When compared to the most efficient optimisers for earlier online learning, namely SGD and RMSProp, batch fine-tuning would be the favoured option when reaching at least 100K data points.

Figure 6 presents the results after the final update stage when taking the best learning rates at the 100K mark for all optimisers. In this scenario, on the TED datasets all optimisers except Adam feature results that are closer to those achieved via batch fine-tuning, although the latter obtained better results overall on both the dynamic and the static in-domain datasets. On NewsCommentary, SGD, RMSProp and Adagrad significantly outperformed batch fine-tuning on the dynamic data, while the latter performed slightly better on the static ID test set but with minor differences. Among optimisers in online learning scenarios, SGD would be favoured when selecting more conservative learning rates, although both RMSProp and SGD would
also be favoured over batch fine-tuning in such a scenario for NewsCommentary. However, a more conservative learning rate also reduces its benefits at earlier stages, and the single case where online learning optimisers outperform batch fine-tuning at later stages might not be relevant in actual usage.

In terms of out-of-domain data, batch fine-tuning performed better in all but one case, namely TED with the best learning rate for initial updates, where Adagrad performed better. Batch fine-tuning performed similarly to the baseline on NewsCommentary, which may be attributed to the relative proximity of NewsCommentary data to the generic training data, and conversely to the higher data difference between TED and the datasets that compose the generic training sets.

6 Conclusions

In this paper, we explored the behaviour of online learning for Neural Machine Translation over time, examining the results obtained with four different optimisers as the number of samples increases and evaluating translation model evolution after repeated network updates with different types of learning rates, from most aggressive to most conservative. We also compared online learning with batch fine-tuning on dynamic and static datasets, as well as out-of-domain test sets, to measure overall model stability.

On the two domains we explored, based on TED and NewsCommentary data, there does not appear to be an optimal configuration, where online learning would be optimal in both the short and long term. SGD and RMSProp both feature a learning rate value which provides early benefits of online learning with relatively minor degradation over time, and might be viewed as the most balanced configuration in our experiments.

However, at least in the domains we explored, batch fine-tuning was shown to be preferable at later stages in terms of model stability across dynamic, static and out-of-domain datasets. For practical adaptive NMT, it might thus be preferable to combine online learning, over limited time steps, with periodic batch fine-tuning over previous model checkpoints on the data accumulated over time.

Abstract

Character-aware neural language models can capture the relationship between words by exploiting character-level information and are particularly effective for languages with rich morphology. However, these models are usually biased towards information from surface forms. To alleviate this problem, we propose a simple and effective method to improve a character-aware neural language model by forcing a character encoder to produce word-based embeddings under Skip-gram architecture in a warm-up step without extra training data. We empirically show that the resulting character-aware neural language model achieves obvious improvements of perplexity scores on typologically diverse languages, that contain many low-frequency or unseen words.

1 Introduction

Neural language models (NLM) usually maintain a fixed vocabulary and map each word to a continuous representation. These models cannot handle new words and are not effective for languages with rich morphology. One solution is to use smaller units, such as bytes, characters, or word pieces learned from word tokens (Wu et al., 2016; Sennrich et al., 2016). However, this approach has to process longer sequences than word-level alternatives and may increase modeling and computational challenges (Cherry et al., 2018). This paper focuses on another way based on word-level models in which a character encoder is used on top of characters of each word to calculate the word representation. They are often referred to as character-aware NLMs (CNLMs) (Ling et al., 2015; Kim et al., 2016; Vania and Lopez, 2017; Gerz et al., 2018; Assylbekov and Takhanov, 2018; Feng et al., 2019). However, the character encoders in CNLMs often show over-representation of orthography rather than semantic meaning in the resulting word embedding despite the fact that training word-based NLMs usually helps learn such semantic meaning (Kim et al., 2016; Vania and Lopez, 2017; Assylbekov and Takhanov, 2018). For example, in CNLMs, the nearest neighbors of the word ‘his’ with cosine similarity are ‘hhs’ and ‘this’ while ‘my’ is far from the nearest neighbors.

To alleviate the over-representation issue in CNLMs, we propose to directly force the character encoder to produce the word-based embedding in a warm-up step before the training of CNLMs starts. Specifically, the character encoder encodes an input word, and the encoded embedding will be forced to be close to the embeddings of its surrounding words and far from the word embeddings of negative samples. Unlike the dynamically constructed embedding of the input word, the embeddings of surrounding words and negative samples are word-based, and thus these embeddings will not be biased to surface forms. The above method is similar to the architecture of the Skip-gram model (Mikolov et al., 2013) with the difference that we use a complex character encoder which is shown to be powerful for languages with rich morphology.

In our experiments¹, we choose the widely used long-short term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and the recent state-of-the-art AWD-LSTM-LM (Merity et al., 2018) for language modeling. For the character encoder, we experiment with bidirectional LSTM (BiLSTM) over character trigrams as this variant has shown better performance than other character encoders on 10 languages (Vania and Lopez, 2017). We evaluate our method in two types of datasets. One contains 14 typologically diverse languages with a large number of low-frequency words and unseen words in the test set. Thus, we can test our method in a real LM setup. Another one contains 5 lan-

¹Our code can be obtained from https://github.com/yukunfeng/warmup_char_lm
guages, where the new words in the test set have been replaced to <UNK>. It is commonly used for evaluating CNLMs in this field.

Our experiments empirically show our method can achieve obviously improved perplexity scores on a wide range of languages. Finally, we analyze the learned word embedding with our character encoder on English word similarity tasks.

2 Related Work

A lot of work has tried to improve CNLMs in recent years, such as analyzing performance of CNLMs with different character encoders and character units (Vania and Lopez, 2017), reusing subword embeddings in CNLMs (Assylbekov and Takanov, 2018), injecting subword-level information into softmax (Gerz et al., 2018), and combining word- and character-level information in CNLMs (Miyamoto and Cho, 2016; Verwimp et al., 2017; Kang et al., 2011; Feng et al., 2019).

As for alleviating the over-representation issue mentioned above, Kim et al. (2016) used a highway network on top of their character encoder and found their highway network can encode semantic features that are not discernible from orthography alone. Assylbekov and Takanov (2018) used syllables and morphemes in a word to construct word embeddings and showed syllable- or morpheme-based CNLMs are less biased towards surface forms than a standard CNLM. However, this approach relies on extra toolkits to extract syllables or morphemes. To our knowledge, there is not much work particularly paying attention to this issue in CNLMs. It is discussed only in a section in the above mentioned work, and the experiment is limited to several languages. Furthermore, the analysis of character encoders is done by manually selecting several words with their nearest neighbors based on cosine similarity, while we formally verify that the character encoder captures more semantic features on 5 English word similarity tasks. Our method is simple and different from the highway network used by Kim et al. (2016). We do not need to change the existing architecture of CNLMs.

Another related work to ours is word representation learning as we utilize the Skip-gram architecture. One goal of this field is to learn word embeddings on large-scale corpus and use them on downstream tasks, which is different from ours. Our method works without extra training data, and we do not aim at transfer learning with other training data like a standard Skip-gram model.

3 Model Description

The whole architecture is shown in Figure 1. We use BiLSTM over character trigrams as our character encoder since this variant performed best on most datasets (Vania and Lopez, 2017). Given a word \( w_t \), we denote its embedding as \( x_t \in \mathbb{R}^d \), where \( d \) is the embedding size. We compute the representation of \( w_t \) in BiLSTM as follows:

\[
x_t = W_f h_{fw}^t + W_b h_{bw}^t + b,
\]

where \( h_{fw}^t, h_{bw}^t \in \mathbb{R}^d \) are the last states of the forward and backward LSTMs, respectively. \( W_f, W_b \in \mathbb{R}^{d\times d} \) and \( b \in \mathbb{R}^d \) are trainable parameters.

We adopt the basic architecture of Skip-gram model for warming up our character encoder. Given an input word \( w_t \) which will be encoded by our character encoder, we then use the encoded embedding to predict a set of output words that surround the input word in a given window. For example, when the window size is 2, the output words are \( w_{t-2}, w_{t-1}, w_{t+1}, w_{t+2} \). We use \( o_t \) to denote the embedding of an output word for \( w_t \).

The input word embedding \( x_t \) of \( w_t \) is computed with Eq. 1. Note that \( o_t \) is word-based and thus will be not biased to its surface form, which is different from \( x_t \). Given a single training example \((w_t, w_{t+j})\), we maximize the objective function:

\[
\log \sigma(x_t^T o_{t+j}) + \sum_{i=1}^{k} \log \sigma(-x_t^T o_{t+i}),
\]

where \( k \) is the size of the negative samples, and \( \sigma \) is the sigmoid function.

After warming up, we use the trained character encoder to initialize the one in our CNLM and then train our CNLM with a standard LM loss.

4 Experiments

4.1 Datasets

We can find common language modeling datasets for evaluating CNLMs in the work of Botha and Blunsom (2014). While these datasets contain languages with rich morphology, they have only 5 different languages. The most large-scale language modeling datasets are from the work of Gerz et al. (2018), who released 50 language modeling datasets covering typologically diverse languages. The difference of the newly released datasets from
the previously common datasets is that many unseen words are kept in the test set. Thus, on the datasets, we can test our methods in a real LM setup. These languages were selected to represent a wide spectrum of different morphological systems and have a large number of low-frequency or unseen words. Thus, these datasets are desirable for checking the performance of CNLMs. Due to the large number of experiments, we chose datasets of only 14 languages from these datasets and tried to cover different language typologies as well as different type/token ratios (TTRs). The statistics of our chosen datasets are shown in Table 1.

To compare with other models, we also set up above mentioned 5 common non-English LM datasets with rich morphology from the 2013 ACL Workshop on Machine Translation, which have been commonly used for evaluating CNLMs (Botha and Blunsom, 2014; Kim et al., 2016; Bojanowski et al., 2017; Assylbekov and Takhanov, 2018; Feng et al., 2019). Note that the new words in the test set have been replaced with special <UNK>, which is not a practical setting. The data statistics is in Table 2.

4.2 Models

The hyperparameters of our LSTM language model are shown in Table 3. The learning rate was decreased if no improvement is observed in the validation set. We trained the Skip-gram architecture in warm-up step for 7 epochs with 5 negative samples for all datasets. We define Char-BiLSTM-LSTM as our CNLM, and Warmed-Char-BiLSTM-LSTM as our CNLM with a warmed character encoder.

To check our idea with a stronger baseline, we used the recent state-of-the-art AWD-LSTM-LM codebase2(Merity et al., 2018). We replaced the word embedding layer of this model with our BiLSTM character encoder. We refer to it as Char-BiLSTM-AWD-LSTM and the warmed one as Warmed-Char-BiLSTM-AWD-LSTM. Due to time constraints, we set the training epoch on all datasets to 200. We refer to the original AWD-LSTM which is word-level as Word-AWD-LSTM. For the other parameters, we followed the setting in the source code. We make sure that all models under our chosen epochs are trained to convergence so that the gain from our method is not due to longer training in warm-up.

4.3 Results on 14 Languages

The results on 14 languages are shown in Table 4. Our Char-BiLSTM-LSTM baseline outperforms Char-CNN-LSTM from (Gerz et al., 2018) on all datasets. It is also shown that as the TTR increases, Char-BiLSTM-AWD-LSTM achieves a better result than Word-AWD-LSTM. One reason may be that higher TTR languages have more low-frequency words and unseen tokens, as shown in Table 1. Thus, utilizing character information is important in these languages. Our proposed Warmed-Char-BiLSTM-LSTM and Warmed-Char-BiLSTM-AWD-LSTM achieves further obvious improvements compared with Char-BiLSTM-LSTM and Char-BiLSTM-AWD-LSTM respectively on most datasets without extra training.

4.4 Results on 5 Common Datasets

The results on common datasets are shown in Table 5. Most work aims at improving CNLMs at different aspects and the gain comes from different new information. For example, the gain of CNLM from Feng et al. (2019) comes from injecting word-level information into CNLM, and Assylbekov and Takhanov (2018) improved CNLMs by using morphemes and reusing weights. Bojanowski et al. (2017) used conventional word-level LSTM-LM instead of CNLM, and their goal is not to improve CNLMs. The gain from their model comes from transferring word embeddings learned through Skip-gram that considers character-level information to word-level LSTM-LM without character-level information. That is, their method used new information for their LSTM-LM while in our method there is no extra new information. As shown in Table 5, our baseline model is strong compared with most models, and our method can further improve it without extra new information.

5 Analysis

5.1 Analysis of Character Encoder

Unlike prior work which analyzes their character encoder by manually selecting several words and their nearest neighbors based on cosine similarity, we formally verify whether our method helps the character encoder capture more semantic features on English word similarity tasks. We chose the English dataset ‘en’ shown in Table 1 as our training set. Specifically, after finishing the training of

For example, we calculated the perplexity of the next word, when a rare word, whose frequency is less than 15, is given as the current word. A similar analysis on language models can be found in Vania and Lopez (2017). For simplicity, we only choose the English dataset ‘en’ and the German dataset ‘de’. To fairly compare with Word-LSTM, our analysis does not contain new words in the test data. As we see in Table 7, Char-BiLSTM-LSTM mainly obtained improvements on rare word group compared with Word-LSTM. When warmed up, Char-BiLSTM-LSTM obtained further improvements both on frequent and rare word groups. Note that the reason of the gain is not that the warm

Abstract

With the increasing adoption of technology, more and more systems become target to information security breaches. In terms of readily identifying zero-day vulnerabilities, a substantial number of news outlets and social media accounts reveal emerging vulnerabilities and threats. However, analysts often spend a lot of time looking through these decentralized sources of information in order to ensure up-to-date countermeasures and patches applicable to their organisation’s information systems. Various automated processing pipelines grounded in Natural Language Processing techniques for text classification were introduced for the early identification of vulnerabilities starting from Open-Source Intelligence (OSINT) data, including news websites, blogs, and social media. In this study, we consider a corpus of more than 1600 labeled news articles, and introduce an interpretable approach to the subject of cyberthreat early detection. In particular, an interpretable classification is performed using the Longformer architecture alongside prototypes from the ProSENet structure, after performing a preliminary analysis on the Transformer’s encoding capabilities. The best interpretable architecture achieves an 88% F2-Score, arguing for the system’s applicability in real-life monitoring conditions of OSINT data.

1 Introduction

With the increasing number of cybersecurity attacks, institutions need to join forces for the prevention and detection of cyberthreats. Malicious entities target companies, but also individuals and public institutions (including health organisations), with an overall expected cost of 6000 bn $ per year (Morgan, 2020). For example, the number of requests on the French malware assistance plat-
form has tripled between 2018 and 2019\(^1\), and this trend has worsened during the pandemic (Pinhasi and Huseman, 2021) due to the increased use of technology, the advent of remote working, coupled with an exponential growth of IoT. In their endless race against hackers, security experts need to detect zero-day vulnerabilities and understand new methods employed by hackers to exploit them (Lewis, 2018). In addition, both institutions and individuals need localized expertise applicable for their environment, given its specificity in terms of employed technologies.

Large companies often have their dedicated entity, the Security Operations Center (SOC), whose experts survey Open-Source Intelligence (OSINT) data to identify new emerging vulnerabilities (Dionísio et al., 2019); however, lower-sized entities and individuals should have this information also readily available. In addition, each data source (and there are a lot of possible venues – e.g., more than 40 major blogs and newspapers are reported by Feedspot (2021)) has its own targeted fields and technologies of main interest, as well as its subjectivity in expressing the breath and impact of the vulnerability. Manual searches in multiple sources is an overall tedious process, and the wide scattering of news feeds makes the day-by-day surveillance a daunting task; as such, an automated detection of zero-day vulnerabilities from OSINT data becomes a necessity (Le Sceller et al., 2017).

Our goal is to provide an automated filtering of daily news feeds to identifying emergent cybersecurity threats as an initial screening for security experts. We emphasize from the beginning the importance of recall, namely it is critical not to disregard potential threats. Moreover, model interpretability is an important dimension of the analysis in order to provide a preliminary grounding for the model’s decisions. Hence, our research question is: To what extent can automated systems detect cybersecurity threats in news articles while ensuring interpretable results?

The paper is structured as follows. The second section introduces related work on real-time identification of threats and interpretable Natural Language Processing (NLP) approaches, while the third section introduces our approach, composed of a deep analysis of the context and the design of an interpretable model. The fourth section presents results alongside performance metrics, followed by discussions and conclusions.

## 2 Related Work

In this section, we review relevant related research on real-time threat identification and interpretable models in NLP. The abundance of OSINT data brought by Twitter has enabled SOCs to develop cyber-threat intelligence with increasing performance, while exploring tweets in different manners (e.g., by CVE(Sabotke et al., 2015) or by account(Dionísio et al., 2019)). Nonetheless, to our knowledge, existing studies focus on performance and do not consider interpretability, which seems crucial for such a critical task.

### 2.1 Real-time Threat Identification

Several papers (Attarwala et al., 2017; Dionísio et al., 2019; Le Sceller et al., 2017) introduced Twitter-based approaches to design a pipeline for threat detection and, more generally, semantic analysis. Dionísio et al. (2019) start from a set of customers, whose experts chose the Twitter cybersecurity accounts to monitor. From these accounts, tweet texts are collected using a keyword-based selection. They rely on a Convolutional Neural Network (CNN) to select only interesting tweets, while also performing named entity recognition, and check performance using True Positive and Negative Rate. A comparison between the dates from first tweet disclosing the threat to the release on the national vulnerability database of a CVSS provides insights on the ability of Twitter to become an efficient cyberthreat detection platform.

Le Sceller et al. (2017) query tweets based on keywords. Their aim is to detect and characterize cybersecurity events using only texts from tweets. A preliminary taxonomy is built to understand how main cybersecurity keywords interact, when taking decisions. The collected texts are embedded using TF-IDF and a clustering algorithm allows for up-to-date unsupervised grouping of tweets. The clustering is applied in a dynamic manner to avoid obscelence, as the keyword search is adapted according to relations and co-occurrences of words from tweets considered interesting upstream. These new keywords for the search are proposed to an external human actor, who takes the decision of adding them or not. Thus, the up-to-dateness of the architecture is guaranteed manually by experts, who

---

\(^1\)https://www.cybermalveillance.gouv.fr/tous-nos-contenus/actualites/rapport-activite-2020
leave a trace of their analysis of new trends within the model.

Abdullah et al. (2018) directly use data from new articles to detect cyberthreats. After crawling various news websites, the authors define manually, together with experts, a certain number of features defining cyberthreats, such as the threat actors, the name of the cyberattack, or the jeopardized domain. The authors create a dictionary for each feature, in which occurrences of each word corresponding to this feature are stored with their context. Using this dictionary, a Conditional Random Field enables the detection of cyberattacks from sentences. Finally, Latent Semantic Analysis supports the categorization of articles, following the type of cyberattack they shed light upon.

2.2 Interpretability in NLP

Two classes of methods tackling interpretability coexist in the literature, namely: a) a posteriori methods, which take as input a model as such, and try to explain its decisions, and b) interpretable architectures whose interpretability is taken into account in their design.

With regards to a posteriori methods, several papers (Ribeiro et al., 2016; Sundararajan et al., 2017) have studied ways to determine and visualize the isolated influence of each variable from the input of a model. Ribeiro et al. (2016) designed LIME (Local Interpretable Model-agnostic Explanations), a tool which enables the local visualization (i.e., in the input space) of the influence of each interpretable component on the decision. The model whose decision we want to explain is locally approximated by a simple-and thus interpretable-classifier. In order to make these local explanations global, a fixed number of explanations are chosen a using Submodular Pick to render, as well as possible, the use of the features by the algorithm. These explanations are then aggregated into a global result. They also introduce metrics on the evaluation of a model’s trustworthiness using their explanation system, and emphasize the importance of an oracle to assess the quality of explanations.

Sundararajan et al. (2017) bring a clear formalization on the problem of the attribution of deep network prediction to its input features. They emphasize the two conditions for a good attribution system, namely: a) sensitivity (i.e., if the input differs by 1 input component from the reference input, the attribution should be non-zero), and b) implementability invariance (i.e., if two architectures produce the same output for the same input, their attributions should be identical). They explain why state-of-the-art methods (especially gradients) do not meet these two criteria, and propose a method that complies – integrated gradient. Their method consists in integrating the gradient along component $i$ to get the attribution of input $i$.

Interpretability by attribution is a method that can be applied to any architecture, but as a consequence it does not consider the underlying mechanics for an architecture to explain the decision. A posteriori methods can also specialise in one type of architecture. In the particular case of the Transformer architecture (Vaswani et al., 2017) based on stacking self-attention layers, visualization tools like Bertviz (Vig, 2019) can be used to underpin an explanation of the model. Nonetheless, Brunner et al. (2019) warn on over-interpretation, when trying to explain self-attention. They especially argue that self-attention scores become a very complex mixture of interwoven words, while going deeper into the architecture, as a token is only responsible on average for 7.5% of the second-layer self-attention gradient. With this in mind, Chefer et al. (2020) do not restrict the influence of tokens to attention scores, but compute relevance and gradients back through the entire architecture, so as to compute the influence of each token on the decision.

The second approach considers interpretability by design. For example, Ming et al. (2019) provide an interpretable architecture for text classification that considers as implementation an RNN encoder; nevertheless, the model can consider any encoder. The idea for their architecture is to learn embeddings which well represent a special class of articles - i.e., "prototypes", and to cover as well as possible the latent space while relating to these articles. Our model builds on top of this architecture and additional details are provided in section 3.3.

3 Method

3.1 Corpora

Our aggregated corpus for training and evaluating our models consists of 1600 news articles from two collections of labeled articles that were obtained using two different approaches: Iorga et al. (2020) introduce a corpus of 1000 news articles on cybersecurity manually labeled by experts from news outlets, and Iorga et al. (2021) consider 600 more
articles that were extracted from selected Tweeter accounts. The distribution in terms of length is displayed in Figure 1; as it can be observed, more than half of the articles exceed the usual length of 512 tokens acceptable by most pretrained language models.

While accounting for the interpretability of our model, a more in-depth analysis of the articles from this aggregated dataset was required. An overwhelming majority of relevant articles disclose new vulnerabilities, either directly or through the description of an attack (or campaign). k-Means clustering was used to confirm this duality, while considering only relevant articles. Silhouette scores were computed for different number of clusters, which were afterwards visualized and cross-checked by hand to observe the split between attacks and explicit vulnerabilities. The optimal silhouette score was 0.15 for 2 clusters, followed by values lower than 0.13 for a higher number of clusters. As such, the duality is also confirmed while inspecting the most frequent tokens for each cluster (see Table 1).

| attack, user, researcher, vulnerability, device, attacker, security, malware, data, malicious |
| vulnerability, security, flaw, attacker, user, cve, update, code, version, windows |

Table 1: Keywords grouped by cluster.

A higher number of clusters would have put forward specific threats like password leaks, which represent a minority of articles and are often linked to attacks. Next, we need to consider the permissiveness of the classification: even when the technology compromised by the cyberthreat is very specific, the automated pipeline needs to label the corresponding articles as relevant. Moreover, the article needs to include specific details about the identified vulnerabilities, for example the corresponding attack vector. However, these details may represent a very limited part of the overall article.

While considering the subtle difference between the introduced topics in cybersecurity articles and the previous observations, the model needs to process the article as a whole, with corresponding inter-dependencies at word, sentence, or even paragraph levels. As such, bag-of-words approaches, such as Multinomial Naive Bayes (MNB, (Kibriya et al., 2004)), though easily interpretable by the user, will only make the most obvious decisions.

Besides the previous aggregated corpus, a second considerably larger and unlabeled corpus was also collected. The creation of this second dataset meets a need for creating an embedding space for the cybersecurity domain. For this purpose, recursive scraping was used on more than 20 news websites to collect webpages, which leads to a corpus of 65.8 million tokens and a vocabulary of 63 thousand words.

3.2 Data Pre-processing

Each article was pre-processed. First, accents, symbols, IP addresses, links, contractions, and residual dots were removed. Second, numbers were replaced by a # to report their presence. The dataset was then randomly split into a train set of 1000 articles and a test set of 600 articles using a stratification approach. It is important to emphasize the importance of recall, as we do not want to turn a "blind eye" on potential threats. Thus, the metric to be optimized for classification is F2-Score.

3.3 Interpretable Model

With the aim of designing an interpretable classifier, we combined the ProSeNet (Ming et al., 2019) architecture with Longformer (Beltagy et al., 2020) as an encoder for the entire articles.

ProSeNet considers a special layer, named the prototype layer, that takes the hidden state (in output of the encoder) as input, and its output is given to a standard classifier (dense layers and a sigmoid, in our case). The principle of the prototype layer is to compute the similarities (sim(x, y) = \frac{x^T y}{||x||^2 ||y||^2}) between the hidden state and learned vectors $p_1, ..., p_k$. These $k$ vectors (i.e., prototypes) are defined in the same latent space as the hidden state; as such, these vectors, modified by backpropagation during the epoch, are projected at the end
of epoch in the latent space of their nearest neighboring articles. If the dataset is large enough to cover the latent space, the training that includes this projection stabilizes, and the user ends up with a classification within which only the comparison between the input document and these prototypes matters for final prediction.

This construction of the decision is similar to human selection: when deciding, for example, if an article is relevant or not, it is natural to relate to similar, previously seen, articles. Further comparisons informs users that, if they want to make reasonable decisions, they should consider a wide range of articles. Thus, the number of prototypes being fixed, what an expert would expect from these prototypes is for each of them to be representative for various types of articles and to properly cover the entire possible semantic space of articles.

Nonetheless, the similarities computed with all prototypes have to be aggregated in making the final binary decision. This is where the method reaches its limits in terms of interpretability, as there is no telling how the classifier mixes the information of proximity to the prototypes in order to take its decision.

When looking at state-of-the-art work on automated text classification, the Transformer-based models stand out, pushing the boundaries of RNNs (LSTMs or GRUs cells) in terms of long-term dependencies encoding. Nonetheless, the quadratic-order computation of self-attention limits the number of tokens allowed as input. A frequently employed solution is to use only part of the text, or make several predictions (e.g., each centered on a paragraph) that are aggregated by means of voting for the final decision. However, the vulnerability in the article might end up being either completely neglected or erased for classification, if its description place in the article is limited. Therefore, the article should be considered as a whole to mitigate the risk of neglecting important details.

The Longformer (Beltagy et al., 2020) architecture overcomes the limits of classic Transformer models by changing the computation of self-attention. Instead of performing number of words operations, a window size is chosen, and relations are measured between the word and a sliding window of size around it. Beltagy et al. (2020) introduce three types of self-attention patterns distributed among the 12 encoding layers of the Longformer. The sliding window attention one has a dilation rate of 1 and it allows the efficient capturing of local information. This local information can then be aggregated thanks to dilated sliding-window self-attention patterns to capture more global information and to increase the receptive field. Global+sliding windows are mainly used in the final layers to provide task-specific tokens.

In our classification task, a single global self-attention is computed in the last encoding layer of the Longformer. The resulting architecture is presented Figure 2.

As the current implementations of ProSeNet are not adapted to our problem, we decided to adapt the implementation of Meyer (2019). The project is released as open-source and is available on Github.

### 3.4 Training Hyper-parameters

The Longformer has a window size of 128 tokens, whereas the other parameters are the default ones. The usual learning rate scheduler for Transformers was used for all training episodes, and a weighted binary cross-entropy was chosen to counterbalance the 2/3-1/3 irrelevant-relevant ratio. The classical Longformer model (i.e., without ProSeNet, with the usual classifier at the end) was trained both with and without pretraining. Pretraining is achieved on masked language modelling using the unlabelled cybersecurity dataset.

The interpretable architecture (Longformer+ProSeNet) relies on 15 prototypes. A first challenge was to make the training stable. The training of the entire architecture takes place as follows: we initialize the encoder with the weights of the previously trained Longformer as standalone, and we freeze it for the first epochs to stabilize training. Then, we unfreeze the layers and set a small learning rate for the last epochs. Four projections are computed during training.

### 3.5 On the Role of ProSeNet

Moreover, we were interested on the importance of the additional ProSeNet layer in terms of data separation between relevant and irrelevant articles. With this goal in mind, we scrutinized the influence of the different training steps (pretrained only, pretrained and finetuned) on the action of Longformer on data.

Nonetheless, when considering the distribution of embeddings in the latent space (see Figure 3),
only two groups emerge; reality is much more complex, as some irrelevant articles are not even linked to cybersecurity at all. This finer-grained characterization of the latent space is precisely what we expect ProSeNet to shed light upon. We fall in line with Ming et al. (2019) on the importance of diversity and sparsity for prototypes; however, it is also important to avoid having prototypes in the part of space where relevant and irrelevant articles coexist without a genuine separation or coherence, because of the lack of data. Prototypes thus need to represent a clearly relevant or clearly irrelevant part of the space. Indeed, they need to be representative for groups of articles, but if these groups are not clearly labeled as relevant or irrelevant, this will lead to a decrease in performance.

In terms of explainability, we emphasize the need for simplicity, as stated in the original study (Ming et al., 2019). Prototypes need to be represented briefly, without losing information required to identify them - as such, we simply present the articles by their title to the user.

4 Results

Table 2 reports the performance of various configurations, including a very simple interpretable baseline - a Multinomial Naive Bayes classifier trained using TF-IDF embeddings, while considering only the top 350 most relevant tokens chosen by feature importance.

In terms of the standard Longformer, the best performance was reached with pretraining, highlighting that additional cybersecurity context provides a significant boost in recall. Transformer-based models completely outperform MNB, particularly in terms of recall (98% for Transformer, only 62% for MNB), but at the heavy cost of interpretability. ProSeNet was designed to tackle this problem, but as we can see in Table 2, classification performance slightly deteriorates, with a 4% decrease in F2-Score when compared to the standard Longformer with pre-training.

5 Discussions

An encountered issue is that only 11 prototypes were actually selected because of duplicates (the links for the selected papers are presented in Table 3). These duplicates appeared during projection, despite adding a loss favoring the variety between prototypes to the weighted binary cross-entropy for training. To understand the emergence of duplicates, we have to remember that the amount of data might not be sufficient to cover well the entire latent space; thus, two prototypes in a poorly covered area are likely to be projected on the same article.

While taking a closer look at the articles, our first intuition (after having studied and tediously labelled the entries), is that the selected article seem to cover quite well the different cases. The balance between relevant and irrelevant articles is fulfilled. Articles 1, 2, 3, and 7 present general studies or miscellaneous events which are linked to cybersecurity, but not all to cyberthreat detection. Articles 4 and 8 study a cyberattack (without the disclosure of any vulnerability) and a legal case involving a cybercrime group; these are irrelevant. In contrast, relevant articles directly show vulnerability disclosure (articles 5, 9, and 10) or through cybercrime...

(articles 6 and 11). The security experts responsible for the initial datasets also confirmed our intuition. Nonetheless, it is important to acknowledge that the evaluation of interpretability has not been achieved by a representative assembly of cybersecurity experts or members of SOCs, even though this is the minimum expected if we want organizations to trust our model. Still, the analysis provided by the experts grounded an encouraging overview in terms of sparsity, diversity, and simplicity (see 3.5).

In order to further support the degree to which the selected prototypes cover the latent space, Figure 4 adds the prototypes to the latent space. At first sight, their distribution does not reflect the previously mentioned diversity, as the articles from the region of indecision from the encoder are mostly not covered by prototypes. This further consolidates our previous argument, i.e. the lack of data, which causes prototypes to be obviously labeled articles, and thus hinders performance.

Moreover, affinity propagation was also been implemented, with the aim of finding a finer-grained split: 54 clusters are identified, which are way too many for only 600 articles. On closer inspection, the grouping was done according to the company affected by the vulnerability. An approach based on keyword mining for each article would be interesting to further explore.

6 Conclusions and Future Work

In this study we introduce a state-of-the-art architecture based on Longformer and ProSeNet to create an interpretable pipeline to automatically label emerging cybersecurity threats. The similarity with the human decision process, coupled with a balanced performance on rather small dataset (i.e., recall - the most important metric - reaches 91%, while precision is at 78%), argue for the model’s adequacy. Thus, in response to the initial research question, our architecture provides an efficient filter, while also ensuring interpretability.

The architecture is in place, but at a crossroads. First, further data collection is required in order to extend the training dataset. Once a substantial number of articles are collected, the quality of our pipeline will be re-assessed, while also including security experts to scrutinize the explanations of our model. This is a long-term endeavour in which
the experts would be asked to chose the closest prototype out of 3 candidates for a given article. Second, we aim to implement a finer-grained clustering of the articles and identify trending topics or sub-domains. In addition, we aim to include a customizable filter that will enable SOCs to select themes for relevant articles, as well as targeted applications, thus accounting for their deployed infrastructure.

Abstract

The widespread presence of offensive language on social media motivated the development of systems capable of recognizing such content automatically. Apart from a few notable exceptions, most research on automatic offensive language identification has dealt with English. To address this shortcoming, we introduce \textit{MOLD}\textsuperscript{1}, the Marathi Offensive Language Dataset. \textit{MOLD} is the first dataset of its kind compiled for Marathi, thus opening a new domain for research in low-resource Indo-Aryan languages. We present results from several machine learning experiments on this dataset, including zero-shot and other transfer learning experiments on state-of-the-art cross-lingual transformers from existing data in Bengali, English, and Hindi.

1 Introduction

The presence of hate speech, cyber-bullying, and other forms of offensive language in online communities is a global phenomenon. Even though thousands of languages and dialects are widely used in social media, most studies on the automatic identification of such content consider English only, a language for which datasets and other resources such as pre-trained models exist (Rosenthal et al., 2021). In the past few years researchers have studied this problem on languages such as Arabic (Mubarak et al., 2021), French (Chiril et al., 2019), and Turkish (Çöltekin, 2020) to name a few. In doing so, they have created new datasets for each of these languages. Competitions such as OffensEval (Zampieri et al., 2020) and TRAC (Kumar et al., 2020a) provided multilingual datasets, which enabled the use of data augmentation methods (Ghadery and Moens, 2020), multilingual word embeddings (Pamungkas and Patti, 2019), and cross-lingual contextual word embeddings (Ranasinghe and Zampieri, 2020) to tackle this problem.

In this paper, we revisit the task of offensive language identification for low resource languages, focusing on Marathi, an Indo-Aryan language spoken by over 80 million people, most of whom live in India. Even though Marathi is spoken by a large population, it is relatively low-resourced compared to other languages spoken in the region. We collect and annotate the first Marathi offensive language identification dataset to date and we train a number of monolingual models on this dataset. Finally, we explore state-of-the-art cross-lingual learning methods to project predictions to Marathi from Bengali, Hindi, and English. We address two research questions in this paper:

RQ1: What is the impact of the dataset size in monolingual and cross-lingual models for offensive language identification? While the Marathi dataset is relatively small, cross-lingual transfer learning methods allow us to take advantage of larger available datasets in other languages.

RQ2: What is the influence of language similarity in cross-lingual predictions for offensive language identification? Previous work used English as the base language to make predictions in lower resourced languages. In this paper we use two Indo-Aryan languages, Bengali and Hindi, to project predictions into Marathi.

Our main contributions are the following:

1. We release \textit{MOLD}, the Marathi Offensive Language Dataset, with nearly 2,500 annotated tweets. \textit{MOLD} is the first dataset for offensive language identification in Marathi.

2. We evaluate the performance of several traditional machine learning models (e.g. SVMs)
and deep learning models (e.g. LSTM) trained on MOLD.

3. We apply cross-lingual transformers to offensive language identification in Marathi. We take advantage of existing data in English and in two Indo-Aryan languages, Hindi and Bengali, to project predictions to Marathi and we compare the results of these strategies. To the best of our knowledge, this is the first paper to study closely-related languages in transfer learning for offensive language identification.

4. In addition to MOLD, we make the code and the models freely available to the community.

2 Related Work

The problem of offensive content online has been widely studied using computational models. Researchers have trained system to recognize various types of such content such as cyberbullying, hate speech, and many others. In terms of computational approaches, early studies approached the problem using feature engineering and classical machine learning classifiers, most notably SVMs (Dadvar et al., 2013; Malmasi and Zampieri, 2017), while more recent work applied deep neural networks combined with word embeddings (Aroyehun and Gelbukh, 2018; Hettiarachchi and Ranasinghe, 2019). With the development of large pre-trained transformer models such as BERT and XLNET (Devlin et al., 2019; Yang et al., 2019), several studies have explored the use of general pre-trained transformers in offensive language identification (Liu et al., 2019; Ranasinghe et al., 2019; Bucur et al., 2021) as well retrained or fine-tuned models on offensive language corpora such as HateBERT (Caselli et al., 2020).

While the vast majority of studies address offensive language identification using English data (Yao et al., 2019; Ridenhour et al., 2020), several recent studies have created new datasets for various languages and applied computational models to identify such content in Arabic (Mubarak et al., 2021), Dutch (Tulkens et al., 2016), French (Chiril et al., 2019), German (Wiegand et al., 2018), Greek (Pitenis et al., 2020), Hindi (Bohra et al., 2018), Italian (Poletto et al., 2017), Portuguese (Fortuna et al., 2019), Slovene (Fišer et al., 2017), Spanish (Plaza-del Arco et al., 2021), and Turkish (Çöltekin, 2020). A recent trend is the use of pre-trained multilingual models such as XLM-R (Conneau et al., 2019) to leverage available English resources to make predictions in languages with less resources (Plaza-del Arco et al., 2021; Ranasinghe and Zampieri, 2020, 2021c,b; Sai and Sharma, 2021). This is made possible by the availability of the aforementioned datasets as well multilingual datasets made available at shared tasks such as HASOC 2019 (Mandl et al., 2019), TRAC 2018 and 2020 (Kumar et al., 2018, 2020a), and two tasks at SemEval: HatEval 2018 (Basile et al., 2019) and OffensEval 2020 (Zampieri et al., 2020).

3 Datasets

We present MOLD and four other datasets used in this work: the Bengali dataset (Bhattacharya et al., 2020) used in the TRAC-2 shared task (Kumar et al., 2020a)—henceforth BE, the Hindi dataset (Mandl et al., 2019) used in the HASOC 2019 shared task—henceforth HI, and the English datasets used in OffensEval, SemEval-2019 Task 6 and SemEval-2020 Task 12—henceforth EN-OLID (Zampieri et al., 2019) and EN-SOLID (Rosenthal et al., 2021), respectively.

To annotate MOLD, we followed OLID’s annotation scheme for English which has been replicated in SOLID and in datasets in Greek (Pitenis et al., 2020), Turkish (Çöltekin, 2020) and many other languages. OLID’s taxonomy comprises the following three levels:

- **Level A**: Offensive language identification: offensive (OFF) vs. non-offensive (NOT)
- **Level B**: Categorization of offensive language: targeted insult or thread vs. untargeted profanity
- **Level C**: Offensive language target identification: individual vs. group vs. other

This hierarchical taxonomy represents multiple types of offensive content in a single annotation scheme (e.g. targeted insults to an individual are often cyberbullying and targeted insults to a group are often hate speech) making it a great fit for cross-lingual learning applied to low-resource languages like Marathi. We used OLID level A labels to annotate MOLD and we map these labels to those included in the Bengali and Hindi datasets.

**MOLD** The Marathi dataset contains data collected from Twitter using the Twitter API. We aimed to achieve a similar distribution of offensive vs. non-offensive content present in OLID, which contains around 33% offensive and 67% non-offensive tweets. To make sure that both classes
were represented, we used both offensive and non-offensive keywords. For the offensive content we used 22 common curse words in Marathi and for the non-offensive content we used search phrases related to politics, entertainment, and sports along with the hashtag #Marathi.

We collected a total 2,547 tweets that were annotated by 6 volunteer annotators who are native speakers of Marathi with age between 20 and 25 years old and a bachelors degree. The annotation task is a binary classification, in which annotators assigned tweets as offensive (OFF) or not offensive (NOT). The annotators could flag a tweet as invalid if it contained four or more non-Marathi words. The final version of MOLD contains 2,499 annotated tweets randomly split 75%/25% into training and testing sets, respectively. We used Cohen’s kappa (Carletta, 1996) to measure agreement between pairs of annotators. We provided a common set of 100 instances to each of the three pairs of annotators and we report scores of 0.91 between A1 and A2, 0.79 between A3 and A4, and 0.77 between A5 and A6. Table 1 shows dataset statistics, including class distribution.

Other Datasets: In addition to the Marathi dataset, we used the four aforementioned publicly available offensive language detection datasets presented in Table 2. OLID (EN-OLID) is one of the most popular offensive language datasets for English and we used its level A annotations (offensive vs. non-offensive) as labels. We used EN-SOLID, the largest available dataset of its kind as our second English dataset. EN-SOLID contains over nine million English tweets labeled in a weakly supervised manner (Rosenthal et al., 2021). EN-SOLID was created using an ensemble of four different models and provides, along with the class labels, the average and standard deviation of the confidence scores predicted by each model. We included only training examples with average confidence scores greater than 0.85 over all models, leaving us with 120,758 examples. Using both EN-OLID and EN-SOLID allows us to investigate the impact of training data size and help us answer RQ1.

To perform transfer learning from a closely-related language to Marathi, we used HI (Mandl et al., 2019). Both the English and Hindi datasets contain Twitter data making them in-domain with respect to MOLD. BE, the Bengali dataset (Bhattacharya et al., 2020), is different than the other datasets as it contain Facebook data and three classes, allowing us to compare the performance of cross-lingual embeddings on off-domain data but in a a language similar to Marathi. For Bengali we merged the classes overtly aggressive and covertly aggressive and map them to EN-OLID’s offensive class. Using both BE and HI in addition to the two English datasets allow us to investigate the impact of language similarity aiming to answer our RQ2.

### 4 Methods and Results

#### 4.1 Monolingual Models

We run several computational models on MOLD. We trained four classical machine learning classifiers, available in Scikit-learn (Pedregosa et al., 2011): Decision Trees, Naive Bayes, Random Forest, and SVM using bag of words (BoW), word unigrams, and word unigrams and bigrams combines using TF-IDF weighting. We took several pre-processing steps before extracting features such as removing numbers, extra spaces, special characters, and stop words.²

We implemented several deep learning models, such as multi layer perceptron (MLP), long short-term memory networks (LSTMs) with embedding layers, and bi-LSTMs with attention and word embedding layers. We used the Marathi word2vec embeddings released in Kumar et al. (2020b). We also experimented with several SOTA transformer models that support Marathi: multilingual BERT (BERT-m) (Devlin et al., 2019) and XLM-Roberta (XLM-R) (Conneau et al., 2019). XLM-R has an additional advantage: the embeddings are cross-lingual. This helps facilitate transfer learning across languages, as presented later in this section. We followed the same architecture described in Ranasinghe and Zampieri (2020) where a simple softmax layer is added to the top of the classification ([CLS]) token to predict the probability of a class label. For XLM-R, from the available two pre-trained models, we specifically used the XLM-R large model.

For both classical and deep learning models we finetuned hyperparameters manually to obtain the best results for the validation set created using a 0.8:0.2 split on the training data. As the deep learning models tend to overfit, we evaluated the model on the validation set once in every 100 training batches. We performed early stopping if the validation loss did not improve over 10 evaluation steps. All the deep learning experiments were run on an Nvidia Tesla K80 GPU.

For classical models, we used the baseline architectures described in Section 3.1 and finetuned the hyperparameters to obtain the best results for the validation set created using a 0.8:0.2 split on the training data. As the deep learning models tend to overfit, we evaluated the model on the validation set once in every 100 training batches. We performed early stopping if the validation loss did not improve over 10 evaluation steps. All the deep learning experiments were run on an Nvidia Tesla K80 GPU.

Table 3 shows the results obtained by all monolingual models on MOLD’s test set in terms of both Macro F1 and Weighted F1. We use both metrics due to the data imbalance in MOLD. With the exception of MLP, all of the deep learning models outperformed the classical ones. This is somewhat surprising as classical models tend to outperform deep models on relatively small datasets like MOLD, but it corroborates the findings from recent competitions on this topic (Basile et al., 2019). Of the deep learning models, XLM-R transformers provided the best results with a 0.91 macro F1 score.

Table 3: Monolingual results for Marathi ordered by macro (M) F1. We also report weighted (W) F1 scores.

4.2 Cross-lingual Models

The main appeal of transfer learning is its potential to leverage models trained on data from outside the domain of interest. This can be particularly helpful for boosting the performance of learning on low-resource languages like Marathi. The recent success of XLM-R cross-lingual transformers with transfer learning in offensive language identification for low resource languages (Ranasinghe and Zampieri, 2020) confirms that this is a feasible approach. In these experiments, however, the transfer learning’s base language was English whereas here we use two languages related to Marathi: Bengali and Hindi, in order to evaluate the extent to which language similarity boosts transfer learning performance.

Transfer Learning We first trained the XLM-R model separately on the BE, HI, EN-OLID and EN-SOLID datasets. Then we saved the weights of the transformer model and the softmax layer and used these weights to initialize the weights of the transformer-based classification model for Marathi. TL row in Table 4 shows the results obtained by the cross lingual models with XLM-R. The use of transfer learning substantially improved the monolingual results. With 8,000 and 4,000 training instances, respectively, the transfer learning model achieved macro F1 scores of 0.9401 from Hindi and of 0.9345 from Bengali, respec-
tively, outperforming the results obtained using the two English datasets, EN-OLID and, especially, EN-SOLID, each contain more instances than either the Hindi or the Bengali dataset, yet they fail to outperform either as the base dataset in our transfer learning experiments, suggesting that language similarity played a positive role in transfer learning.

**Zero shot learning** To further observe the impact of language similarity in transfer learning, we performed Zero shot learning, where the XLM-R model was trained on the other datasets and tested on the Marathi test set. According to the results in Zero-shot row of Table 4 HI outperforms all the other languages in Zero shot too.

</tr>
</tbody>
</table>

Table 4: Transfer learning results ordered by macro (M) F1 for Marathi. We also report weighted (W) F1 scores.

**Few shot learning** Finally, we evaluated each of the languages performance in few shot learning with Marathi. We retrained offensive language identification XLM-R models from other languages on 100, 200, 300 etc. instances from Marathi. As shown in Figure 2 HI tops other languages in all the few shot experiments making it further clear that transfer learning from a more similar language is effective in offensive language identification.

5 Conclusion and Future Work

This paper introduced MOLD, the first offensive language dataset for Marathi. We evaluated the performance of several machine learning models trained to identify offensive content in Marathi. Our results show that applying cross-lingual contextual word embeddings substantially improved performance over monolingual models. Furthermore, we showed that XLM-R with transfer learning from Hindi outperforms all of the other methods we tested. The results obtained by our models confirm that closely related languages provide an advantage in our transfer learning experiments, answering our RQ2. This is likely due to the fact that Hindi and Marathi are typologically related and also because these languages are in a situation of language contact sharing cultural background.

To the best of our knowledge, this paper is the first to address the question of language similarity in cross-lingual learning for offensive language identification. With respect to our RQ1, our results show that the difference in performance between transfer learning strategies from OLID and from SOLID is minimal. SOLID is more than eight times larger than OLID, suggesting that beyond a certain point, more instances do not necessarily yield significant performance improvements in transfer learning. Finally, we believe that the findings presented in this paper can open a wide range of avenues to offensive language identification applied to other low resource languages, particularly from the Indo-Aryan family.

**MOLD** is the official dataset for Marathi at the HASOC 2021\(^3\) shared task on Hate Speech and Offensive Content Identification in English and Indo-Aryan Languages. We are expanding the annotation of this dataset to the levels B and C of OLID’s annotation taxonomy. This will provide us with the opportunity to test computational models to identify the type and target of offensive posts in Marathi. As future work, we would like to evaluate the performance of transfer learning from Dravidian languages spoken in India such as Tamil and Telugu to analyze the interplay between language similarity and cultural overlap in cross-lingual offensive language identification as in Ranasinghe and Zampieri (2021a).

Abstract

Machine reading comprehension (MRC) is one of the most challenging tasks in natural language processing domain. Recent state-of-the-art results for MRC have been achieved with the pre-trained language models, such as BERT and its modifications. Despite the high performance of these models, they still suffer from the inability to retrieve correct answers from the detailed and lengthy passages. In this work, we introduce a novel scheme for incorporating the discourse structure of the text into a self-attention network, and, thus, enrich the embedding obtained from the standard BERT encoder with the additional linguistic knowledge. We also investigate the influence of different types of linguistic information on the model’s ability to answer complex questions that require deep understanding of the whole text. Experiments performed on the SQuAD benchmark and more complex question answering datasets have shown that linguistic enhancing boosts the performance of the standard BERT model significantly.

1 Introduction

Machine reading comprehension (MRC) reflects the ability to read and understand an unstructured text and answer questions regarding it. Aiming to find the relevant answer to a question in the form of a text span, the MRC models should demonstrate deep understanding of the language and text organization.

Transformer models that achieve state-of-the-art results on multiple natural language processing (NLP) tasks have been successfully applied to the MRC. However, while the ideal MRC model should read most words superficially and pay attention only to the essential ones (Wang et al., 2017), the attention mechanism in the standard transformers attends to all words without explicit constraint which results in inaccurate concentration on some less important text spans. Lately, the researchers have actively examined the ability of the deep learning (DL) models to understand language and build accurate linguistic-enhanced internal representation.

Recent works have revealed that traditional DL models that ignore additional linguistic knowledge, such as syntax or semantic, achieve lower accuracy on such complex tasks as natural language understanding (NLU) or MRC (Roth and Lapata, 2016; Marcheggiani and Titov, 2017; He et al., 2018). It has been shown that incorporating explicit syntactic (Hu et al., 2019) and semantic (Zhang et al., 2020a) relations into the attention mechanism leads to better linguistically motivated word representations beneficial for the MRC task.

Moreover, providing exact, concise answers frequently requires not just syntactic/meaning similarity but an overall structure of thoughts expressed by an author (Galitsky et al., 2013), i.e., some claims introduced by an author and logical connections existing among them. This information is encoded by discourse structure of a text that, as long as syntax and semantic, is believed to provide valuable information that could help the model to capture all the hidden dependencies existing in the text and to pay attention only to the relevant words while answering the corresponding question.

In this paper, we explore if and how discourse-level features (discourse relations connecting the text spans), fed to a neural MRC model on top of syntactic and semantic features or independently, can help to answer complex, long, multi-sentence questions. We intend to develop a neural method
that selects relevant words by only considering the related subset of words, w.r.t. syntactic, semantic, and discourse-level importance. To provide feature encoding we use a self-attention network (SAN) enriched with the discourse features (such as explanation, condition, etc.) retrieved from a text and combine it with the classical transformer encoder to build linguistically-enhanced text representation.

Overall, the contribution of this paper is three-fold: first, we introduce a novel discourse-aware transformer-based model to construct the enriched internal representation of the text. Second, we develop an ensemble MRC model that combines syntax, semantic, and discourse MRC components. Third, we conduct experiments on various question-answering (QA) datasets to assess the ability of the linguistically enriched model to answer complex questions and estimate the influence of each source of linguistic information.

2 Related Work and Background

2.1 Machine Reading Comprehension

Span-based MRC, which is the main focus of this work, is quite a challenging task, as we expect the model not only to identify the relevant document that contains a possible answer but to retrieve the exact text fragment that answers the question. There has been a lot of studies on solving this task with attentive models (Kadlec et al., 2016; Yuan et al., 2018; Guo et al., 2019).

Recently, the pre-trained contextual language models (LMs) such as ELMO (Peters et al., 2018), BERT (Devlin et al., 2019), or a series of GPTs (Radford et al., 2018) have shown state-of-the-art results on the number of NLU benchmarks which has attracted the researchers’ interest toward utilizing these models for MRC. Despite the increasing popularity of these LMs, several studies have revealed that textual representation provided by them relies purely on the context of each word and, generally, neither the syntactical nor semantic organization of the text is considered. As this information is crucial for MRC, the novel techniques to incorporate syntactic and semantic knowledge into the pre-trained LMs have been the main focus of the latest works.

2.1.1 Syntactic-aware Models

Recent attempts to turn neural network algorithms into more structure-aware ones have discovered the incorporation of external memories in the context of recurrent neural networks. The idea is to use multiple memory slots outside the recurrence to piece-wise store representations of the input. Read and write operations for each slot can be modeled as an attention mechanism with a recurrent controller. Cheng et al. (2016), for example, leverage memory and attention to empowering a recurrent network with stronger memorization capability and more importantly the ability to discover relations among tokens. This is realized by inserting a memory network module in the update of a recurrent network together with attention for memory addressing. The attention acts as a weak inductive module discovering relations between input tokens and is trained without direct supervision. The experiments performed on NLI datasets showed that the superiority of the modified model over the vanilla LSTMs.

In more recent work (Zhang et al., 2020b), the authors benefit from the performance of the BERT model on span-based MRC tasks and sponsor it with the syntax-guided SAN. They design an informative method that can selectively pick out important words by only considering the related subset of syntactically important context inside each input sentence explicitly. With the guidance of syntactic structure clues, the syntax-guided method could give more accurate attentive signals and reduce the impact of the noise brought about by lengthy sentences. The authors extend the self-attention mechanism with syntax-guided constraint, to capture syntax-related parts with each concerned word. Specifically, they adopt a pre-trained dependency syntactic parse tree structure to produce the related nodes for each word in a sentence, namely syntactic dependency of interest, by regarding each word as a child node, and the syntactic dependency of interest consists of all its ancestor nodes and itself in the dependency parsing tree. The syntax encapsulating into the model should provide a better understanding of the long or unanswerable questions, which is a big obstacle for the existing MRC models.

2.1.2 Semantic-aware Models

Frequently, DL models suffer from insufficient contextual semantic representation and learning. So, the way of constructing semantic-aware LMs has also attracted wide attention in research.

To provide contextual semantic representation to the DL models, Strubell et al. (2020) propose linguistically-informed self-attention (LISA), which is used for the semantic role labeling (SRL) task. The model proposed by the authors is end-to-end, and it is trained to predict part of speech
tags, provide parsing, attend to syntactic parse dependents, and, finally, assign semantic role labels to the model. This architecture has been applied to enlarge the contextual representation provided by BERT with the additional semantic information.

In (Zhang et al., 2020a), the authors propose to use SRL task to integrate the text representation provided by BERT with the contextual explicit semantic embedding, the introduced model is called \textit{Sem-BERT}. Sem-BERT is intended to handle multiple sequence inputs, the words in the input sequence are passed to semantic role labeling to obtain multiple predicate-derived structures to form a semantic embedding. In parallel, the input sequence is segmented to subwords (if any) by BERT word-piece tokenizer, then the subword representation is transformed back to word-level via a convolutional layer to obtain the contextual word representations. Finally, the word representations $H$ and semantic embedding $H_{\text{sem}}'$ are concatenated to form the joint representation.

Despite there is a number of works encapsulating the syntactic and semantic information about the text into the DL models, there is still a lack of research that considers discourse organization, which also introduces relevant linguistic knowledge essential for MRC, and other downstream challenges. In this work, we propose a way to encode the discourse structure of the text by neural network and enrich the text embeddings constructed by BERT with this information. Then, we aim to assess the influence of discourse, semantic, and syntactic features on the MRC task.

\subsection{Discourse Structure}

In this section, we introduce the definition of discourse structure that we propose to integrate into the MRC model. Any coherent text is structured so that we can derive and interpret the information. This structure shows how discourse units (text spans such as sentences or clauses) are connected and relate to each other. Discourse analysis reveals this structure and describes the relations that hold between text units in the document. Several theories have been proposed in the past to describe the discourse structure, among which the Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) is one of the most popular. RST divides a text into minimal atomic units, called Elementary Discourse Units (EDUs). It then forms a tree representation of discourse called a Discourse Tree (DT) using rhetorical relations (Elaboration, Explanation, etc.) as edges, and EDUs as leaves. EDUs linked by a rhetorical relation are also distinguished based on their relative importance in conveying the author’s message: the nucleus is the central part, whereas the satellite is the peripheral part. Nucleus units consist of basic information and satellite units contain additional information about the nucleus.

An exploration of coherence relations in frameworks such as RST has experienced a revival in the decade in English and a few other languages (Matthiessen and Teruya, 2015; Maziero et al., 2015; Zeldes, 2016) which has led to a grown number of applications of discourse analysis. For example, discourse parsers are used in argumentation mining in online discussions, summarization, QA systems, and machine translation (Benamara et al., 2017; Durrett et al., 2016; Peldszus and Stede, 2016; Chakrabarty et al., 2020). We claim that incorporating this additional discourse information provided by state-of-the-art parsers could be beneficial for DL models performing MRC. We are motivated to improve the self-attention layer appended to the top of the transformer encoder to enrich the contextualized word representation with information from its neighbors and the relations from the dependency parse trees.

\section{MRC System Extended with Discourse Relations}

In this paper, we present the novel discourse-aware attentive model designed to perform the MRC task. Our approach is inspired by syntax-guided BERT (Zhang et al., 2020b), while instead of encapsulating the syntactic dependencies among the words, we pre-process the discourse parse tree and observe the EDUs as long as the specific discourse relations connecting them.

We introduce the architecture of the transformer-based encoder empowered with the discourse knowledge about the input text in Section 3.1. As we aim to assess the influence of all three types of linguistic information, in Section 3.2, we present the final MRC system designed as the ensemble of state-of-the-art syntactic, semantic, and the proposed discourse-aware attention components.

\subsection{Discourse-aware Model}

In this section, we describe a method for incorporating discourse relations into the transformer-based model explicitly. As well as the syntactic
dependency parse tree, the discourse structure can be represented as a hierarchically organized tree, where the leaves are the text spans and the edges denote the type of relations connecting them. Thus, we propose to modify the SAN appended to the top of vanilla transformer-based encoder to make it able to process the discourse text organization, and, thus, to utilize this additional linguistic feature for MRC.

3.1.1 Discourse-aware Self-attention Layer

Our discourse-aware language model is trained to provide the vector representation of the text enriched by the discourse relations connecting text units. To obtain this representation we use the standard transformer encoder to calculate contextual representation of the text, then the obtained vector is passed through the discourse-aware SAN, which is designed to encapsulate the discourse structure into the embedding of the sequence. Finally, the discourse-aware representation is aggregated with the output of the pure transformer, this final embedding goes through the task-specific layer to perform the MRC task. The overall model architecture is presented in Fig. 1.

Generally, the main difference between the discourse-aware language model and the traditional transformer-based model is as follows. In traditional transformers, the word attends to both sides of the context, while in the discourse-aware model we would like each word to attend to its discourse-dependent ancestors. This forces a multi-head attention mechanism to analyze the dependency among tokens w.r.t. the rhetoric relations connecting them. As we have already mentioned, the discourse structure of the text is represented by the DT. In this section, we will present the approach for incorporating this DT into the SAN.

To provide the discourse structure of the text we use a state-of-the-art discourse parser (Joty et al., 2013) which constructs a hierarchically organized dependency tree for the input text. The text annotated with discourse relations will be transmitted to the attention network. Whereas the SAN cannot encapsulate the whole discourse tree, we need to detect the essential dependencies existing among words that should be included in the model. Each discourse unit (sequence of words) corresponding to some leaf in DT is connected to its ancestor non-terminal node labeled by the rhetoric relation referred to this EDU. For example, in the passage and its DT shown in Fig. 3, the words do not attend to all of the left and right neighbors in the context, on the contrary, the words finds and clinicians are connected to their ancestor labeled by Attributions, while the pneumonia attends to its ancestor Cause which also depends on Attributions. This sequence of connections fully reflects the discourse organization of the text.

Formally, given input token sequence $S = \{s_1, s_2, ..., s_n\}$ of length $n$, we first pass it through the discourse parser to split into the EDUs and generate the discourse dependencies existing between them. The input sequence after parsing is enriched with the discourse relations $S_{rel} = \{rel_1, edu_1, rel_2, edu_2, ..., rel_m, edu_m\}$ of length $m$ where $edu_i = \{s_k, s_{k+1}, ..., s_{k+K}\}$, and $K$ is the number of tokens assigned to the $i$th EDU. We should notice that $edu_i$ could be an empty set if $rel_i$ connects two non-terminals nodes corresponding to the sub-trees in the DT (see contrast-elaboration relations in Fig. 3). Then, we should retrieve the ancestor nodes for each of the word $s_i$ and the rhetoric relation $rel_i$. To provide this we traverse the discourse dependency tree, and the ancestor node set $P_i$ is derived for each $s_i$ and $rel_i$. Finally, in an analogy with syntax-guided SAN a discourse dependency of interest mask $M$ is obtained. $M$ is $(n + m) \times (n + m)$ matrix, where the elements in each row denote the dependency mask of all tokens to the row-index token. $M[i, j] = 1$ means that token $s_i$ is the ancestor node of token $s_j$.

$$M[i, j] = \begin{cases} 1 & \text{if } j \in P_i \text{ or } j = i \\ 0 & \text{otherwise.} \end{cases}$$

To obtain the discourse-aware representation of the text we project the last layer output $H$ of size $L$ calculated by the original transformer encoder into the distinct key, value, and query representations of dimensions $<L \times d_k, L \times d_q, L \times d_v>$, respectively, denoted $<K'_i, Q'_i, V'_i>$ for each headword $i$. Then a dot product is computed to score key-query pairs with the dependency of interest mask to obtain attention weights of dimension $L \times L$, denoted $A'_i$:

$$A'_i = \text{Softmax}\left(\frac{M \cdot (Q'_iK'_iT)}{\sqrt{d_k}}\right)$$

The attention weight $A'_i$ is multiplied by $V'_i$ to obtain the discourse-aware token representations: $W'_i = A'_iV'_i$. $W'_i$ for all heads are concatenated and passed through a feed-forward layer. After passing through another feed-forward layer, a layer
normalization is applied to the sum of output and initial representation to obtain the final $H'_{\text{disc}} = \{h'_0, h'_1, ..., h'_n\}$.

Finally, we summarize the two text representations, where the former is obtained from the standard transformer encoder $H$, and the latter is the discourse-aware text representation $H'_{\text{disc}}$, finally $H_{\text{disc}} = H + H'_{\text{disc}}$.

### 3.1.2 Answer Detection

Having identified the model for calculating discourse-aware text representation, we could proceed with the MRC task. MRC is the ability to answer the question based on the input paragraph of the text. As we have already mentioned, in this work, we consider a so-called span-based MRC, where the answer should be found as the span of the input passage referring to the question. Formally, we can define the span-based MRC by a triple $< P, Q, A >$, where $P$ is the text paragraph which is the basis for the question $Q$, and $A$ is the correct answer to the question.

The input data which is fed to the transformer encoder is performed as $[\text{CLS}] P [\text{SEP}] Q [\text{SEP}]$, where the $[\text{CLS}]$ and $[\text{SEP}]$ are the special tokens utilized in the BERT model.

We use BERT model as the transformer encoder, so, the $[\text{CLS}]$ token representation calculated by the BERT encoder for the input sequence is used as the contextualized representation $H$ of the whole text passage and question. Finally, $H$ goes through the linguistically enriched SAN in order to obtain $H_{\text{ling}}$ and $H_{\text{ling}}$, where $\text{ling} \in \text{[synt, sem, disc]}$ that refers to the syntax, semantic, and discourse-aware SAN, respectively. $H_{\text{ling}}$ is fed to a linear layer to obtain the probability distribution over the start and end positions of the answer in the text through a softmax layer.

In the work, we propose to analyze the influence of various linguistic characteristics on the MRC. So, for the experiments, we will use both the standalone $H_{\text{ling}}$, and their combination, calculated as the sum of the individual $H_{\text{ling}}$.

### 3.2 MRC Pipeline

Fig. 2 demonstrates the architecture of the whole pipeline that we introduce to perform the MRC task. All in all the main components of the model are as follows:

1. Linguistic data preparation, which extracts, organizes, and aligns linguistic features at various levels of knowledge abstraction. There the system parses the input text passage to obtain relevant linguistically enriched structures that will be further utilized in neural model performance. Discourse after-parser is responsible for enrichment of the input sequence with the discourse relations revealed form the DT, $S_{\text{rel}}$.

2. Deep learning component actually performing MRC. This block provides encoding of the input passage and related questions using the classical transformer encoder as long as the additional linguistic feature extraction. The output of the context aggregation block is the representation $H_{\text{ling}}$, which is the sum of context-based text embedding and the embedding provided by linguistically-guided SAN.
Finally, this $\overline{H}_{ling}$ is used to perform the MRC task.

The discourse SAN block is the one introduced in Section 3.1.1. To provide the syntactic- and semantic-aware models we use the state-of-the-art models described in Sections 2.1.1 and 2.1.2. Specifically, we implement syntax-guided SAN by (Zhang et al., 2020b) and Sem-Bert by (Zhang et al., 2020a). These models are able to encapsulate the corresponding linguistic features into the transformer-based models that help to achieve an accuracy gain for the tasks related to MRC.

4 Experiments

In this work, we rely on four QA datasets with long, complex, multi-hop questions to observe if/how syntactic, semantic, and, mainly, discourse-level features help to provide the correct answers. As the baseline, we use fine-tuned BERT model. Besides, we compare the performance of our system with the current state-of-the-art results published or obtained from the leaderboard for the corresponding dataset.

4.1 Datasets and Setup

The experimental evaluation has been performed on several extracting reading comprehension English datasets. First, we verified the model on the well-known SQuAD datasets (Rajpurkar et al., 2016, 2018). then we evaluated how the introduced MRC model can cope with the more complex questions that require language comprehension and understanding of the full text rather than just a small paragraph. As the example of complex questions datasets, we consider NewsQA (Trischler et al., 2017), QA in Context (QuAC) dataset (Choi et al., 2020), and multi-sentence questions (MSQ) (Burchell et al., 2020).

Stanford Question Answering Dataset (SQuAD) is a reading comprehension dataset, consisting of questions posed by crowd-workers on a set of Wikipedia articles, where the answer to every question is a segment of text from the corresponding reading passage. SQuAD contains more than 100,000 question-answer pairs on 500 articles, which is significantly larger than previous reading comprehension datasets. We use two versions of this corpus: SQuAD 1.1 and SQuAD 2.0, where the latter also includes unanswerable questions so that we can test the ability of the model to detect the questions that cannot be answered based on the provided paragraph. F1 score that measures the weighted average of the word-level precision and recall rate is used to evaluate the performance of the models.

NewsQA dataset consists of 100K QA pairs written by humans for CNN news articles. Answers are typically the multiword spans of the source text, as in the SQuAD there are unanswerable questions.
presented. The main challenge of this dataset is that a significant proportion of questions cannot be solved without reasoning, i.e. understanding conceptual overlap or identifying the synonyms.

**MSQ dataset** uses the Stack Exchange Data Explorer, an open-source tool for running arbitrary queries against public data from the Stack Exchange network. The authors of this corpora chose 93 sites within the network and queried each site for entries with at least two question marks in the body of the question. Also, the authors filtered too short (under 5 characters) and too long (over 300 characters), and badly formed questions. After cleaning and processing, 162,745 questions from 93 topics were extracted. This dataset includes the questions that consist of several sequential questions, and in order to answer them right, they should be considered as the one. We are not aware of any works that has attempted to improve QA performance on MSQs so far.

**QuAC dataset** has 100K QA pairs created by two crowd workers who are asking and answering questions about a hidden Wikipedia text. This dataset is aimed at enabling the MRC model to answer the latest question by comprehending not only the given context passage but all the dialogue that has been seen so far.

### 4.2 Results

To assess the influence of different linguistic features on the model performance we divided our experiments into two parts. Firstly, we provide the results on SQuAD datasets, then we present the evaluation on the more complex (w.r.t. the questions' design) NewsQA, QuAC, and MSQ datasets. In all experiments, we calculate F1 score as the weighted average between precision and recall. The results achieved by the introduced MRC model are presented in the bottom block of the table. We also show the results of the state-of-the-art models presented in the literature or public leaderboards (* symbol is used to refer to the unpublished works) for the available datasets (upper block). The results achieved by the MRC models relying on discourse information are in bold.

**SQuAD.** Our performance on both SQuAD 1.1 and 2.0 test data is shown in Table 1. The default MRC (baseline) employs neither syntactic nor semantic information, this is a typical fine-tuned cased BERT used as the encoder for the question and the passage. As we move towards syntactic, semantic, and discourse levels the average performance gain is 2.2, 3.4, and 3% respectively. The improvement of the integrated system is 5.4%. Despite the fact that the introduced model could not outperform the best both single (such as ALBERT) and ensemble (FPNet) models, we can observe that it boosts the default linguistic-free baseline essentially.

**Complex datasets.** Table 2 shows the result on NewsQA, QuAC, and MSQ. As we proceed to-

**Table 2:** F1 scores (%) on complex questions datasets. The performance of other MRC models on MSQ dataset has not been published yet.
wards evaluation in the datasets of more complex questions, the performance drops up to 20%. Analogously to Table 1, the default MRC employs none of the additional linguistic information. Whereas the absolute performance value is lower than in Table 1, the performance boost due to linguistic information is higher. The average contributions of syntactic, semantic, and discourse levels are 5.3, 5.2, and 6.5% respectively. One can observe that contribution of discourse-level features is the highest in this evaluation domain of longer, multi-sentence questions (MSQ). The improvement of the integrated system is almost 11% for MSQ, and 9.5% on average. Hence, the more long and complex the questions are, the higher the impact of linguistic information, especially discourse-level. We should also mention that the introduced ensemble model outperforms both the stand-alone fine-tuned BERT and current state-of-the-art models for NewsQA and achieves comparable results on QuAC.

4.3 Case Study

Finally, let us consider a case study, where the linguistic-free BERT model provides the wrong result answering the question, while the introduced discourse-aware MRC model can answer the question correctly. Bellow, there are an input passage and the question regarding it.

**P:** **Viruses, bacteria, and fungi** can all cause pneumonia. In the United States, common causes of viral pneumonia are influenza and respiratory syncytial virus. A common cause of bacterial pneumonia is Streptococcus pneumonia. However, clinicians are not always able to find out which germ caused someone to get sick with pneumonia.

**Q:** Who experience difficulties finding causes for pneumonia?

The answer found by ELMO is **Viruses, bacteria, and fungi**, which, indeed, is not correct. The correct answer is **clinicians**. MRC fails miserably here associating **virus, bacteria, and fungi** with **Who**. Also, MRC failed to match the question with the sentence “However, clinicians are not always able to find out which germ caused someone to get sick with pneumonia.”. The introduced discourse-aware model answers the question as “Clinicians are not always able to find out.”. Let us consider the discourse structure for the passage and the question to understand the influence of discourse knowledge while dealing with this example.

The DT for this passage is shown in Fig. 3. In accordance with the constructed DT, we have a mapping between: Q: attribution → P: attribution, Q: cause → P: cause, Q: “causes” → P: “caused”. This information allows the model to attend each word to the relevant text spans in the input passage and, thus, to find the correct answer to the question.

![DT for Passage](image)

**Figure 3:** The discourse tree (DT) for text to chose an answer from (on the top) and for the question (on the bottom) with the mappings between corresponding nodes.

5 Conclusion

In this paper, we analyzed various linguistically enriched deep neural models and assessed the influence of semantic, syntax, and discourse on their performance on MRC tasks. While, modern systems are usually linguistic-free or rely on some independent linguistic characteristic, such as syntax or semantic individually, we claim that their combination could provide even higher accuracy gain. We also introduce the approach to incorporate discourse structure into the transformer-based model, which has been proven to be necessary for answering complex multi-sentence questions.

We have shown that the combination of three additional features encoded into a neural MRC is able to answer lengthy and complex questions better than the linguistic-free models, even the ones fine-tuned on the observed datasets. The introduced discourse-aware MRC model outperformed standalone syntax-guided (Zhang et al., 2020b) and semantic-enhanced models (Zhang et al., 2020a) for all the observed datasets. Although our MRC system did not achieve state-of-the-art results on some of the evaluation datasets (e.g., on the SQuAD), it demonstrated the superiority of integrated syntax/semantic/discourse subsystems in multiple diverse QA domains with complex questions.

A Dynamic Head Importance Computation Mechanism for Neural Machine Translation

Akshay Goindani Manish Shrivastava

Abstract
Multiple parallel attention mechanisms that use multiple attention heads facilitate greater performance of the Transformer model for various applications e.g., Neural Machine Translation (NMT), text classification. In multi-head attention mechanism, different heads attend to different parts of the input. However, the limitation is that multiple heads might attend to the same part of the input, resulting in multiple heads being redundant. Thus, the model resources are under-utilized. One approach to avoid this is to prune least important heads based on certain importance score. In this work, we focus on designing a Dynamic Head Importance Computation Mechanism (DHICM) to dynamically calculate the importance of a head with respect to the input. Our insight is to design an additional attention layer together with multi-head attention, and utilize the outputs of the multi-head attention along with the input, to compute the importance for each head. Additionally, we add an extra loss function to prevent the model from assigning same score to all heads, to identify more important heads and improvise performance. We analyzed performance of DHICM for NMT with different languages. Experiments on different datasets show that DHICM outperforms traditional Transformer-based approach by large margin, especially, when less training data is available.

1 Introduction
Transformer based NMT systems perform well on multiple translation tasks (Vaswani et al., 2017). Multi-head attention is a very important component of the Transformer model (Vaswani et al., 2017). Multiple heads improve performance compared to a single head, as they allow the model to jointly look at different subspaces, and hence capture enhanced features from sentences. For example, a head can capture positional information by attending to adjacent tokens, or it can capture syntactic information by attending to tokens in a particular syntactic dependency relation (Voita et al., 2019). However, the performance of the transformer-base model with 8 heads at each layer is only 1 BLEU point higher than that of a similar model with just a single head at each layer (Voita et al., 2019). This is due to the fact that majority of the heads learn similar weights, and therefore, multiple heads attend to the same parts of the input. Hence, most of the heads are redundant, leading to an increased computational complexity without improving performance.

To avoid this redundancy, one approach is to prune the redundant heads based on certain importance score. In this work, we focus on designing an importance computation method to compute the importance score for each head. Some recent work has analyzed the importance of heads by considering average attention weights of each head at some specific position (Voita et al., 2018). However, average of attention weights is a static measure of the head importance as it does not consider the varying importance of each head with respect to the input. The importance of a head is dynamic, as a head can be very important for a particular word, but can be less important for other words. Thus, in this work, we propose a Dynamic Head Importance Computation Mechanism (DHICM) to calculate the importance score for each head, and this can be later utilized to design a pruning strategy. Our key idea is to apply a second level attention on the outputs of all heads, to dynamically calculate the importance score for each head, that varies with the input, while training. We also propose to add a new loss term to prevent our approach from assigning equal importance to all heads.
Note that we apply DHICM for both self attention heads and encoder-decoder attention heads present in the encoder and decoder of the transformer architecture.

To evaluate the performance of our method, we considered multiple translation tasks with different language pairs such as Hindi-English, Belarusian-English, German-English. Results show that DHICM achieves a much higher performance compared to the standard transformer model, particularly, in low-resource conditions where much less training data is available. Moreover, DHICM requires only $\sim d^2$ additional parameters ($d$ is the word embedding dimension), that is much less than the total number of parameters in the transformer base model. The transformer model has a large number of hyperparameters, due to which, it is computationally challenging to search for their optimal values. Thus, much of the previous work used default values of the hyperparameters (Gu et al., 2018; Aharoni et al., 2019). However, these are not guaranteed to yield optimal performance on different datasets. Grid search over all hyperparameters is computationally intensive due to the exponential number of combinations across all possible values. Therefore, in this work, we perform grid search over a subset of hyperparameters, i.e., architecture hyperparameters and regularisation hyperparameters, and experiments show that the hyperparameter values obtained from our method yield significantly better performance compared to the default values. To summarize, our work makes the following major contributions:

- We propose a Dynamic Head Importance Computation Mechanism for transformer based NMT systems, to compute the importance scores for all heads dynamically with respect to an input token.

- We propose to add an additional loss function that helps to compute different attention for different heads, and filter the most important heads.

- Our hyperparameter tuning method yields significantly better performance than the default values.

2 Background

2.1 Single-Head Attention

Given a sequence of $N$ $d$-dimensional vectors $X = (x_1, x_2, ..., x_N)$ and a query vector $y \in \mathbb{R}^d$, a single-head attention is a weighted aggregate of $x_i, i \in \{1, 2, ..., N\}$, followed by a linear transformation. The weights are obtained using a function $F(x_i, q)$ e.g., multi-layer perceptron (Bahdanau et al., 2014) or scaled dot product (Vaswani et al., 2017), and the attention $A_h(X, y|W_v, W_o)$ is computed as $A(X, y) = W_o \sum_{i=1}^{N} F(x_i, y) W_v x_i$, where $W_o$ and $W_v$ are learnable weights. In a transformer based NMT system, there is an encoder and a decoder. The encoder encodes the input sequence of tokens and outputs a sequence of vectors $X$. The decoder uses $X$ to generate a sequence of tokens. If the query vector $y$ is generated using the encoder, then the computed attention is known as self-attention. Whereas if the query vector $y$ is generated from the decoder, then the computed attention is known as encoder-decoder attention.

2.2 Multi-Head Attention

Multi-head attention mechanism runs through multiple single head attention mechanisms in parallel (Vaswani et al., 2017). Let there be a total of $H$ heads, where each head $h \in \{1, 2, ..., H\}$ corresponds to an independent single head attention. The output of each head $A_h(X, y|W_v^h, W_o^h)$ is calculated independently, and the final output of multiple heads is calculated using the outputs of all heads, i.e., $\Sigma_{h=1}^{H} A_h(X, y|W_v^h, W_o^h)$, where, $W_v^h, W_o^h$ are learnable weights for each head $h$.

3 Approach

3.1 Dynamic Head Importance Computation Mechanism (DHICM)

In the traditional transformer model, the output of the multi-head attention is a linear transformation over the concatenation of outputs of all heads. Therefore, the outputs of all heads have equal contribution. However, since all heads are not equally important to the input (Sec. 1), we propose to compute the importance of each head with respect to the input dynamically.

Our idea is that an additional attention layer will allow the model to pay more attention to the head that is more important to the input.
Thus, we design a second level attention that uses the input and output of all heads to compute attention scores, i.e., importance for all the heads with respect to the input, described as follows. Let $x \in \mathbb{R}^d$ be a $d$-dimensional input to the multi-head attention module, and $O^h$ be the output of head $h \in \{1, 2, ..., H\}$ (without applying the linear transformation $W^h$ described in Sections 2.1 and 2.2). We first learn a function $G(x, O^h)$ to determine the attention, i.e., importance score for head $h$. To approximate $G(x, O^h)$, we considered both multi layer perceptron and scaled dot product. In our experiments, we observed that both achieve similar performance, and since scaled dot product requires less number of parameters, we used the latter to compute $G(x, O^h)$:

$$ G(x, O^h) = \frac{\exp(s(x, O^h))}{\sum_{h=1}^{H} \exp(s(x, O^m))} \quad (1) $$

where,

$$ s(x, O^h) = \frac{O^h_T W^T U x}{\sqrt{d_m}} \quad (2) $$

Here, $W \in \mathbb{R}^{d_m \times d_k}, U \in \mathbb{R}^{d_m \times d}$ are learnable parameters, and $d_k, d_m$ are scaling factors for the multi-head attention and second level attention, respectively. We also add a dropout layer (Srivastava et al., 2014) after computing $Ux$ in Equation 2. Next, we compute the output of the second-level attention layer (DHICM) using the attention scores for each head, as follows:

$$ DHICM(x, O) = W_s \sum_{h=1}^{H} G(x, O^h)V O^h \quad (3) $$

where, $O = (O^1, O^2, ..., O^H)$, and $V \in \mathbb{R}^{d_m \times d_m}$ are learnable parameters. The output of the second level attention is then passed to the feed forward network. Note that DHICM learns only $\sim d^2$ additional parameters corresponding to $W, U, W_s, V$ in the second layer added, and this is much less than the total number of parameters in the standard transformer model (typical value of $d$ is 512).

**Objective** Let $L_c$ represent the cross entropy loss that is minimized to ensure that the model generates accurate tokens. However, by only considering $L_c$ as the objective, it might be possible that the model learns equal values of $G(x, O^h)$ for all $h \in \{1, 2, ..., H\}$. This would indicate that all heads are equally important to the input $x$, and thus, prevent us from filtering the most important heads. To avoid this, we add an extra loss term to penalize the model if the value of $G(x, O^h)$ becomes equal for all $h \in \{1, 2, ..., H\}$. More formally, let $a \in R^H$ be a vector representing the importance score of all heads according to the model, where $a_h = G(x, O^h)$ is the importance score of head $h$. Let $b \in R^H$ be a vector representing equal importance of all heads, i.e., $b_h = \frac{1}{H}$, where $H$ is a constant. Both $a$ and $b$ denote the importance distribution of the heads, where $a$ is learned by the model using the second level attention, and $b$ is a uniform distribution with equal importance for all heads. In order to avoid the model from assigning equal importance to all the heads, we maximize the Kullback-Leibler divergence (KL Divergence) between distributions $a$ and $b$. Note that both the distributions sum up to 1, i.e., $\sum_{h=1}^{H} a_h = 1$, and $\sum_{h=1}^{H} b_h = 1$, and that $a_h > 0, b_h > 0$ for all $h \in \{1, 2, ..., H\}$. Specifically, we add an extra loss term $L_{KL}$ as the KL Divergence between $a$ and $b$, given as:

$$ L_{KL}(a||b) = \sum_{h=1}^{H} a_h \ln \frac{a_h}{b_h} \quad (4) $$

The overall loss $L$, where we minimize $L_c$ and maximize $L_{KL}$, is computed as:

$$ L = L_c - \lambda \cdot L_{KL} \quad (5) $$

where $\lambda$ is a hyperparameter used to control the effect of $L_{KL}$ on the overall loss $L$. The objective is to minimize the overall loss $L$.

Table 2: Default and Optimal Hyperparameters

WMT17 (Bojar et al., 2017) shared translation tasks to evaluate the performance of our proposed method. Table 1 reports the number of parallel sentences in training, validation and test splits of different datasets that are considered in our experiments. To compare with (Iida et al., 2019), we used WMT17 De-En training corpus as training set and newstest13 as validation set. Similar to (Iida et al., 2019), we concatenated newstest14 and newstest17 to make one test set. We call this WMT17 dataset with the modified test set as WMT17-CS dataset. To assess the performance of our method for low resource language pairs, we used Hindi-English (Hi-En) parallel corpus obtained from HindEnCorp0.5 (Bojar et al., 2014). Also, we created smaller training sets from the complete IWSLT14 training set. We randomly sampled 10K, 20K, 30K, 40K, 80K, 120K and 160K sentence pairs from the full training data. The validation and test datasets were the same across all training sets. We also evaluated the performance of our method on extremely low resource language pairs. We used Belarusian-English (Be-En) parallel corpus from TED talks (Qi et al., 2018) that contains only 4.5K parallel sentences in the training set. The HindEnCorp0.5 dataset contains 270K sentence pairs, out of which we randomly sampled 7K sentence pairs each for validation and test sets, and used the remaining sentences as the training set. We used moses toolkit (Koehn et al., 2007) to tokenize German, Belarusian and English sentences, and IndicNLP Library\(^1\) to tokenize Hindi sentences. For open-vocabulary translation, we segmented words using byte-pair encoding (BPE)\(^2\) (Sennrich et al., 2015). For Be-En parallel corpus, we learned 5K merge operations for both Be and En separately. For other datasets, we combined the source and target sentences of the training set for learning BPE. We learned 10K merge operations for IWSLT14 dataset, and 20K merge operations for other datasets.

4.2 Hyperparameter Optimization

The transformer model has a large number of hyperparameters, and hence the total number of combinations of possible values for these hyperparameters is exponential. Therefore, although the language pairs are different from the original pairs used to determine the default values, much of the previous work uses the default hyperparameters (e.g., (Gu et al., 2018; Aharoni et al., 2019)). However, different languages have different characteristics, and using the hyperparameters tuned for one language pair, might not yield the optimal performance for another language pair. Furthermore, the amount of data available for training also affects the choice of hyperparameters. Hence, for each language pair, we perform extensive hyperparameter tuning to get better performance. Since there are exponential number of combinations, grid search is computationally very intensive, and random search is not guaranteed to yield optimal hyperparameters. Hence, we perform hyperparameter search using different values for a subset of hyperparameters. We majorly tune on two types of hyper-parameters - architecture hyper-parameters (e.g., number of attention heads, feed-forward dimension), and regularization hyper-parameters (e.g., dropout, attention dropout, activation dropout, label smoothing). The remaining hyper-parameters such as word embedding size, number of layers, for both

\(^1\)IndicNLP Library

\(^2\)https://github.com/rsennrich/subword-nmt
encoder and decoder are set to their default values (similar to (Vaswani et al., 2017)), and kept constant throughout the search. We first tune the architecture hyperparameters and keep the regularization hyperparameters constant with their default values. Next, we tune the regularization hyperparameters using the optimal values for architecture hyperparameters. Since we consider only a small subset of hyperparameters, the number of combinations are not exponential, and hence we are able to use grid search to tune the hyperparameters. The optimal hyperparameters chosen are the ones that correspond to the minimum loss on the validation set. Also, we use early stopping (described in Section 4.3) to prevent our model from overfitting. Although our hyperparameter tuning method does not guarantee a global optimum, we observe a substantial improvement over the default hyperparameters in our experiments (Section 5). The values of default and optimal hyperparameters obtained using our hyperparameter search, are reported in Table 2.

4.3 Experimental Setup and Baselines

We consider the Standard Transformer-base model (Vaswani et al., 2017) as a baseline, and for implementation, we used fairseq toolkit (Ott et al., 2019). We also analyzed the effect of applying our proposed approach DHICM to different layers of both encoder and decoder of the transformer model, and observed that applying the second level attention at the last layer of both encoder and decoder yields the best score.

We refer to the hyperparameters reported in the Standard Transformer-base model (Vaswani et al., 2017) as the Default Hyperparameters, and those obtained using our hyperparameter search described in Section 4.2 are referred to as the Optimal Hyperparameters. We trained all the models on 4 Nvidia GeForce RTX 2080 Ti GPUs. The number of layers of encoder and decoder was set to 6, number of tokens per batch was set to 8000, and the word embedding dimension \(d\) was set to 512. We used Adam optimizer (\(\epsilon = 10^{-6}, \beta_1 = 0.9, \beta_2 = 0.98\)) (Kingma and Ba, 2014) with a learning rate of \(5 \times 10^{-4}\). We used inverse square root learning rate scheduler with 4000 warmup steps, and used beam search with beam size of 5 for generating the sentences. In our proposed approach, we add two additional hyperparameters, that is, \(\lambda\) (described in Section 3.1), and a dropout in the second level attention (described in Section 3.1).

The optimal values for the dropout added are provided in Table 2, and we set \(\lambda\) as 0.1, for all experiments, corresponding to the minimum loss on the validation set. We save model checkpoints after every epoch and select the best checkpoint based on the lowest validation loss. In order to minimize overfitting, we stop training if the validation loss does not decrease for 10 consecutive epochs.

For training the models on smaller, randomly sampled training sets from the full IWSLT14 training set (Sec. 4.1), we used the optimal hyper-parameters learned using the full IWSLT14 training set. We used BLEU (Papineni et al., 2002) as the evaluation metric to compare the performance of our approach with two versions of the baseline model, (i) T-base, which is the Transformer-base model trained using Default hyperparameters, and (ii) T-optimal, which is the Transformer-base model trained using Optimal hyperparameters (Sec. 4.2). Please note that, for all our experiments, the hyperparameters for T-optimal and DHICM are same.

5 Results

Table 3 shows the performance of different methods. We observe that T-optimal outperforms T-base, and this demonstrates that the optimal hyperparameters found in our extensive hyperparameter search yield higher performance compared to the default hyperparameters in (Vaswani et al., 2017). Also, DHICM achieves a higher BLEU score, and outperforms T-optimal on HindEnCorp and WMT17-CS datasets by 3.45 and 1.12 BLEU points, respectively. We also performed experiment on the extremely low resource language pair Be-En, and observed that T-base achieved 4.09 BLEU score, and

T-optimal achieved 5.49 BLEU score. Thus, T-optimal outperformed T-base by 1.4 BLEU points. Moreover, DHICM achieved 6.29 BLEU score, thus outperforming T-optimal by 0.8 BLEU points. We also compared the performance of our method with the multi-hop multi-head attention model (Iida et al., 2019) on WMT17-CS De-En dataset. We observed that DHICM outperforms (Iida et al., 2019) by 1.77 BLEU points.

Table 4 shows the BLEU score achieved by the models trained with smaller training sets that are randomly sampled from full IWSLT 2014 training set. We observe that the performance of all methods increases with an increase in the training set size, and DHICM achieves a much higher performance compared to T-base for all training set sizes. The performance of T-optimal and DHICM is similar for larger datasets, however, for low-resource datasets, our approach outperforms T-optimal by a large margin.

Since the hyperparameters for both T-optimal and DHICM are same, we can see that the gain in the performance of our method is due to the proposed second layer attention over the multi-head attention. In addition, our proposed loss function (Section 3.1) prevents the model from assigning the same importance to all heads. Thus, we are able to filter more important heads.

6 Analysis

Our proposed approach DHICM outperforms T-base and T-optimal by a large margin in the low resource conditions. We further analyzed the performance of the baseline model and DHICM, and observed that DHICM learns better word alignment especially, in low resource conditions. One of the reasons for learning better alignment can be that for each word, all heads are not equally important. The second level attention that we designed in our model allows the tokens to pay more attention to the heads that capture more relevant information for translation. Since the heads that are more relevant receive more attention, the parts of the input to which these heads attend, in turn receive more attention, and thus, the alignment becomes better. For example, providing more attention to the heads that capture the syntactic or semantic information, and relatively less attention to the heads that capture positional information. This justifies our hypothesis mentioned in Section 3.1.

We also verified this using the encoder-decoder attention distribution of the models shown in Figure 1 (low resource conditions) and Figure 2 (high resource conditions). The decoder of the transformer model uses the outputs of the encoder to generate the tokens in the target language. Each generated token pays some attention to each token in the source language. The attention distribution matrix shows the attention paid by the generated tokens in the target sentence (rows) to the tokens in the source sentence (columns). In Figure 1a and Figure 2a, we can see that most of the tokens on the source side get similar attention for the baseline approach. Moreover, the highest attention a source token receives is approximately 0.12 and 0.5 in Figure 1a and Figure 2a, respectively. This implies that the most important source token for translation does not receive enough attention, resulting in a poor word alignment. On the contrary, for DHICM (Figure 1b and Figure 2b), we observe a large variance in the distribution of the attention paid by a target token to the source tokens. Thus, more appropriate source tokens receive higher attention scores (∼0.8) in DHICM, leading to a better word alignment, as shown in both Figure 1b and Figure 2b. Also when 160K training sentences are used for IWSLT14, although the performance of the baseline and DHICM is similar, DHICM learns better word alignments compared to the baseline (shown in Figure 2), as DHICM helps the model to pay more attention to more relevant source tokens. Moreover, DHICM allows the model to pay higher attention (∼0.8) to the appropriate source words compared to the baseline model where highest attention received by a source token is ∼0.5. This shows that for both low resource and high resource conditions, DHICM helps the model to pay higher
attention to the more relevant source tokens.

We also analysed the additional attention layer introduced in DHICM. We compute the attention paid by each token to each head. Using the second level attention, we compute the attention paid by a particular token to all the heads and plot the attention values to create an attention distribution matrix. Figure 3 shows the attention distribution for the second level attention added on top of the multi-head self attention in the last layer of the encoder. The attention distribution matrix shows the attention paid by each source token (rows) to all the 4 heads (columns). The distribution shows that each token pays different amount of attention to each head, and this justifies our hypothesis that all heads are not equally important. Also, different tokens pay different amount of attention to a particular head, which also supports our hypothesis that the importance of a head is dynamic in nature, i.e., it varies as the input token changes. The attention distribution matrix also shows that the additional loss term indeed allows the model to compute different importance scores for different heads. In Figure 3, we can see that the second head gets the least attention from all the tokens. This shows that our proposed method identifies the least important heads, and thus, by incorporating DHICM, an appropriate pruning strategy can be developed to prune the least important heads.

7 Related Work

Some recent work has shown that most of the heads in a multi-head attention model become
redundant during test time (Michel et al., 2019). (Voita et al., 2018, 2019) analyzed the heads in a multi-head attention model, based on some importance score that is calculated after the model is fully trained. In contrast, in this work, we propose to calculate the importance scores dynamically while training.

A recent work (Iida et al., 2019) proposed to apply attention on top of the output of multi-head attention. However, they apply an additional attention layer only on the encoder, whereas, in our proposed method, we apply the second level attention on both encoder and decoder, that helps the generated target words to pay significant attention to appropriate source words, which in turn enhances the encoder-decoder attention distribution as shown in Figure 1b. Moreover, their proposed approach might learn equal attention weights for the additional attention layer, which would make all the heads equally important. In such a case, their approach would perform similar to transformer base model, even after adding more number of parameters compared to the standard transformer. To address this, we add an extra loss term in our method, to penalize for learning similar weights for the second level attention. This helps our method to compute different importance scores for different heads. Furthermore, during the calculation of the final attention, they transform the output of each head using a different transformation matrix for each head, while our proposed approach DHICM uses a single transformation matrix for the outputs of all heads. Thus, DHICM learns much fewer number of parameters in addition to achieving greater performance (the number of additional parameters learned in their approach is 550K, whereas DHICM learns 500K additional parameters).

8 Conclusion and Future Work

In this work, we proposed an effective Dynamic Head Importance Computation Mechanism (DHICM) to dynamically calculate the importance of different heads during training. Our idea is to calculate the importance with an additional attention layer along with the standard multi-head attention. We also proposed a loss function to prevent our method from computing equal importance for all heads, which together with the second-level attention facilitates to dynamically identify heads that are most important to the input word. Thus, the target words generated pay significantly high attention to the more appropriate/relevant source words. We also performed extensive hyperparameter tuning on a subset of hyperparameters, and observed that the optimal hyper-parameters obtained from our search yield a much higher BLEU score compared to the default hyper-parameters. Experiments on multiple translation tasks show that DHICM outperforms the standard transformer model by a large margin, especially in low resource settings. In the future, we will use the importance scores of the heads computed using DHICM and implement a strategy for pruning the less important heads. We would also like to explore further in the direction of reducing redundancy in multi-head attention.

Abstract

In this paper, we attempt to improve upon the state-of-the-art in predicting a novel’s success by modeling the lexical semantic relationships of its contents. We created the largest dataset used in such a project containing lexical data from 17,962 books from Project Gutenberg. We utilized domain specific feature reduction techniques to implement the most accurate models to date for predicting book success, with our best model achieving an average accuracy of 94.0%. By analyzing the model parameters, we extracted the successful semantic relationships from books of 12 different genres. We finally mapped those semantic relations to a set of themes, as defined in Roget’s Thesaurus and discovered the themes that successful books of a given genre prioritize. At the end of the paper, we further showed that our model demonstrate similar performance for book success prediction even when Goodreads rating was used instead of download count to measure success.

1 Introduction

Since its publication in 1868, approximately 1.78 million copies of Louisa May Alcott’s Little Women have been sold, which equates to about 1,000 copies a month for 152 years. Every publisher in the industry hopes to find a manuscript that can sell even 10,000 copies in its lifetime. This begs the question: what makes Little Women a timeless success? Recently, researchers have attempted to use machine learning and natural language processing to answer this question, among others.

Predicting the success of a novel by analyzing its content is a challenging research problem. Thousands of new books are published every year, and only a fraction of them achieve wide popularity. Therefore, the ability to predict a book’s success prior to publication would be exceptionally useful to the publishing industry and enable editors to make better decisions. Many factors contribute to a book’s success including, but not limited to plot, setting, character development, etc. Additionally, there are some other factors that contribute to a book’s popularity that an author and publisher cannot control like the time when a book is published, the author’s reputation, and the marketing strategy. In this paper, we only focus on the content of the book to predict its popularity.

In this paper, we explore whether novels in a spe-
cific genre have certain dominant themes in common based on stylometric features, and if so, what meaning we can attribute to those themes as it relates to a book’s success. To attain this objective, we investigated ways to enable using the entire book’s content for stylistic modeling using frequencies of lexical production rules of CFGs for each novel (see Figure 1) followed by semantic word association of those rules to Roget’s Categories and Themes for better interpretation. In this work, we followed widely used feature reduction technique for SVM modeling to reduce the large lexical feature space for lengthy novels and experiment with different techniques using POS, Unigram, WordNet, and lexical production rules. In this article we present the following contributions:

- We built the largest dataset containing a total of 17,962 books. We included books from 4 additional genres and reclassified 2 of the genres included in (Ashok et al., 2013) as follows: Mystery→Detective; Love→Romance.

- We introduced our feature reduction methods to greatly improve prediction performance with our best model achieving 94% accuracy for success prediction.

- We mapped both WordNet’s semantic word relations and context free grammar rules to a set of themes, as defined in Roget’s Thesaurus. With these mappings, we discovered the themes that successful books of a given genre prioritize.

2 Related Works

Roget’s Thesaurus is a widely used English-language thesaurus. A British lexicographer, Peter Mark Roget (1779–1869), created the thesaurus in 1805. The first version of the thesaurus comprised of nearly 15,000 words and was released to the public on 29 April 1852 (Roget and Roget, 1886). Since then each successive edition was improved with more words, with the most recent edition containing more than 100,000 words. In previous work, Jarmasz and Szpakowicz (2004) showed that Roget’s is an excellent resource for measuring semantic similarity and Roget’s word clusters have higher correlation than many other prominent word groups e.g., Wordnet (Miller, 1998; Jarmasz, 2012).

Syntactic features, such as CFG productions have been found to be very effective in different NLP tasks. Raghavan et al. (2010) used CFGs for authorship attribution achieving very high accuracy such as 96%. Rayson et al. (2002) presented systematic analyses based on lexical and syntactic features for genre detection of a literary works showing that novels involve more use of verbs and adverbs. On the other hand, Douglas and Brussard (2000) showed that informative writing tend to use nouns, prepositions, determiners and coordinating conjunctions more. CFGs were also used in several other works, such as gender attribution by tracing stylometric evidence by (Sarawgi et al., 2011), and native language detection by exploiting parse structures (Wang and Zong, 2011).

In the earlier work, Ashok et al. (2013) used stylistic approaches, such as unigram, bigram, part-of-speech distribution, grammatical rules, constituents, sentiment, and connotation as features and used Liblinear SVM (Fan et al., 2008) for the book success classification task. They used books from 8 genres, and they were able to achieve an average accuracy of 73.5% across all genres. Maharjan et al. (2017) used a set of hand-crafted features in combination with a recurrent neural network and generated feature representation to predict success. They obtained an average F1-score of 73.5% for 8 genres. In a more recent work by Maharjan et al. (2018a), they used the flow of emotion throughout a book for success prediction and obtained an F1-score of 69%.

In this paper, we used widely used feature reduction technique for SVM modeling. Guyon et al. (2002) used SVM weights for assigning ranks in the feature selection process. They verified that the top-ranked genes found by SVM have biological relevance to cancer and the SVM classifier with SVM selected features worked better than other classifiers in determining the relevant features along with the classification task.

3 Dataset Construction

3.1 Original Dataset

The original dataset from Ashok et al. (2013) is quite small as it only includes the first 1,000 sentences from 800 books split into 8 different genres, which are further split into successful and unsuccessful classes, each having 50 books. Additionally, many of the files included have less than 1,000 sentences, or contain automatically generated text from Project Gutenberg instead of the text from the proper novel. Finally, the books included are prelabeled with their successful/unsuccessful class.
where download counts are absent, which limits further testing. Considering these issues, we decided to build upon (Ashok et al., 2013) by creating a cleaner and more complete dataset. Additionally, we present multiple models that are both more accurate and more general than the best performing model in (Ashok et al., 2013), unigram. From these models, we discovered more interesting and revealing qualities that separate successful from non-successful books.

3.2 New Dataset

We downloaded and used 17,962 English novels from Project Gutenberg: an online catalog of over 60,000 books, which are available to download for free in various formats (Gutenberg). We filtered the 60k books as follows: a) only English books, and b) only fiction books. We used a bash script\(^1\) to harvest the novels from Project Gutenberg according to the webmaster’s guidelines\(^2\).

After downloading the books, we used the NLTK API for data processing (Bird et al., 2009). For each book, we extracted the unigram and bigram frequencies, the part-of-speech (POS) tag using the Stanford CoreNLPParser frequencies, the lexical and non-lexical context free grammar production rules also using the Stanford CoreNLPParser, the Roget’s Thesaurus Category frequencies, and the WordNet Synset frequencies (Roget, 1852; Prince-

We utilized 12 linguistic models for our quantitative analysis. 6 of the models are our own implementation of models used in (Ashok et al., 2013). Our 6 additional models have not been used to make these types of qualitative conclusions until now. These models include WordNet (Princeton University, 2010), Roget’s Thesaurus (Roget, 1852), two models that map WordNet to different levels of Roget’s Thesaurus, and two models that map context free grammar rules to Roget’s Thesaurus. Mapping examples are given in Table 2 and explained below.

\end{table}

4 Methodology

4.1 Linguistic Models

We utilized 12 linguistic models for our quantitative analysis. 6 of the models are our own implementation of models used in (Ashok et al., 2013). Our 6 additional models have not been used to make these types of qualitative conclusions until now. These models include WordNet (Princeton University, 2010), Roget’s Thesaurus (Roget, 1852), two models that map WordNet to different levels of Roget’s Thesaurus, and two models that map context free grammar rules to Roget’s Thesaurus. Mapping examples are given in Table 2 and explained below.

**Unigram:** The frequency of unique words in text.

**Part-of-Speech Distribution:** The authors of Ashok et al. (2013) demonstrated the value of PoS tag distribution in success prediction, and Koppel et al. (2006) presented the relationship between PoS tagging and genre detection and authorship attribution. Therefore, we reevaluated the application of PoS tag distribution for success prediction.

**Context Free Grammar Rule Distribution:** We also reevaluate the analysis of CFG rule distribution as presented in (Ashok et al., 2013), and use the same four categories:

- \(\Gamma\): lexical production rules (productions where the right-hand symbol (RHS) is a terminal symbol (word)).
Table 2: Mapping to Roget examples for WordNet and $Γ^G$. For each model, the **ORIGINAL FEATURES** are combined in the **ROGET CATEGORY** column, which in turn is combined in the **ROGET THEME** column.

<table>
<thead>
<tr>
<th>Model</th>
<th>Original Feature</th>
<th>Roget Category</th>
<th>Roget Theme</th>
</tr>
</thead>
<tbody>
<tr>
<td>WordNet</td>
<td>blaze, glitter, sunny light</td>
<td>Nom$\rightarrow$Adj$\rightarrow$life</td>
<td>Organic Matter</td>
</tr>
<tr>
<td>$Γ^G$</td>
<td>Nom$\rightarrow$Adj$\rightarrow$bad Nom$\rightarrow$Adj$\rightarrow$illegal Nom$\rightarrow$Adj$\rightarrow$lawful Nom$\rightarrow$Adj$\rightarrow$unconstitutional</td>
<td>Nom$\rightarrow$Adj$\rightarrow$wrong Nom$\rightarrow$Adj$\rightarrow$wrong Nom$\rightarrow$Adj$\rightarrow$wrong Nom$\rightarrow$Adj$\rightarrow$wrong</td>
<td>Nom$\rightarrow$Adj$\rightarrow$Moral</td>
</tr>
</tbody>
</table>

- **$Γ^G$**: lexical production rules prepended with the grandparent node.
- **$γ$**: nonlexical production rules (productions where the RHS is a non-terminal symbol).
- **$γ^G$**: nonlexical production rules prepended with the grandparent node.

**WordNet**: WordNet is large lexical database of English words. The WordNet database groups nouns, verbs, adjectives, and adverbs into sets of cognitive synonyms called Synsets. Each Synset expresses a distinct concept and is represented by a single word. Since Synsets represent conceptual synonyms, they are able to be linked through conceptual and semantic relationships (Princeton University, 2010). WordNet has a total of 117,659 Synsets, each represented by a single, unique word, and our model uses the frequencies of these Synsets in each book. Not only does WordNet fit our semantic relation analysis methodology, but it has been used for the relevant task of metaphor identification in (Mao et al., 2018).

**Roget’s Thesaurus**: A tree structured thesaurus with six root nodes, which we will refer to as Roget Classes or Classes for short. Each Class is divided in sections, which results in 23 total sections. These sections represent 23 unique concepts that are both general enough to encompass a wide range of ideas, but also specific enough to retain clear meaning. Therefore, we refer to these sections as Themes, and they are the critical piece to interpreting the results of class prediction. Themes are further divided into subsections, levels, etc. before terminating in 1,039 groups of synonyms, which we will refer to as Categories. The Categories are comprised of 56,769 total words, with about half appearing in multiple Categories (Roget, 1852). Our Roget model uses the frequencies of these Categories in each book. Furthermore, the authors of (Aman and Szpakowicz, 2008) demonstrated the possible applications of Roget’s Thesaurus for emotion detection with natural language processing, and (Kennedy and Szpakowicz, 2010) used the thesaurus for the related process of text summarizing.

**Mapping WordNet to Roget**: Since Roget’s Thesaurus has fewer synonym groups than WordNet (1,039 vs. 117,659), and those groups are hierarchically abstracted with each of the 1,039 Roget Categories belonging to one of the 23 Roget Themes, we mapped WordNet’s Synsets to Roget’s Thesaurus to discover more meaningful insights into the distinct characteristics of successful novels. We mapped WordNet to Roget Categories (WNRC), and then subsequently to Roget Themes (WNRT).

**Mapping Lexical Production Rules to Roget**: Since the RHS of lexical production rules are words, they can also be mapped to Roget’s Thesaurus. Using the RHS of the lexical production rules for each book we derived $Γ^G$ to Roget Categories ($Γ^G$RC) and subsequently to Roget Themes ($Γ^G$RT).

### 4.2 Implementation

We used the sci-kit learn implementation of LibLinear SVM with 5-fold cross validation for class prediction (Pedregosa et al., 2011; Fan et al., 2008). To tune the weighted linear SVM parameter C, we used the tool gridsearchCV (Pedregosa et al., 2011) and performed a search over the values ranging $1e(-4to3)$. Part-of-speech tag features are scaled with unit normalization, while all other features are scaled using tf-idf. We used two strategies for the class prediction task: predicting class by genre and predicting class independent of genre. We chose this model over neural models as it gives us better scope to interpret book success with hand crafted features. After the initial training and testing of each model, we employed an exhaustive feature reduction method, similar to our success labeling process, to maximize performance (see Figure 2).

For a given model, we start with the mean feature weight learned during training. We remove all features from the dataset with $|weight|$ less than the $|mean|$ feature weight. Next, we train and test the model on this reduced fea-
Figure 2: Feature reduction process: WordNet success prediction accuracy vs. number of features.

The prediction accuracy for each model across all books, and each model by genre, both before and after feature reduction are shown in Table 4 and Table 5, respectively. As illustrated in both settings, the performance of nearly every model improved after we reduced the features with $\gamma^G$ showing the largest improvement of an average of 24.3% when reduced by genre and WordNet improving the most by 16.1% when reduced independent of genre.

The best performing models are indicated in bold.

Table 4: Accuracy of prediction model for ALL BOOKS of new dataset, with original and optimal reduced feature set ($R$).

models were overfitting the dataset. This observation further motivated us to build a much larger dataset. For the classification task on newly constructed dataset, we applied the 5-fold cross validation method on all the genre specific datasets for evaluating each machine learning model. While for the feature reduction task, features were reduced using training weights from the training set, then tested on the test set. We had continued reducing the training set until the resulting features did not improve performance on the remaining test set.

5 Experimental Results

Using the original small dataset (Ashok et al., 2013), the prediction accuracy for each model by genre is presented in Table 8 at Appendix A1, and highlights another primary reason for increasing the size of the dataset. As each of the models was found to be achieving 100% accuracy in success prediction, we were convinced that those
ture set and record the accuracy. For each subsequent test, starting at a step value of 0.25, we take only the features with weights greater than or equal to $Mean(OriginalWeights) + (StdDev(OriginalWeights) * Step)$. This process continues, increasing the step value by 0.25 after each iteration, until one of the following conditions is met: 100% classification accuracy is achieved, maximum accuracy is found (determined if multiple consecutive subsequent feature sets produce decreasing performance), or the number of features is reduced to less than 1% of the original number of features. Additionally, as explained previously, the processes of mapping WordNet to Roget’s Thesaurus is a feature reduction technique in its own right. Table 3 illustrates the degree of feature reduction when WordNet and $\Gamma^G$ are mapped.

Table 3: Number of features of ADVENTURE books before/after reduction for WordNet and $\Gamma^G$ models.
6 Interpreting Book Success Prediction

While our reduced $\Gamma^G$ and WordNet models display excellent performance in both test settings (by genre and independent of genre), the resulting feature sets are not self-explanatory. In other words, the respective lexical production rules and Synsets that the models deem most important do not necessarily highlight some interesting aspect of successful books. This is where Roget’s Thesaurus proves most valuable.

We figured that if we looked up the Roget Theme of the RHS for each lexical production rule and the Roget Theme for each WordNet Synset we would find that the successful and unsuccessful books prioritize different Themes. With this hypothesis in mind, we mapped the reduced WordNet and reduced $\Gamma^G$ models to new $\Gamma^{GR}$ models by first looking up the Roget Category of each Synset and RHS, respectively, from the reduced feature sets, and then summing the frequencies in each group of Synsets/symbols. As we did with each previous model, we reduced the new WNRC and $\Gamma^{GR}$ models we mapped again, this time from $\Gamma^{GR}$ produced the highest accuracy for each genre except DETECTIVE. For DETECTIVE novels, $\gamma^{GR}$ outperforms all models with 100% accuracy.

Figure 2 illustrates the pattern of performance improvement that each model exhibits through the feature reduction process both by genre and independent of genre. As the number of features is reduced, the average accuracy for success prediction increases until the algorithm finds the best set of features and achieves peak performance. Then accuracy sharply drops as the feature set is reduced further. The fact that each model demonstrates such behavior validates the effectiveness of our feature reduction method.

</table>

In Table 4 and Table 5. When predicting novel success by genre and independent of genre, $\Gamma^{GR}$ shows the best results predicting a book’s success class with an accuracy of 94.0% and 80.1%, respectively. Furthermore, when predicting success by genre, $\Gamma^{GR}$ achieves the highest accuracy for each genre except DETECTIVE. For DETECTIVE novels, $\gamma^{GR}$ outperforms all models with 100% accuracy.

We figured that if we looked up the Roget Theme of the RHS for each lexical production rule and the Roget Theme for each WordNet Synset we would find that the successful and unsuccessful books prioritize different Themes. With this hypothesis in mind, we mapped the reduced WordNet and reduced $\Gamma^G$ models to new $\Gamma^{GR}$ models by first looking up the Roget Category of each Synset and RHS, respectively, from the reduced feature sets, and then summing the frequencies in each group of Synsets/symbols. As we did with each previous model, we reduced the new WNRC and $\Gamma^{GR}$ models. From the WNRC and $\Gamma^{GR}$ models we mapped again, this time from Roget Categories to the 23 Roget Themes, which produced the WNRT and $\Gamma^{GR}$ models. Mapping examples are given in Table 2 and its outcome is detailed in the Figure 3.

We did not expect the performance of the WNRC and $\Gamma^{GR}$ models, since they were conceived strictly as intermediary maps between WordNet/$\Gamma^G$ and Roget Themes. $\Gamma^{GR}$ produced the highest baseline results of all the models without any feature reduction used in our experiments with 81.9% average accuracy by genre. Furthermore, $\Gamma^{GR}$ accurately predicts success classification per genre.
at an average rate of 88.4%. What’s impressive about the accuracy of \(\Gamma^{GRCR}\), when compared to that of \(\Gamma^G\), is the large difference in number of features used in each model as shown when predicting DETECTIVE novels in Table 3.

With these impressive results from \(\Gamma^{GRCR}\), we expected \(\Gamma^{GRRT}\) and \(\Gamma^{GRT}\) to follow suit despite learning with a feature set of at most 13 features. However, this was not the case as \(\Gamma^{GRRT}\) predicts the success of a book by its genre with an average accuracy of only 69.9%. As previously stated, the motivation for the construction of WNRT and \(\Gamma^{GRRT}\) was strictly to find a common thread between successful novels in each genre. Therefore, the poor performance of the WNRT and \(\Gamma^{GRRT}\) models does not undercut the reasoning behind its conception, and the high accuracy of WordNet, WNRCR, \(\Gamma^G\), and \(\Gamma^{GRCR}\) supports our claim that each is a general model that can reveal underlying characteristics of successful books.

Additionally, WNRT and \(\Gamma^{GRRT}\) do not improve performance after feature reduction when classifying independent of genre. This outcome also supports our original hypothesis as it shows that the models require each of the 23 Roget Themes in order to make the most accurate prediction. The lack of improvement in WNTR and \(\Gamma^{GRRT}\) when predicting success class independent of genre also demonstrates the relationship between a novel’s genre and its prioritization of certain Themes.

### 6.1 Successful Categories and Themes for a Genre

Figure 4 illustrates the top 30 discriminative positive and negative Roget Categories based on the model weights for CHILDREN’s book success prediction. Greener Categories are positively weighted for success while redder Categories are negatively weighted. Specifically, we see positive weights for Themes of “Formation of Ideas” and “Related to Space.” These Themes align with what readers should expect from CHILDREN’s stories: developing new ideas (Formation of Ideas) as a character grows and has new experiences in the physical world around them (Related to Space). It’s interesting however that “Communication of Ideas” shows negative weight for this genre. This suggests that CHILDREN’s stories are more concerned with how a person grows and develops their own ideas, rather than how they communicate them. This pattern of the prioritization of expected Themes holds true across all genres, with few exceptions. Therefore, we can conclude that lexical choices focusing on Themes that conform to genre norms produce more successful novels.

Figure 3: This heatmap presents how the mapping of \(\Gamma^G\) to \(RT\) helps to interpret success of ADVENTURE books. The plot presents both +ve/-ve Roget Themes on the row, and successful/unsuccessful books on the column. Each cell represents the relative frequency of observing \(\Gamma^G\) in an \(RT\). We observe that authors of successful books used certain CFGs that result in higher frequency in +ve RT cells, while the unsuccessful books have higher frequency in the -ve RT cells.

Figure 4: This sunburst presents a comprehensive review of the most discriminative Roget Category/Classes based on the classification model weight for a single genre, CHILDREN. We have considered top 30 discriminative features for both successful (Green) and unsuccessful books (Red).
6.2 Thematic Analysis Based on Lexical Choices

After mapping the resulting feature weights of our WordNet\textsuperscript{R$^R$} and \textsuperscript{GR} models to Roget Themes, we were able to highlight the most important Themes when classifying the success of a novel given its genre. Table 6 gives the most important themes in predicting the success of CHILDREN’S novels and the successful and unsuccessful semantic word groups within those themes. These results clearly identify words associated with "school" and "grammar" as key contributors to unsuccessful CHILDREN’S novels, while words like "secret," "enthusiastic," and "selfishness" contribute to successful CHILDREN’S novels.

The indicated Themes align with intuitive expectations for CHILDREN’S books, especially the presence of FORMATION OF IDEAS and MORAL. To verify these results, we looked at the most downloaded CHILDREN’S book, *Little Women*. We ranked each book in the CHILDREN’S genre according to the frequency of each prioritized Theme listed in Table 7. Then, we looked to see where *Little Women* ranked for each of the Themes. *Little Women*’s use of the top Themes matches up as expected, as it ranks in the top three for four of the five most important Themes, and eighth for the fifth as shown in Table 7. The opposite is true for the least downloaded books, which all rank at the bottom for use of the most important Themes.

Our Thematic observations hold true for each genre, but there is not one Theme shared by all 12 genres. This adheres to the observation we made about WNRT and \textsuperscript{GR} and each model’s lack of improvement after feature reduction for predicting success across all books independent of genre.

7 Experiments with Goodreads Rating

The discoveries made in our research are just the beginning of what can be done with our dataset. In addition to the data utilized for this project, we also extracted Goodreads Rating\textsuperscript{3} as proposed in

\begin{table}[h]
\centering
\begin{tabular}{|l|l|l|}
\hline
\textbf{Theme} & \textbf{Successful} & \textbf{Unsuccessful} \\
\hline
Affections & enthusiastic, lively, tenderness & inactive, sluggish, dull \\
Communication of Ideas & secret, untruth, language & school, grammar, taciturnity \\
Formation of Ideas & incredulity, impossibility, curiosity & dissent, sanity, memory \\
Moral & glutony, impurity, selfishness & punishment, virtue, duty \\
Personal & expecting, blemish, hopelessness & aggravation, dejection, dullness \\
\hline
\end{tabular}
\caption{Top 5 most important Themes for classifying CHILDREN novels and corresponding most predictive successful/unsuccessful thematic words}
\end{table}

Table 7: Ranking the use of the most important CHILDREN’S themes for #1 downloaded CHILDREN’S book, *Little Women* relative to other CHILDREN’S books in the dataset (Maharjan et al., 2019). We could collect the rating for 7,541 books from a total of 17,962 books scraped from Project Gutenberg, where each book has been rated by at least 5 readers. We labeled all the books having average rating $\geq 3.5$ as successful, and $< 3.5$ as unsuccessful (presented in Table 10 at Appendix A2). In Appendix A1, Table 9 demonstrates the performances of previous and our models, respectively. When predicting novel success by genre, \textsuperscript{GR} shows the best results predicting a book’s success class with an average weighted F1-score of 92.2% outperforming previous state-of-the-art results (75% for the genre attention with RNN method (Maharjan et al., 2018b)) as well. This result validates the applicability of our proposed model for book success prediction.

8 Conclusion

We created the largest dataset for evaluating book success, and presented a novel study of how context free grammar rules and semantic word association of influence a book’s success. Our empirical results demonstrate that our large dataset combined with our feature reduction technique can predict a book’s success with better accuracy than the current state-of-the-art methods. The analysis performed in this project shows the relationship between thematic word groups and a book’s popularity, with our best model that uses context free grammar lexical production rules (\textsuperscript{GR}) achieving a prediction accuracy of 94.0%. Finally, we illustrated that readers expect certain themes to be prioritized over others based on a book’s genre, and the proper use of those themes directly contributes to a book’s popularity.

Abstract

Recent research in opinion mining proposed word embedding-based topic modeling methods that provide superior coherence compared to traditional topic modeling. In this paper, we demonstrate how these methods can be used to display correlated topic models on social media texts using SocialVisTUM, our proposed interactive visualization toolkit. It displays a graph with topics as nodes and their correlations as edges. Further details are displayed interactively to support the exploration of large text collections, e.g., representative words and sentences of topics, topic and sentiment distributions, hierarchical topic clustering, and customizable, predefined topic labels. The toolkit optimizes automatically on custom data for optimal coherence. We show a working instance of the toolkit on data crawled from English social media discussions about organic food consumption. The visualization confirms findings of a qualitative consumer research study. SocialVisTUM and its training procedures are accessible online\(^1\).

1 Introduction

Web sources, such as social networks, internet forums, and customer reviews from online shops, provide large amounts of unstructured text data. Along with the steady development of new platforms and the increasing number of internet users, the interest in methods that automatically extract the expressed opinions along with the corresponding topics and sentiments in text data has increased in recent years. Scholars and organizations from different fields can utilize such methods to identify patterns and generate new insights. Examples are opinion researchers investigating current opinions on political and societal issues, consumer researchers interested in consumers’ beliefs about the consumption and production of goods (Danner et al., 2020), and marketing managers curious about the public perception of their products and services (Berger et al., 2020; Murphy et al., 2014). (Kirchhoff, 2019)

These domain-specific use cases are of interest for research disciplines which taken by itself are not directly related to natural language processing (NLP). Consequentially, there is a constant need to provide state-of-the-art NLP methods such that domain researchers from other fields can take advantage of them. The requirements therefore are simple usage, automatic hyperparameter optimization, minimal effort for manual labeling of text data, and built-in visualizations to give an abstract overview of the discussed topics and their relation

\(^1\)https://github.com/ghagerer/SocialVisTum

---

Figure 1: SocialVisTUM applied to our use case organic food - The topics, their occurrence (in brackets) and respective correlations.
with each other.

While these practical requirements are important for domain experts, modern opinion mining approaches target specific machine learning objectives. Recently, there is a trend towards unsupervised neural methods for opinion target detection. Attention-based aspect extraction (ABAE) enables clustering of short review texts with significantly higher coherence as traditional LDA-based topic modeling, and it gives 70% F1 score for classification (He et al., 2017). This is improved recently (Karamanolakis et al., 2019; Angelidis and Lapata, 2018; Luo et al., 2019), which underlines the recent impact and potential of related techniques.

However, these have not been utilized for visualizations based on correlated topic modeling (Blei and Lafferty, 2006), where all pairs of topics “are” analyzed to determine if two topics generally tend to occur in the same texts of a given dataset. Thus, the similarity between topics can be defined. This is successfully used to connect topics (nodes) among each other based on their correlations (edges) leading to more abstract and more meaningful meta topics (graph-clusters) which additionally improves topic coherence. Consequently, these meta topics, e.g., company-related events or research sub-disciplines (Liu et al., 2014; Maiya and Rolfe, 2014), can be successfully identified by graph-based visualization techniques. However, there is a lack of related prototypes on texts discussing consumption related issues in product reviews or social media. To the best of our knowledge, there is also no related integration of sentiment analysis into a system available for potential end users, i.e., domain experts. As according text data from customers is available on a large scale in social media, this can be considered as a shortcoming in the field.

To address all denoted issues, we propose the SocialVisTUM toolkit, a new visualization and labeling tool to give users a comprehensible overview of the topics discussed in social media texts. It integrates a neural method for unsupervised sentence and comment clustering based on word vectors and attention. We denote the respective clusters as topics hereafter. In addition, we provide a graph-based visualization showing the topics as labeled nodes and the correlation between them as edges. A force-directed graph layout maintains readability even while many relevant topics and topic relations are displayed. (Kirchhoff, 2019)

In our interactive graphical user interface, the number of topics displayed and the correlation threshold required to display a connection between two topics can be dynamically adjusted. Further, contextual topic information is provided, such as the number of respective topic occurrences in the social media texts as node diameter, the correlation between the topic occurrences as edge width, example sentences from the data for each topic, a list of representative words for each topic, and the regarding sentiment distribution of a topic. It is a common practice to represent topics merely by word lists (Blei et al., 2003; Chen et al., 2014), which tend to be insufficient to comprehensively express a topic on our given dataset. (Kirchhoff, 2019)

To avoid manual labeling and to give users an immediate impression of each topic, topic labels are generated automatically based on a custom algorithm utilizing the most common WordNet hypernym in a topic’s top words. Furthermore, we find that topic hypernym statistics can serve as a metric for automatic hyperparameter optimization, which in our case gives practical advantages over widely used coherence scoring metrics.

In addition to a more detailed description of our SocialVisTUM toolkit, we show the results of a case study based on social media texts from online commenters debating about organic food consumption. We demonstrate that the correlated topics give a meaningful graph representation of the social media discussions supporting the understanding of the concerns of consumers. In this regard, we also show how the combined illustration of different types of relevant topic and sentiment information and automatic labeling of clusters are a contribution.

2 Related Work

Correlated topic models were introduced 2006 (Blei and Lafferty, 2006; Li and McCallum, 2006) to improve topic coherence and to provide graph visualizations based on topics as nodes and their correlations as edges. This shows potential to improve text mining for the end user as “powerful means of exploring, characterizing, and summarizing large collections of unstructured text documents” (Maiya and Rolfe, 2014). Meta topics, such as research domains and their inter-disciplinary overlaps, can thus be described clearly, automatically, and empirically (Blei and Lafferty, 2007).

These correlated topic models are applied for
more sophisticated visualization approaches. TopicPanorama models technology-related topics from various text corpora, including newspaper articles, blogs, and tweets (Liu et al., 2014). Here, the domain expert is given the option to interactively modify the matching result of the labeled topic graph. Another topic visualization called topic similarity networks is particularly addressing the visualization of large document sets (Maiya and Rolfe, 2014). While claiming good scalability regarding the number of documents, beneficial methods to achieve automatic topic labeling are successfully quantified. TopicAtlas provides a graphical user interface to explore text networks, such as hyperlinked webpages and academic citation networks. For manual mining purposes, topic models are generated and related to one another to facilitate manual navigation and finding of relevant documents (He et al., 2016). These examples show a steady, meaningful, and promising development regarding the visualization of correlated topic modeling, partially also applied to social media texts such as micro-blogs. However, these examples do not include sentiment analysis as means to conduct market research and quantify customer satisfaction in specific and not yet explored market domains. Furthermore, the widely used latent Dirichlet allocation (LDA) technique tends to be incoherent on short texts, such as, product reviews or social media comments, and thus insufficient to detect opinion targets in an unsupervised manner (He et al., 2017).

Automatic topic coherence optimization can be seen as desirable for a topic modeling visualization toolkit such as SocialVisTUM, which tries to minimize manual optimization efforts for non-technical users. Therefore, we refer to two widely used coherence definitions (Ghosh, 2020). Firstly, word co-occurrence-based methods measure how often pairs of representative topic words co-occur in the training data set or in an external reference data set. In that regard, it has been shown that the evaluation methods UMass, UCI and NPMI correlate with human judges (Stevens et al., 2012; Newman et al., 2010; Mimno et al., 2011; Bouma, 2009; Ding et al., 2018) and are considered to be a default metric for topic coherence. Secondly, word embedding similarity based coherence scores are recently utilized as these are also based on word co-occurrence statistics (Pennington et al., 2014) and behave similar to NPMI coherence scoring (Ding et al., 2018), resulting in high correlation with human perception. These methodologies show the undesirable effect of no distinct local optimum when the hyperparameters of the models are changed, e.g., number of clusters or vocabulary size. On our data, these parameters increase together with the coherence scores, while the subjective performance, i.e., the human perception, actually decreases. We describe this effect and our solution in the case study section.

3 Clustering Architecture

The unsupervised neural network model called attention-based aspect extraction (ABAE) (He et al., 2017) clusters sentences based on GloVe word embeddings (Pennington et al., 2014) and attention (Bahdanau et al., 2014) to focus on the most important words in a sentence. Every sentence \( s \) is represented by a vector \( z_s \) that is defined as the weighted average of all the word vectors of that sentence. The weights are attentions calculated based on the contribution of the respective words to the meaning of the sentence and the relevance to the topics. These topics are defined by the actual centroids. In their publication, the topics are mapped to aspect classes for unsupervised aspect extraction, which we do not do for our case. (Kirchhoff, 2019)

The topics are initialized as the resulting centroids of k-means clustering on the word embeddings of the corpus dictionary. These are then stacked as topic embedding matrix \( T \). During training, ABAE calculates sentence reconstructions \( r_s \) for each sentence. These are linear combinations of the topic embeddings from \( T \) and defined as

\[
r_s = T^T \cdot p_t, \tag{1}
\]

where \( p_t \) is the weight vector over \( K \) topic embeddings. Each weight corresponds to the probability that the input sentence belongs to the associated topic. \( p_t \) is obtained by reducing the dimension of \( z_s \) to the number of topics \( K \) and applying softmax such that

\[
p_t = \text{softmax} (W \cdot z_s + b), \tag{2}
\]

where \( W \) and \( b \) are trainable and matrix weights and a bias vector respectively. The topic embeddings \( T \) are updated during training to minimize the reconstruction error \( J(\theta) \) between \( r_s \) and \( z_s \) based on the contrastive max-margin objective function. Since words and topics share the same dimensionality, cosine similarity between both can be used to
look up the most similar words representing each topic, similar to the way LDA (Blei et al., 2003) represents topics as word distributions. (Kirchhoff, 2019)

4 The SocialVisTUM Toolkit

Visualization Figure 2 shows an example of the visualization and labeling tool. Topics are represented as nodes with according labels, and the number of texts assigned to the topics is given in parentheses next to the label. The node size increases based on the number of topic occurrences. The edges of the topic connections are labeled by the topic correlations. The link thickness increases with a higher positive correlation. A graph layout based on repelling forces between nodes helps to avoid overlaps, which is especially useful when many nodes and links are displayed. A second force keeps the graph centered. Users can also move nodes around to get a more comprehensible overview. (Kirchhoff, 2019)

Topic Nodes and Correlations After training the ABAE model, the sentences are assigned to topics based on the maximum topic probability from $p_t$, see formula 2. The correlation between two topics $i$ and $j$ is calculated based on the probabilities $(p_{ti})_i$ and $(p_{tj})_j$ of each given sentence $t$. This yields a value in the range of $[-1, 1]$ for every pair of topics specifying the strength of the corresponding relatedness. (Kirchhoff, 2019)

Hiding Insignificant Topics An occurrence threshold slider defines the percentage of sentences that must be about a topic to display the associated node. Another slider can be used to set the correlation threshold to define the required positive or negative correlation to display the associated connections. These sliders are especially helpful to maintain a clear visualization by limiting the number of shown topics and connections when there are many of them available.

Topic Inspection Users can double-click a node to receive additional information about a topic, i.e., representative words and sentences, as shown in Figure 5 on the left and right respectively. As representative words, the top 10 words are shown sorted by the distance of their embeddings to the selected topic centroid in ascending order. The representative sentences are the ones with the highest probability from $p_t$ for the given topic. During topic inspection mode, only nodes that are connected to the clicked node and the associated links are displayed. A double click on the same node brings back the whole graph again.

Colorization of Topic Nodes In an updated version of SocialVisTUM, we introduce two meaningful colorings of the topic nodes for correlated topic clustering and sentiment analysis.

Firstly, we perform a hierarchical clustering algorithm such that those topics which are strongly correlated with each other are colorized in one and the same color respectively. A dynamic slider GUI element helps to adjust the correlation threshold accordingly. One example outcome is shown in 2.

Secondly, we perform sentiment analysis using the Valence Aware Dictionary and sEntiment Reasoner or VADER method (Gilbert, 2014). It is a lexicon and rule-based sentiment analysis tool that is specifically attuned to sentiments expressed in social media settings. It gives positive, negative, and neutral scores to represent the proportion of text in that sentence that falls in these categories. For each sentence, we use the compound score, i.e., the sum of all lexicon ratings normalized between -1 (most negative) and +1 (most positive). We then calculate the average sentiment score for each topic based on all respective topic sentences. In Figure 3, positive sentiment is shown as green topic nodes, and negative as red. (Roy and Zhao, 2020)
Table 1: Example topics, automatically assigned topic labels, and representative words. The value next to the topic label denotes how often the label occurs as a shared hypernym. The number of hypernyms on the right tells in how many word comparisons a shared hypernym is identified. Taken from (Kirchhoff, 2019).

</tr>
</tbody>
</table>

Automatic Topic Labels We introduce an approach to label topic nodes automatically. It is based on shared hypernyms, i.e., the lowest common denominator for words, which we identify using the representative topic words denoted in the previous paragraph and the lexical database WordNet (Miller, 1995). First, we retrieve the hypernym hierarchy for every representative topic word, as shown in Figure 4, and compare every word with every other word in the word list. Next, at each comparison, we save the hypernym with the lowest distance to the compared words in the hypernym hierarchy. We denote these as shared hypernyms. We only consider hypernyms if their distance to the word is smaller than half of the distance to the root hypernym to avoid unspecific labels like entity and abstraction. Eventually, we employ the hypernym that occurs most often as topic labels. If no hypernym can be identified, we use the most representative word instead. In the example shown in figure 4, we identify dairy product as the lowest shared hypernym of yoghurt and butter, and food as lowest shared hypernym of yoghurt and bread. (Kirchhoff, 2019)

The quality of a shared hypernym chosen as topic label can be approximated by inspecting the number of its hypernym occurrences – see table 1. Topic labels occurring frequently as shared hypernym are usually suitable (e.g., animal (102) and compound (91)) in contrast to topic labels that rarely occur (e.g. group_action (9) or smuckers (0)). Thus, we conclude that the number of hypernym occurrences of each topic is suitable to estimate the topic coherence for hyperparameter optimization – see section 5.2 later on. (Kirchhoff, 2019)

Changing Labels To change the label of a topic, the user can click on the associated label of a node. This opens a prompt allowing the user to change the topic label. The user can download a JSON file with the updated labels by clicking on the Create file button on the sidebar. (Kirchhoff, 2019)

5 Case Study

We demonstrate SocialVisTUM’s potential for social media data exploration on a new data set.

5.1 Data Set

We crawled online user comments on organic food from multiple forums (e.g., Reddit, Quora, Disqus) and the comment sections of news websites (The Washington Post, The New York Times, Chicago Tribune, HuffPost, and many more). The goal is to discover the discussed topics and opinions in social media regarding the organic food consumption.

Relevant articles from the platforms are found by the search terms “organic food”, “organic agriculture”, and “organic farming”. We further filtered for domain relevance by applying naive Bayes classification on bag of words trained on 1000 random and accordingly labeled texts (84.70% accuracy with 10-fold cross validation). From the left texts, we retain comments containing either of the words food and organic. The left data set consists of 515,347 sentences totaling 83,938 posts, which are used to train the ABAE topic model. We use the 300-dimensional pre-trained GloVe embeddings and fine-tuned them on the data. (Kirchhoff, 2019)

5.2 Hyperparameter Estimation

Some hyperparameters of the utilized ABAE topic model are the number of topic clusters and the vocabulary size. To optimize these automatically, we define a new metric, the average number of shared hypernyms (ANH). We first derive the frequency of all shared hypernyms for each topic, which is already done for automatic topic labeling in section 4. The ANH is the sum of hypernym frequencies over all topics divided by the number of topics. (Kirchhoff, 2019)
In our case study, we identified the following advantages of ANH over the widely used coherence score (CS). First, an increasing number of topics does not always increase the ANH, as a high number of topics leads to many incoherent topics with fewer shared hypernyms, i.e., a lower ANH. Second, a medium-sized vocabulary (~10,000 words) produces the most coherent topics according to ANH and manual inspection. Table 2 shows an excerpt of the results for varying parameters.

5.3 Interpretation

We applied SocialVisTUM to our case of organic food yielding the topics displayed in figure 1. A consumer researcher in the domain of organic food manually refined the automatic labeling based on the most similar words of each topic. The topics reflect previous findings of a qualitative content analysis on a small sub-sample of our data set (Danner and Menapace, 2020). The correlated topics allow market researchers to investigate the context in which topics are discussed.

Figure 5 takes a closer look at the example topic *pesticides*, which is concerned with different pesticides and their toxicity. The topic *pesticides* is correlated with the topic *organic_production_standards*, which references different organic or related production methods, such as bio-dynamic, hydroponic, or bio-intensive agriculture. This correlation suggests that, for the commenting users in our data set, the non-use of chemical-synthetic pesticides is an important characteristic of organic compared to non-organic production. Further topics correlated with *pesticides* propose that the commenting users are concerned about the use of *pesticides* in farming and that they discuss the issue of *pesticides*, possibly the residues thereof, in the context of different *food_products*.

6 Conclusion

In this paper, a case of the proposed SocialVisTUM demonstrates the visualization of coherent topics on a given corpus of social media texts about organic food. The graph-based visualization with topics as nodes and topic correlations as edges reflects the topics and patterns found in a related qualitative content analysis (Danner and Menapace, 2020). The presentation of additional topic information, such as word lists, representative sentences, topic importance, and meaningful predefined labels, provide a basis for the understanding and interpretation of a topic for domain experts. The integrated hyperparameter optimization automatically yields interpretable topics and helps tailoring the model to the given data set. For future work, we plan to evaluate the correlated topics on other corpora and in other use cases. In addition to Pearson correlation, other correlations could improve the approach. We plan to integrate multi-lingual word features, such as BERT (Devlin et al., 2018), for cross-cultural comparisons.

Apples to Apples: A Systematic Evaluation of Topic Models

Ismail Harrando, Pasquale Lisena and Raphaël Troncy
EURECOM, Sophia Antipolis, France
{firstname.lastname}@eurecom.fr

Abstract
From statistical to neural models, a wide variety of topic modelling algorithms have been proposed in the literature. However, because of the diversity of datasets and metrics, there have not been many efforts to systematically compare their performance on the same benchmarks and under the same conditions. In this paper, we present a selection of 9 topic modelling techniques from the state of the art reflecting a diversity of approaches to the task, an overview of the different metrics used to compare their performance, and the challenges of conducting such a comparison. We empirically evaluate the performance of these models on different settings reflecting a variety of real-life conditions in terms of dataset size, number of topics, and distribution of topics, following identical preprocessing and evaluation processes. Using both metrics that rely on the intrinsic characteristics of the dataset (different coherence metrics), as well as external knowledge (word embeddings and ground-truth topic labels), our experiments reveal several shortcomings regarding the common practices in topic models evaluation.

1 Introduction
The automatic analysis of textual data has gained increasing levels of attention over the last few decades. The cost of manually analysing and annotating the ever-growing quantity of content created and shared on the Web continues to be prohibitively expensive. Topic modelling is an NLP task where, given a corpus of documents, the objective is to find the underlying meaningful clusters of documents (or topics) that are thematically coherent (use consistent and related vocabulary) and assign each document to one or more of these topics. As a text mining technique, it allows the analysis of big volumes of textual documents through clustering them into coherent sets addressing similar subjects (or topics), and labeling them using keywords that are understandable by the end-user. It has the advantage of not relying on any labeled data to achieve good results, as the training of topic models is done in an unsupervised matter. Moreover, the resulting topics and representations can then be used to perform other NLP tasks such as trend prediction (Lau et al., 2012), text summarization (Lin and Hovy, 2000), improving named entity recognition (Newman et al., 2006), and content recommendation (Papneja et al., 2021).

Because of the unsupervised nature of the task, the evaluation of the quality of topic modelling techniques relies usually on metrics that do not require human annotation or ground-truth labels. Most of the used “coherence” metrics – further detailed in Section 3.1 – attempt to measure how much the resulting topics reflect some statistical characteristics of the original dataset and its word co-occurrences distribution. These metrics utilise different definitions of what a “coherent topic” is, and they only contingently agree with humans judgement (Chang et al., 2009). Coupled with the different approaches for document preprocessing and the variety of used evaluation datasets, this complexity leads to several nuances in the evaluation process that are not widely acknowledged in the literature at large. Thus, comparisons can be inconsistent and sometimes misleading.

In this work, we selected a diverse array of topic modelling algorithms (probabilistic, algebraic, embedding-based and neural) from the literature and we provide a thorough comparison using a unified evaluation protocol. This protocol evaluates each topic model on several datasets, using a variety of metrics that range from intrinsic evaluation of the clustering quality to ones that assess the alignment between the extracted topics and the human-assigned labels. With this strategy, we aim to illustrate the inconsistency of these metrics when
varying several subtle evaluation conditions. We analyse the results and we discuss the differences in performances across the different algorithms, datasets and parameters.

The remainder of this paper is organised as follows. In Section 2, we describe some related work, detailing some state-of-the-art topic modelling techniques. Different metrics for evaluating topic models are introduced in Section 3, while Section 4 describes the datasets we use for this purpose. In Section 5, we extensively analyse 9 topic models using coherence and ground truth related metrics. Finally, we provide some conclusions in Section 6.

2 Related Work

2.1 Topic Modelling Techniques

One of the first yet still widely used techniques is Latent Dirichlet Allocation (LDA) (Blei et al., 2003), an unsupervised statistical modelling approach that considers each document as a bag of words and creates a randomly assigned document-topic and word-topic distributions. Iterating over words in each document, the distributions are updated according to the probability that a document or a word belongs to a certain topic. The Hierarchical Dirichlet Process (HDP) model (Teh et al., 2006) considers instead each document as a group of words belonging with a certain probability to one or multiple components of a mixture model, i.e. the topics. Both the probability measure for each document (distribution over the topics) and the base probability measure – which allows the sharing of clusters across documents – are drawn from Dirichlet Processes (Ferguson, 1973). Unlike most other topic models, HDP infers the number of topics automatically. Gibbs Sampling for a DMM (GSDMM) applies the Dirichlet Multinomial Mixture model for short text clustering (Yin and Wang, 2014). This algorithm works by computing iteratively the probability that a document join a specific one of the N available clusters. This probability consists of two parts: 1) a part that promotes the clusters with more documents; 2) a part that advantages the movement of a document towards similar clusters, i.e. which contains a similar word-set.

Recently, pre-trained Word vectors such as word2vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014) have been used to help to enhance topic-word representations, as achieved by the Latent Feature Topic Models (LFTM) (Nguyen et al., 2015). One of the LFTM algorithms is Latent Feature LDA (LF-LDA), which extends the original LDA algorithm by enriching the topic-word distribution with a latent feature component composed of pre-trained word vectors. In the same vein, the Paragraph Vector Topic Model (PVTM) (Lenz and Winker, 2020) uses doc2vec (Le and Mikolov, 2014) to generate document-level representations in a common embedding space. Then, it fits a Gaussian Mixture Model to cluster all the similar documents into a predetermined number of topics – i.e. the number of GMM components.

Topic modelling can also be performed via linear algebraic methods. Starting from the high-dimensional term-document matrix, multiple approaches can be used to lower its dimensions. Then, we consider every dimension in the lower-rank matrix as a latent topic. A straightforward application of this principle is the Latent Semantic Indexing model (LSI) (Deerwester et al., 1990), which uses Singular Value Decomposition as a means to approximate the term-document matrix (potentially mediated by TF-IDF) into one with fewer rows – each one representing a latent semantic dimension in the data – and preserving the similarity structure among columns (terms). Non-negative Matrix Factorisation (NMF) (Paatero and Tapper, 1994) exploits the fact that the term-document matrix is non-negative, thus producing not only a denser representation of the term-document distribution through the matrix factorisation but guaranteeing that the membership of a document to each topic is represented by a positive coefficient.

In recent years, neural network approaches for topic modelling have gained popularity giving birth to a family of Neural Topic Models (NTM) (Cao et al., 2015). Among those, doc2topic (D2T) uses a neural network which separately computes N-dimensional embedding vectors for words and documents (with N = number of topics) before computing the final output using a sigmoid activation. The distributions topic-word and document-topic are obtained by getting the final weights on the two embedding layers. The Contextualized Topic Model (CTM) (Bianchi et al., 2020) uses Sentence-BERT (SBERT) (Reimers and Gurevych, 2019) – a neural transformer language model designed to compute sentences representations efficiently – to generate
a fixed-size embedding for each document to contextualise the usual Bag of Words representation. CTM enhances the Neural-ProdLDA (Srivastava and Sutton, 2017) architecture with this contextual representation to significantly improve the coherence of the generated topics.

2.2 Topic Models Comparison

To the best of our knowledge, no extensive comparison of recent topic models – covering multiple metrics and datasets under the same preprocessing condition – has been made. Some previous works have tried to compare different topic models on certain datasets and metrics. A review of statistical topic modelling techniques is included in Newman et al. (2006). Schofield and Mimno (2016) provide a comparison resulting from the effect of preprocessing on the performance of LDA on multiple corpora. Jelodar et al. (2017) offer a survey of topic modelling techniques based on LDA, as well as their different applications in recent literature. Yi and Allan (2009) and Alexander and Gleicher (2016) compare several topic models, evaluated as tools for performing Information Retrieval downstream tasks such as Topic Alignment, Change Comparison, Document Retrieval and Query Expansion. Several evaluation metrics based on top-words analysis was suggested by Newman et al. (2010). Alghamdi and Alfalqi (2015) compare 4 topic models (LDA, LSI, PLSA and CTM): this survey studied both their capability in modelling static topics, as well as in detecting topic change over time, highlighting the strengths and weaknesses of each. Burkhardt and Kramer (2019) provide a survey for the adjacent task of multi-label topic models, underlining its challenges and promising directions. Qiang et al. (2020) give an extensive performance evaluation of multiple topic models in the context of the Short Text Topic modelling sub-task (e.g. tweets). Finally, Doogan and Buntine (2021) studied several topic model coherence measures to assess how informative they are in several applied settings revolved around interpretability as an objective. They showed how standard coherence measures may not inform the most appropriate topic model or the optimal number of topics when measured up against human evaluation, thus challenging their utility as quality metrics in the absence of ground truth data.

2.3 Metrics

While our work utilises multiple comparison metrics (detailed in Section 3.1), it is worth highlighting that many other evaluation metrics were proposed in the literature to expose different characteristics of the studied topic models such as Classification Accuracy and Perplexity (Qiang et al., 2020), Entropy and Held-out Likelihood (Schofield and Mimno, 2016), Stability (Alexander and Gleicher, 2016), and Top-word Ranking (Greene et al., 2014), whereas finding a universally useful metric for topic modelling evaluation is still an open problem (Blei, 2012; Doogan and Buntine, 2021; Hoyle et al., 2021).

3 Metrics

The evaluation of machine learning techniques often relies on accuracy scores computed comparing predicted results against a ground truth. In the case of unsupervised techniques like topic modelling, the ground truth is not always available. For this reason, in the literature, we can find:

- metrics which enable to evaluate a topic model independently from a ground-truth, among which, coherence measures are the most popular ones (Röder et al., 2015; O’Callaghan et al., 2015; Qiang et al., 2020);
- metrics that measure the quality of a model’s predictions by comparing its resulting clusters against ground truth labels, in this case a topic label for each document.

3.1 Coherence Metrics

The coherence metrics rely on the joint probability $P(w_i, w_j)$ of two words $w_i$ and $w_j$ that is computed by counting the number of documents in which those words occur together divided by the total number of documents in the corpus. The documents are fragmented using sliding windows of a given length, and the probability is given by the number of fragments including both $w_i$ and $w_j$ divided by the total number of fragments. This probability can be expressed through the Pointwise Mutual Information (PMI), defined as:

$$PMI(w_i, w_j) = \log \frac{P(w_i, w_j) + \epsilon}{P(w_i) \cdot P(w_j)}$$ (1)

A small value is chosen for $\epsilon$, in order to avoid computing the logarithm of 0. Different metrics based on PMI have been introduced in the literature,
differing in the strategies applied for token segmentation, probability estimation, confirmation measure, and aggregation. The UCI coherence (Röder et al., 2015) averages the PMI computed between pairs of topics, according to:

$$C_{UCI} = \frac{2}{N(N-1)} \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} PMI(w_i, w_j) \quad (2)$$

The UMASS coherence (Röder et al., 2015) relies instead on a different joint probability:

$$C_{UMASS} = \frac{2}{N(N-1)} \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \log \frac{P(w_i, w_j)+\epsilon}{\rho(w_i, w_j)} \quad (3)$$

The Normalized Pointwise Mutual Information (NPMI) (Chicarcos et al., 2009) applies the PMI in a confirmation measure for defining the association between two words:

$$NPMI(w_i, w_j) = \frac{PMI(w_i, w_j)}{-\log(P(w_i, w_j)+\epsilon)} \quad (4)$$

NPMI values go from -1 (never co-occurring words) to +1 (always co-occurring), while the value of 0 suggests complete independence. The most common implementation of $C_{NPMI}$ applies NPMI as in Eqn (4) to couples of words, computing their joint probabilities using sliding windows.

This measure can be applied also to word sets. This is made possible using a vector representation in which each feature consists in the NPMI computed between $w_i$ and a word in the corpus $W$, according to the formula:

$$\hat{v}(w_i) = \{NPMI(w_i, w_j) | w_j \in W\} \quad (5)$$

The vectors related to each word of the topic are then compared using the cosine similarity $C_V$.

Fang et al. (2016) introduce Word Embeddings-based Coherence. This metric relies on pre-trained word embeddings such as GloVe or word2vec and evaluates the topic quality using a similarity metric between its top words. In other words, a high mutual embedding similarity between a model’s top words reflects its underlying semantic coherence. In this paper, we will use the sum of mutual cosine similarity computed on the GloVe vectors\(^2\) of the top 10 words of each topic.

$$C_{WE} = \frac{2}{N(N-1)} \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \cos(v_i, v_j) \quad (6)$$

where $v_i$ and $v_j$ are the GloVe vectors of the words $w_i$ and $w_j$.

In practice, these metrics are computed at the topic level and then aggregated using the arithmetic mean, in order to provide a coherence value for the whole model.

### 3.2 Metrics Which Relies on a Ground Truth

The most used metric that relies on a ground truth is the Purity, defined as the fraction of documents in each cluster with a correct prediction (Hajjem and Latiri, 2017). A prediction is considered correct if the original label coincides with the original label of the majority of documents falling in the same topic prediction. Given $L$ the set of original labels and $T$ the set of predictions:

$$Purity(T, L) = \frac{1}{|T|} \sum_{i \in T} \max_{j \in L} |T_i \cap L_j| \quad (7)$$

Other metrics are used in the literature for evaluating the quality of classification or clustering algorithms, applied to the topic modelling task:

1. Homogeneity: a topic model output is considered homogeneous if all documents assigned to each topic belong to the same ground-truth label (Rosenberg and Hirschberg, 2007);

2. Completeness: a topic model output is considered complete if all documents from one ground-truth label fall into the same topic (Rosenberg and Hirschberg, 2007);

3. V-Measure: the harmonic mean of Homogeneity and Completeness. A V-Measure of 1.0 corresponds to a perfect alignment between topic model outputs and ground truth labels (Rosenberg and Hirschberg, 2007);

4. Normalized Mutual Information (NMI) is the ratio between the mutual information between two distributions – in our case, the prediction set and the ground truth – normalised through an aggregation of those distributions’ entropies (Lancichinetti et al., 2009). The aggregation can be realised by selecting the minimum/maximum or applying the geometric/arithmetic mean. In the case of arithmetic mean, NMI is equivalent to the V-Measure.

In this work, we use their implementations as provided by scikit-learn (Pedregosa et al., 2011).
4 Datasets

In this section, we introduce the datasets that we use in our experiments. The features of each dataset are reported in Table 1.

A common pre-processing is performed on the datasets before training, consisting of:

- Removing numbers, which, in general, do not contribute to the broad semantics of the document;
- Removing the punctuation and lower-casing the text;
- Removing the standard English stop words;
- Lemmatisation using Wordnet, to deal with inflected forms as they are a single semantic item;
- Ignoring words with 2 letters or less. In facts, they are mainly residuals from removing punctuation – e.g. stripping punctuation from people’s produces people and s.

The same pre-processing is also applied to the text before topic prediction.

4.1 20 NewsGroups

The 20 NewsGroups collection (20NG) (Lang, 1995) is a popular dataset used for text classification and clustering. It is composed of English news documents, distributed fairly equally across 20 different categories according to the subject of the text. We use a reduced version of this dataset, which excludes all the documents composed by the sole header while preserving an even partition over the 20 categories. This reduced dataset contains 11,314 documents. We pre-process the dataset to remove irrelevant metadata – consisting of email addresses and news feed identifiers – keeping just the textual content.

4.2 Agence France Presse

The Agence France Presse (AFP) publishes daily up to 2000 news articles in 5 different languages, together with some metadata represented in the NewsML XML-based format. Each document is categorised using one or more subject codes, taken from the IPTC NewsCode Concept vocabulary. In the case of multiple subjects, they are ordered by relevance. In this work, we only consider the first level of the hierarchy of the IPTC subject codes.

We extracted a subset containing 125,516 news documents in English released in 2019.

4.3 Yahoo! Answers Comprehensive Q&A

The Yahoo! Answers Comprehensive Q&A (later simply Yahoo) contains over 4 million questions and their answers, as extracted from the Yahoo! Answers website. Each question comes with metadata such as title, date, and category, as well as a list of user-submitted answers. We construct documents by concatenating the title, body and best answer for each question – following Zhang et al. (2015) – and preprocess the documents in the same way as mentioned above. Then we create 2 subsets:

- **Yahoo balanced**, in which each category is represented by the same number of documents (1000) for a total of 26,000 documents;
- **Yahoo unbalanced**, in which the number of documents sampled from each category is proportional to its presence in the overall dataset, for a total of 22,121 documents.

These two subsets have been realised having a number of documents of the same order of magnitude. This allows to compare the differences in performance with balanced and unbalanced sets.

Table 1 summarises the properties of these datasets. The datasets present multiple differences, namely the size, the length of the documents and the distribution of documents per topic (i.e. ground truth label).

5 Experiment and Results

Evaluating an unsupervised task such as Topic Modelling is inherently challenging, and despite the variety of metrics, it is still an open problem (Hoyle et al., 2021). While intrinsic metrics (coherence) try to measure the underlying quality of the topical clusters generated by each model, they do not always match with human judgement. Two very coherent topics (according to the metric) can still fall under the same topic label for a human, and vice-versa. Topic models aim to maximise the posterior probability of a document belonging to a coherent topic, regardless of how it maps to human-perceived categories. For instance, Christianity and Atheism can be both filed as two independent topics or one topic (religion) by a human annotator, and while neither arbitrary option is wrong, it constitutes a big difference to how we would evaluate the topic modelling algorithms. They have no means

6https://answers.yahoo.com
of inferring what humans find to be *topically distinct* beyond co-occurrence statistics, making the comparison to human-annotated labels (as a “gold standard”) quite insufficient. Because of these challenges, few works in the literature (O’Callaghan et al., 2015; Alexander and Gleicher, 2016; Alghamdi and Alfalqi, 2015; Qiang et al., 2020) go beyond simple comparisons that only use one metric or dataset, eclipsing merits and shortcomings of the other methods. We attempt to provide a more thorough comparison using multiple evaluation datasets – varying in size, document length, number of topics, and label distribution – and metrics from the literature as a step towards a better understanding of the available options and their usability for different potential use-cases.

### 5.1 Varying the datasets

This section reports a comparison between 9 topic modelling algorithms described in Section 2. Our experimental setup goes as follows:

- For each dataset, we pre-process every document using the process described in Section 4;
- We train each topic model on each dataset, selecting the hyper-parameters through an optimisation process based on grid search, in order to maximise the $C_{NPMI}$ score. The use of a coherence metric as an optimisation objective is justified by the common use-case scenario, in which ground-truth labels are not present. The full set of parameters is documented in the repository\(^7\);  
- For each trained model, we compute all the intrinsic (coherence) metrics and the ground-truth-based ones.

For the experiment, we rely on To-ModAPI (Lisena et al., 2020), an open-source topic modelling API that is built to easily train, evaluate and compare several topic models. This framework provides a common interface for training, performing topic inference, and evaluating using coherence and ground truth. It includes all the metrics described above.

The number of topics – which must be provided in input to the algorithm for training – has been set to 20, 17 and 26 respectively when training on 20NG, AFP, and Yahoo, to mimic the original number of labels in each corpus. HDP has not been concerned with the choice of the number of topics, because it automatically infers it. For the first two datasets, we perform another training using the same hyper-parameters but increasing the number of topics to 50, to study its effect on the performance on the various metrics.

While all the obtained results are available in the appendix\(^8\), we will report in Figure 1 a selection of the most noticeable scores, namely $C_{NPMI}$, Word Embeddings coherence and V-Measure.

$C_{NPMI}$ values are in line with all the other coherence metrics in terms of ranking (listed in the appendix for brevity), i.e. LDA shows consistently good coherence scores across all datasets, followed by NMF and PVTM.

For the CTM model, we obtained a significantly lower coherence value than the one reported by Bianchi et al. (2020). Further investigation and experiments revealed the impact of an additional preprocessing step which reduces the vocabulary to the 2000 most frequent words. This further preprocessing improves the NPMI score of CTM from $-0.028$ to 0.116, while lowering the one of LDA from 0.133 to 0.126. This confirms the limits of topic modelling comparison and enforces the call for a standard procedure.

Word embeddings coherence demonstrated a better correlation with human judgement (Fang et al., 2016). Unsurprisingly, the two models that rely on word embeddings (LFTM, PVTM) tend to perform notably better (Figure 1).

The V-measure results included in Figure 1 are particularly relevant for understanding the correlation between the predicted topics and the ground-truth labels.}

Figure 2: NPMI of each model on the 20NG dataset when varying the number of topics.
truth, as it summarises three metrics – homogeneity, completeness and purity. This metric relies on human choices – made either by the editors for AFP or the website users for 20NG and Yahoo – and so it approximates the correlation between the topics as decided by the algorithms and the human (subjective) judgement on the same matter. Again, LDA is leading in overall performances, while other models – LFTM, PVTM, GSDMM – have good scores on particular datasets. The Yahoo dataset is particularly challenging for all models (the maximum value for V-measure is 0.33 for LDA), as compared to AFP (0.55 for LDA) or 20NG (0.59 for PVTM). This is probably due to a combination of document length, noise and errors in user-submitted content, and the potential overlap in topics. Increasing the number of topics systematically improves the results on AFP, raising the Homogeneity and Purity scores. This happens because the more a topic is granular, the highest is the chance that it maps correctly to the human label is correct. However, this is not observed on 20NG. Given the difference in size between 20NG and AFP, we conclude that the dimension of the former is not allowing it to extract smaller coherent topics, but rather causes an over-specialisation of them.

In summary, LDA still achieves the best scores overall, being often the first (or among the firsts) in ranking for every metric, whereas the other algorithms excel in particular contexts and can be specifically suitable for a given dataset. Increasing the number of topics is particularly helpful on bigger datasets, as it allows the topic models to find smaller yet more coherent subtopics within the collection, avoiding the drawback effect of being too specific. About label balance as tested through the Yahoo dataset, it appears that the balancing in the dataset has not a large impact in final results. On the contrary, training on the unbalanced version is often producing better coherence and V-measure. The reason can be found in the complete dropping of smaller categories, thus reducing the number of classes and achieving a higher-scoring topic/label mapping.

5.2 Varying the number of topics

To evaluate the effect of the choice of the number of topics (usually unknown beforehand), we train our models – except HDP, which infers the number of topics automatically – on 20NG using the same hyperparameters and varying only the number of topics. The results are shown in Table 2.

While there is a slight yet consistent improvement in the NPMI score for PVTM, we observe that increasing the number of topics does not consistently improve or hurt the coherence of the produced models. The fact that the score for 20 topics is usually the highest is probably due to the model finetuning, applied on this configuration. Finetuning every model for every number of topics requires a study of the co-optimisation of hyperparameters, which is out of the scope of this paper.

5.3 Varying the seed

For the models which allows to configure the random seed, we perform the evaluation on 20NG using the same hyperparameters except the seed (which we varied to have the values from 1 to 5). Even among 5 runs, we observe quite some variance in the metrics that is purely due to randomness which can be quite substantial. We report these results in Figure 2. While the effect is not very pronounced, it can be misleading. We thus recommend for topic models relying on random initialization to evaluate their models using different seeds, to guarantee a statistically significant comparison.

6 Conclusions and Future Work

In this work, we empirically evaluated 9 topic modelling algorithms using different coherence and ground-truth-based metrics on 3 text corpora reflecting a variety of properties, using a common evaluation framework. The results reveal several differences between the trained models, which obtain better or worse performances depending on the evaluation setting. Among these, LDA proves to be the most consistent performer overall, while embedding-based models prove to be less prone to generating meaningless topics.

The task of evaluating topic models remains a challenging one because of the inherent lack of a
ground-truth, the subjectivity of what constitutes a “coherent topic”, and the variety of settings wherein it is used. While every newly proposed topic model claims to improve on the existing state-of-the-art under some specific conditions, it is a worthwhile effort to revisit those claims and review them on a broader set of challenges and a unified pipeline, revealing their strengths and shortcomings. We also hope that by showing that no single metric can reflect the overall performance of any given topic model, we join a growing number of words drawing attention to the brittleness of most automatic metrics for topic models and the need of re-evaluating the standard practices of evaluation in the topic modelling literature.

As an extension to this work, we intend to study how other factors such as language, preprocessing and dataset characteristics can influence the performance on the metrics, as well as develop a unified protocol for evaluation that can allow us to draw more interesting insights into how the different topic modelling approaches fare in real use cases and downstream applications.

Abstract
This article describes research on claim verification carried out using a multiple GAN-based model. The proposed model consists of three pairs of generators and discriminators. The generator and discriminator pairs are responsible for generating synthetic data for supported and refuted claims and claim labels. A theoretical discussion about the proposed model is provided to validate the equilibrium state of the model. The proposed model is applied to the FEVER dataset, and a pre-trained language model is used for the input text data. The synthetically generated data helps to gain information that improves classification performance over state of the art baselines. The respective F1 scores after applying the proposed method on FEVER 1.0 and FEVER 2.0 datasets are 0.65 ± 0.018 and 0.65 ± 0.051.

1 Introduction
Misleading claims and news are becoming pervasive in our lives. Sometimes these are extremely difficult to identify. As a result, they can cause serious problems. This makes the research on claim verification essential. Fake news can be broadly classified into three categories (Rubin et al., 2015): i) Serious fabrications (uncovered in mainstream or participant media, yellow press or tabloids); ii) Large-scale hoaxes; and iii) Humorous fakes (news satire, parody, game shows). To solve this problem, research on this subject has evolved from knowledge-base oriented methods to sophisticated deep learning-based techniques.

Related Work
In (Mihalcea and Strapparava, 2009), the authors used natural language processing (NLP) techniques to detect fake news. They used tokenization and stemming for preprocessing the data and applied Naive Bayes and Support Vector Machine (SVM) algorithms for classification. In recent research, the linguistic style and text source are considered the most critical factors to decide the genuineness of a fact or claim (Rashkin et al., 2017), (Baly et al., 2018), (Pérez-Rosas et al., 2017).

Sometimes multiple sources of particular claims are used as external resources for claim verification. In (Rashkin et al., 2017), researchers compared the linguistic characteristics of real news with satire, hoaxes, and propaganda. They presented a case study based on the data collected by PolitiFact.com, where they used Glove for embedding, and Long Short Term Memory (LSTM) for prediction. To improve their result, they concatenate the Linguistic Inquiry and Word Count (LIWC) features (Pennebaker et al., 2001) with LSTM output vectors before the activation layer.

LIWC features have played a vital role in claim verification research. LIWC extracts essential words that are part of psycho-linguistic categories and help in content analysis according to (Krippendorff, 2018; Neuendorf and Kumar, 2015). Their research work was extended by Kashyap et al. (Popat et al., 2018), who proposed an end-to-end framework for credibility analysis. This framework is capable of aggregating information from external evidence articles, the language of these articles, and the trustworthiness of their sources. It also generates informative features for user-comprehensible explanations (Popat et al., 2018).

Using external information sources is an effective technique for claim verification, e.g., researchers in (Pochampally et al., 2014), (Pasternack and Roth, 2011), (Ge et al., 2013), (Li et al., 2014), and (Wan et al., 2016) used external sources for similar types of tasks. Ravali et al. proposed a novel method based on correlations between different sources of news in (Pochampally et al., 2014). To find the correlation between sources, joint precision and joint recall are used.
Jeff Pasternack et al. introduced a generalized fact-finding framework in (Pasternack and Roth, 2011) to resolve conflicting claims. Similarly, (Ge et al., 2013), (Li et al., 2014), (Wan et al., 2016) also used potentially inconsistent sources and information to verify facts and claims. Liang Ge et al. (Ge et al., 2013) proposed a procedure that calculates the degree of information consistency, identifies the underlying reason(s) for any inconsistencies, and calculates a consistent score for each item. In (Li et al., 2014), researchers proposed an optimization framework in which truths and reliable sources are considered as two sets of unknown variables, and the framework aims to minimize the deviation between the truths and the multi-source observations. A generalized algorithm called TruthFinder is proposed in (Wan et al., 2016), which utilizes the information of different related websites to perform fact-checking.

In recent research on this topic, deep learning techniques are becoming popular. In (Choudhary and Arora, 2020), a sequential neural model is proposed, which helps to identify syntactic, grammatical, sentimental, and readability features for fake news detection. Yang et al. (Yang et al., 2018) proposed text and Image information based Convolution Neural Network (TI-CNN), which uses both text and images as evidence for fact-checking. In this model, CNN is used for feature extraction from both text and images.

Recently, the FEVER dataset has gained a lot of traction (Thorne et al., 2018b), (Thorne and Vlachos, 2019), (Thorne et al., 2019). Hence, we use FEVER for claim verification. In earlier research with FEVER, most researchers followed a pipeline suggested by the baseline model (Thorne et al., 2018a), which consists of three sequential phases. The phases are: identifying relevant Wiki articles, extracting the appropriate supporting sentences, and determining the truthfulness of the claim. Earlier researchers implemented the Wiki article phase by Wikipedia API, token matching techniques and the AllenNLP framework (Gardner et al., 2017). For sentence selection, most earlier researchers have used TF-IDF, sequence matching neural network, and some ranking methods. The classification task is done using a TF-IDF approach in the base model, however later on neural network models, natural language inference models, and deep learning models were used.

Here, a GAN (Goodfellow et al., 2014) based method is proposed for claim verification. This model is inspired by two GAN based Positive Unlabeled (PU) learning models such as GenPU (Hou et al., 2017) and Yang et al. (Yang et al., 2020). Fig. 1 shows the proposed model. This model has three subunits, \( P, N \), and \( L \). Each subunit consists of a generator \( (G_x) \) and discriminator \( (D_z) \) pair. Subunit \( P \) and \( N \) are responsible for generating positive and negative synthetic data; subunit \( L \) is responsible for binary class label generation of the synthetically generated data. Subunit \( P \) and \( N \) have positive \((X_p)\) and negative \((X_n)\) input data. The positive data consists of supported claims and respective evidence, while the negative data consists of refuted claims and respective evidence.

This model uses three generators \( (G_p, G_n, G_y) \) and three discriminators \( (D_p, D_n, D_y) \). \( G_p \) is responsible for generating positive claims and \( D_p \) discriminates between original and synthetically generated positive claims. \( G_n \) and \( D_n \) are responsible for similar functions for negative claims. \( G_y \) and \( D_y \) get the data generated by \( G_y \) and \( G_n \) and generate a class label \((0/1)\) and \( D_y \) is the discriminator for \( G_y \).

2 Proposed Methodology

As described above, three GAN units are used. These units are responsible for generating positive samples Equation 1, negative samples Equation 2 and class labels Equation 3. Algorithm 1 details the training of the generators and discriminators.

\[
\min_{G_p} \max_{D_p} V(D,G) = \mathbb{E}_{x \sim p_p(x)} \log(D_p(x)) + \mathbb{E}_{z \sim p_z(z)} \log(1 - D_p(G_p(z)))
\]
The proposed model can handle only supported and refuted claims. \( D_y \) is trained with both supported and refuted claims, while \( D_p \) and \( D_n \) are trained with only supported and refuted claims separately. Hence, \( D_y \) is a more powerful discriminator compared to \( D_p \) and \( D_n \). There is a possibility that \( D_p \) or \( D_n \) will assign some sentences generated by \( G_p \) and \( G_n \) wrongly. As \( D_y \) has the global view of both supported and refuted claims, it is better able to classify them. Consider a situation: \( G_p \) generates \( Y_p \) (a synthetic positive claim). In the next step, \( Y_p \) is the input to \( G_y \) and \( G_p \) is generating 1 (positive class label). The output of \( G_y \) and input of \( G_p \) is the input to the discriminator state \((D_y)\). If \( D_y \) classifies \( Y_p \) as real, then no penalty is incurred by \( G_y \) and \( G_p \) otherwise both \( G_p \) and \( G_y \) are penalized. Consider another situation, where \( G_y \) generates 0 (negative class label) for an input of \( Y_p \) and \( D_y \) also classifies the \( Y_p \) as fake, then a penalty will be added to \( G_p \), not \( G_y \). So \( D_y \) is acting as a global discriminator. Equation 4 is the loss function for the generator \( G_y \), where \( \pi_p \) and \( \pi_n \) are the probabilities of positive and negative claims in the dataset.

\[
L(y) = \pi_p[D_y(G_y(pz)) \log(D_y(G_y(pz)))) + (1 - D_y(G_y(pz)))] (1 - D_y(G_y(pz))) + \pi_n[D_y(G_n(z)) \log(D_y(G_n(z)))) + (1 - D_y(G_n(z)))]
\]

For a GAN, achieving equilibrium is very important. In the present context, to find the equilibrium condition, first, we need to find the optimal conditions for discriminators. Using the optimal conditions of the discriminators, the minimization conditions for the generator can be obtained. Considering the generators \((G_p, G_n, G_y)\) are fixed, and \( \pi_p \) and \( \pi_n \) are the probabilities of positive and negative claims in the dataset, at the equilibrium condition the distribution of positive generated data \((p_{gp}(x))\) and negative generated data \((p_{gn}(x))\) will follow the Equations 5 and 6, where \( p_{gp}(x) \) and \( p_{gn}(x) \) are the positive and negative class probability distributions.

\[
p_{gp}(x) = \pi_p(x)
\]

\[
p_{gn}(x) = \pi_n(x)
\]

The optimal discriminator functions \( D^*_p(x) \), \( D^*_n(x) \), \( D^*_y(x) \) can be derived by differentiating Equations 1, 2 and 3 (Hatua et al., 2021a).

\[
D^*_p(x) = \frac{p_p(x)}{p_p(x) + p_gp(x)}
\]

\[
D^*_n(x) = \frac{p_n(x)}{p_n(x) + p_{gn}(x)}
\]
Using Jensen–Shannon divergence (JSD) (Fuglede and Topsoe, 2004), we can show that the argmin generators are achieved when the following conditions are satisfied:

$$p_p(x) = p_{gp}(x) \quad (10)$$

$$p_n(x) = p_{gn}(x) \quad (11)$$

$$p_y(x) = \pi_p p_{gp}(x) + \pi_n p_{gn}(x) \quad (12)$$

### 3 Data

FEVER is a publicly available dataset for claim verification with three types of claims: i) supported, ii) refuted, iii) Not Enough Information (NEI). For every supported and refuted claim, there is supporting/refuting evidence, while for the NEI class there is no evidence. All evidence provided in the FEVER dataset is collected from Wikipedia. In most cases, the first few lines of a particular Wikipedia page are taken in FEVER dataset as the evidence. Table 1 shows two examples of claim, evidence pairs and their class labels. For the experiments, we used only Supported and Refuted claims.

FEVER training subset has 80,035 Supported claims, 29,775 Refuted claims, and 35,639 NEI claims. The FEVER 1.0 validation set and test set have 3,333 Supported claims, 3,333 Refuted claims, and 3,333 NEI claims respectively. FEVER 2.0 has 391 Supported claims, 396 Refuted claims, and 387 NEI claims respectively. For the experiments, we used only Supported and Refuted claims.

### 4 Experiments

The workflow of the experiment is given in Fig 2. In the first phase, data is preprocessed as described in Section 4.1. This preprocessed data is used as input to the proposed model for training. The Supported claim, evidence pairs are input to the positive synthetic data generator subunit, and the Refuted claim, evidence pairs are input to the negative synthetic data generator subunit. Once the proposed model is trained with the preprocessed data, the model is used for the testing phase using the test dataset. Finally, the model’s performance is compared with the results of other standard methods and SOTA models. The steps of the experiments are detailed below.

#### 4.1 Data preprocessing

For this experiment, only ‘Supported’ and ‘Refuted’ claims are considered from the training dataset. In the training dataset, every claim has one or more statements (evidence). For a particular claim, its corresponding statements are concatenated separately. For example, suppose claim (C) evidence (E) and label (L) are: \([C; E : < e_1, e_2, e_3 >, L]\). The input data format for subsequent processes will be: \(x = [< C; e_1, L >, < C; e_2, L >, < C; e_3, L >]\).

#### 4.2 GAN Implementation

The implementation of GAN is the central part of this research. Two types of GANs are implemented: text generating GAN and binary class label generating GAN. The text generating GANs generate synthetic text data for supported and refuted claims. The binary class label generating GAN generates the binary class label for each generated claim. To implement text generating GAN, we use LaTextGAN (Donahue and Rumshisky, 2018). LaTextGAN follows two phases for the implementation. During the first phase, it creates an encoded space, and in the second phase, it follows the traditional GAN (Goodfellow et al., 2014) implementation steps and generates synthetic data in the encoded space. Finally, the synthetically generated data is decoded into normal text data. On the other hand, the implementation of binary labels generating GAN is similar to the implementation of the traditional GAN (Goodfellow et al., 2014). The evidence for the synthetically generated sentences are selected from the Wikipedia database (Thorne et al., 2018b) using cosine similarity (Huang et al., 2008).
Claim: Tetris has sold millions of physical copies.
Evidence: It was announced that Tetris has sold more than 170 million copies, approximately 70 physical copies and ...
Label: True

Evidence: Roddick was ranked in the top 10 for nine consecutive years between 2002 and 2010, and won five Masters Series in that period.
Label: False

Table 1: Two claim, evidence pairs from FEVER

<table>
<thead>
<tr>
<th>Claim</th>
<th>Evidence</th>
<th>Label</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tetris has sold millions of physical copies.</td>
<td>It was announced that Tetris has sold more than 170 million copies, approximately 70 physical copies and ...</td>
<td>True</td>
</tr>
<tr>
<td>Andy Roddick lost 5 Master Series between 2002 and 2010.</td>
<td>Roddick was ranked in the top 10 for nine consecutive years between 2002 and 2010, and won five Masters Series in that period.</td>
<td>False</td>
</tr>
</tbody>
</table>

In this case we have selected one evidence for every synthetically generated sentence. The synthetically generated data and the evidence are concatenated and processes following the steps mentioned in Section 4.1.

4.3 New GenPU Based Baselines

These baselines are inspired from the GenPU. To explore further we have modified GenPU in two variants: Inverted GenPU and Symmetric GenPU. In case of Inverted GenPU the value functions for the positive and negative text generating GAN are exchanged. Hence the respective value functions become the equations mentioned in Equation 13, 14 and 15.

\[
D^*_n = \arg\max_{D_n} \mathbb{E}_{x \sim p_p(x)} \log(D_n(x)) + \mathbb{E}_{z \sim p_z(z)} \log(1 - D_n(G_n(z)))
\]

\[
\min_{G_n} \max_{D_n} V(D, G) = - \mathbb{E}_{x \sim p_p(x)} \log(D_n(x)) - \mathbb{E}_{z \sim p_z(z)} \log(1 - D_n(G_n(z)))
\] (13)

\[
\min_{G_p} \max_{D_p} V(D, G) = \mathbb{E}_{x \sim p_p(x)} \log(D_p(x)) + \mathbb{E}_{z \sim p_z(z)} \log(1 - D_p(G_p(z)))
\]

(14)

\[
\min_{G_n} \max_{D_n} V(D, G) = \mathbb{E}_{x \sim p_p(x)} \log(D_n(x)) + \mathbb{E}_{z \sim p_z(z)} \log(1 - D_n(G_n(z)))
\]

(15)

In Symmetric GenPU the equations for both the value functions are same. The value functions for Symmetric GenPU are presented in Equation 16 and 17.

\[
\min_{G_p} \max_{D_p} V(D, G) = \mathbb{E}_{x \sim p_p(x)} \log(D_p(x)) + \mathbb{E}_{z \sim p_z(z)} \log(1 - D_p(G_p(z)))
\]

\[
\min_{G_n} \max_{D_n} V(D, G) = \mathbb{E}_{x \sim p_p(x)} \log(D_n(x)) + \mathbb{E}_{z \sim p_z(z)} \log(1 - D_n(G_n(z)))
\]

(16)

4.4 Other methods

The performance of the proposed method and new baselines is compared with other GAN based methods and classifiers. The GAN (LeakGAN (Guo et al., 2017) and LaTextGAN (Donahue and Rumshisky, 2018)) based models generate synthetic data and the synthetically generated data is added to the original dataset and it helps to create an extended feature space of the FEVER dataset and gives leverage to new features. This synthetically generated data is further classified using positive-unlabeled (PU) learning which considers supported facts as positive class and are added to the existing training dataset. Finally, this extended dataset is used for the training process. The synthetic data is generated using LeakGAN and LaTextGAN separately and two different sets of results are collected to compare the performance. The result of this method (Hatua et al., 2021b) for both the datasets is compared with the proposed method in Table 2, and Table 3. Other baselines include deep learning and machine learning based classification methods such as: BERT based classifier (Devlin et al., 2018), Graph Convolution Network (GCN) (Scarselli et al., 2008), Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), Convolution Neural Network (CNN) (Lawrence et al., 1997), Support Vector Machine (SVM) (Drucker et al., 1996), Naive Bayes (Lewis, 1998), Random forest (Pal, 2005), and Stochastic Gradient Descent (SGD) (Friedman, 2002).

To implement BERT based classifier Hugging-
face BERT (Devlin et al., 2018) pretrained transformer is used as tokenizer for the training, validation and testing dataset. The vocabulary size of the pretrained model is 30522 and the size of the hidden layer is 768. Later the pre-tuned model is fine tuned to classify the claims. In GCN, point wise mutual information between words is calculated to generate the graph. To implement the CNN five kernels of sizes 2, 3, 4, 5 and 6 are used. For LSTM the input data is encoded using GloVe (Pennington et al., 2014). The learning rate and batch size for GCN, CCN and LSTM are 0.001, 64 respectively. The Random forest is equipped with 1000 trees and the Scikit learn library (Pedregosa et al., 2011) is used for machine learning models.

5 Results

All models are trained with the FEVER training dataset and tested with FEVER 1.0 and FEVER 2.0 test dataset. In Tables 2, and 3 detailed results for each of the models are presented. Each experiment is repeated five times. The result for FEVER 1.0 is also compared with previous research work by Yang et al. (Yang et al., 2020).

In Tables 2, and 3 we see that the F1 score for the proposed method is better than the new baselines and previous research.

The gradual change of precision, recall, and F1 score for the FEVER 1.0 and FEVER 2.0 is presented in Fig. 3, and Fig. 4. Moreover, to visualize the distribution of original and synthetic data, t-SNE plots of the positive and negative generated data are shown in Figures 5, and 6. The perplexity of the t-SNE plot is 30, and the learning rate is 120. It can be observed that the distribution of synthetically generated data has less overlap with the original data.

Figure 3: Precision, Recall and F1 Score for FEVER 1.0 Dataset

Figure 4: Precision, Recall and F1 Score for FEVER 2.0 Dataset
generated positive data is very similar to that of original positive text data, while the distribution of the negative synthetic data is similar to the original negative text data. The positive synthetic data is much more similar to the positive text data compared to the similarity between negative synthetic data and negative text data.

The proposed GAN based model starts with some random values and tries to generate synthetic data, which helps to achieve a better F1 score. In the training process, after every epoch, we have calculated the F1 score for both the test datasets and observed a gradual improvement of the F1 score.

Fig. 7a, 7b, and 7c depicting the positive loss, negative loss and label generating loss. We can see the three losses are decreasing over epochs gradually,
which also suggests that all the generator discriminator pairs are training to achieve the equilibrium state. To test the gradual progression of the synthetically generated data, we also measure the similarity scores between original (positive and negative) data and synthetic data (positive and negative) while training the model. It has been observed that for the generated data, the similarity score gradually improves over epochs, as shown in Fig. 8, and 9. To measure the similarity 20,000 synthetically generated data are randomly selected and Cosine similarity (Singhal et al., 2001), Manhattan distance (Sinwar and Kaushik, 2014), Euclidean distance (Aggarwal et al., 2001) are calculated.

6 Conclusion

We propose a multiple GAN-based model that employs the GAN’s synthetic data generation capability to solve claim verification problems. The model generates synthetic data for supported, refuted claims and their class labels using three separate generator discriminator pairs. The synthetic data eventually helps in the fact-checking task for FEVER 1.0 and FEVER 2.0 test datasets. The results have shown that the proposed model starts with random data generation, and as the training progresses, it generates synthetic data similar to the original data.

Different statistical and analytical similarity metrics confirm that the similarity between original data and synthetically generated data increases as the training progresses. This gradual improvement of data quality shows the effectiveness of the model. The proposed model produces an F1 score of 0.65 ± 0.018 and 0.65 ± 0.051 for FEVER 1.0 and FEVER 2.0, respectively.

Dataset quality is a subtle issue, e.g., see (Verma et al., 2019; Verma and Marchette, 2019). In the future, this model can be extended to a multi-class classifier, and a similar set of experiments can be carried out on other publicly available standard datasets to test this proposed model’s effectiveness across different datasets.

Semi-Supervised and Unsupervised Sense Annotation via Translations

Bradley Hauer, Grzegorz Kondrak, Yixing Luan, Arnob Mallik, Lili Mou

Abstract

Acquisition of multilingual training data continues to be a challenge in word sense disambiguation (WSD). To address this problem, unsupervised approaches have been proposed to automatically generate sense annotations for training supervised WSD systems. We present three new methods for creating sense-annotated corpora which leverage translations, parallel bitexts, lexical resources, as well as contextual and synset embeddings. Our semi-supervised method applies machine translation to transfer existing sense annotations to other languages. Our two unsupervised methods refine sense annotations produced by a knowledge-based WSD system via lexical translations in a parallel corpus. We obtain state-of-the-art results on standard WSD benchmarks.

1 Introduction

Word sense disambiguation, the task of identifying the meaning of a word in context, is one of the central problems in natural language understanding (Navigli, 2018). It is a well-studied benchmark for evaluating contextualized representations of words (Loureiro et al., 2021), and is better understood than tasks such as WiC (Pilehvar and Camacho-Collados, 2019). Modern WSD methods can be divided into supervised and knowledge-based approaches. The former depend on sense-annotated corpora such as SemCor (Miller et al., 1994), while the latter rely instead on semantic knowledge bases such as WordNet (Miller, 1995).

While supervised WSD systems typically outperform knowledge-based systems (Scarlini et al., 2020b), their utility is limited by the availability of sufficiently large sense-annotated corpora for training. This includes systems based on contextualized embeddings (Bevilacqua and Navigli, 2020). In particular, there is a severe lack of high-quality sense-annotated corpora for languages other than English. This limitation has motivated the development of methods aimed at automatically disambiguating a large number of word tokens in a given unannotated corpus, ideally covering a wide range of word and sense types, while minimizing noise (Pasini and Navigli, 2017; Scarlini et al., 2019; Barba et al., 2020). The automatically tagged corpus can then be used to train a supervised WSD system, satisfying the dependency on training data without the need for manual annotation.

Following recent theoretical work Hauer and Kondrak (2020) on establishing the semantic equivalence of mutual translations, we introduce three translation-based methods for generating sense-tagged corpora. All three methods make use of lexical knowledge bases, and semantic information obtained from word-level translations. Semi-supervised LABELPROP creates a synthetic parallel corpus (bitext) by applying machine translation to a monolingual manually-annotated corpus, and projecting annotations to the target language. Similarly, unsupervised LABELGEN applies a knowledge-based WSD system to the English side of a bitext, and projects the resulting sense annotations across bitexts onto other languages. Finally, unsupervised LABELSYNC produces sense-annotated corpora in two languages at once by independently applying a knowledge-based WSD system to each side of a raw bitext, and then refining the initial annotations based on the confidence scores and multilingual information.

Our experiments on standard WSD test sets demonstrate that the new methods achieve state-of-the-art results in both semi-supervised and unsupervised sense annotation. We train two different reference supervised WSD systems on the generated data, and apply the resulting models to multilingual WSD benchmarks. Our results compare favourably to models trained on data produced by
the previous state-of-the-art sense annotation methods. Indeed, some of the results obtained with our unsupervised methods rival those obtained by training on a manually sense-annotated corpus.

Our contributions are as follows: We present three novel, scalable methods that can generate annotated corpora for any language for which a suitable lexical knowledge base is available. We show that these methods achieve state-of-the-art results on multiple languages. We make our code and corpora available.¹

2 Related Work

The sense tagging systems that we consider in this work, including our three novel methods, can be divided into four types according to two criteria (Figure 1). The first criterion is whether the method involves supervision in the form of a sense-annotated corpus. The second criterion is whether the method operates as a traditional self-contained WSD system, or instead assigns sense tags to a subset of the words in a corpus which can then be used to train a supervised WSD system. In this section, we discuss the most relevant examples of each of the four resulting types.

**Supervised WSD** systems rely on sense annotations to train disambiguation models, which are evaluated on benchmark datasets. Examples include GlossBERT (Huang et al., 2019), EWISE (Kumar et al., 2019), and EWISE (Bevilacqua and Navigli, 2020). Because they require labelled training data in the target language, such systems are generally impractical for languages other than English, nor are they directly comparable to our proposed methods.

**Knowledge-Based WSD** systems remain important due to the limited coverage of existing annotated corpora, as well as their English bias. These include graph-based systems such as UKB (Agirre et al., 2014), UKB enhanced with SyntagNet (Maru et al., 2019), and EWISE (Bevilacqua and Navigli, 2020). Because they require labelled training data in the target language, such systems are generally impractical for languages other than English, nor are they directly comparable to our proposed methods.

**Semi-Supervised Corpus Tagging** systems depend on sense annotated corpora in one language to produce sense annotations in other languages. The current state-of-the-art method in this setting is MuLaN (Barba et al., 2020), which propagates sense annotations from SemCor and WordNet Gloss Corpus (WNG, Langone et al., 2004) to semantically similar contexts in Wikipedia corpora using contextual word representations from mBERT. Our LABELPROP method differs by leveraging machine translation to directly propagate sense annotations across word alignment links.

**Unsupervised Corpus Tagging** systems produce sense annotations “from scratch”. Train-O-Matic (Pasini and Navigli, 2017) annotates Wikipedia in multiple languages by applying the Personalized PageRank (PPR) algorithm to BabelNet. OneSeC (Scarlini et al., 2019) combines Wikipedia categories and BabelNet synset representations to produce WSD training data, and outperforms Train-O-Matic. However, both Train-O-Matic and OneSeC annotate nominal instances only, and hence are not applicable to all-words WSD. On the other hand, EuroSense (Delli Bovi et al., 2017) jointly disambiguates content words of all parts of speech in a parallel corpus using a knowledge-based WSD system. Our LABELSYNC and LABELGEN methods differ in that they explicitly leverage lexical translation information obtained from a bitext.

![Figure 1: Typology of relevant sense tagging systems. Our own systems are shown in double-lined boxes.](https://www.cs.ualberta.ca/~kondrak)

Other work on using translations for WSD: Resnik and Yarowsky (1999) propose to distinguish senses only if a “minimum subset” of languages translate them differently. Apidianaki (2009) demonstrates how senses can be induced

¹https://www.cs.ualberta.ca/~kondrak
by clustering lexical translations, and proposes an unsupervised WSD system based on such induced sense inventory and translation information. Lefever et al. (2011) frame WSD as translation selection, and propose a method based on multilingual feature vectors. Finally, Taghipour and Ng (2015) annotate English words with their Chinese translations using manually crafted sense-to-translation mappings. These methods are not comparable with our work as they do not link their sense annotations to the WordNet sense inventory, and therefore are not applicable to modern WSD datasets.

3 Semi-Supervised LABELPROP

In this section, we introduce LABELPROP, a novel label propagation approach for constructing multilingual sense-annotated corpora. The idea is to translate a sense-annotated corpus in order to propagate the sense tags across the translations. No sense-annotated data is required in the target language. The method is composed of three steps: translation identification, knowledge-base filtering, and nearest neighbor filtering (Figure 2).

3.1 Translation Identification

Given a sense-annotated source corpus, we first translate the corpus into the target language using pre-trained neural machine translation models. Each sentence containing at least one source sense-annotated word is translated independently. If the translation of an annotated source word can be identified through word alignment, we annotate the translation with the same BabelNet synset as the aligned source word. This procedure is based on the assumption that lexical translations in context are semantically equivalent, and therefore very likely to express the same concept (Hauer and Kondrak, 2020).

For alignment, we use BABALIGN (Luan et al., 2020), a high-precision alignment tool which leverages translation information from BabelNet to improve on a base alignment system. In particular, BABALIGN augments the input corpus with lexical translation pairs to bias the aligner towards aligning words which are mutual translations. It also corrects alignments to maximize the number of aligned words that share BabelNet synsets. This emphasis on recovering word-level translation information makes BABALIGN particularly well-suited to our method.

3.2 Knowledge-Based Filtering

The sense-projection procedure in the previous step may annotate a word with a BabelNet synset which does not actually contain that word. These invalid sense annotations may occur due to non-literal translation (i.e., the word and its translation do not express the same concept), errors in translation or alignment, or omissions in BabelNet. Since each sense of a word must correspond to a specific synset, such invalid annotations are discarded.

3.3 Nearest Neighbor Filtering

In order to further increase the precision, we apply a semi-supervised WSD method to each target translation that is sense annotated by the previous steps. For each word, we verify that the annotation propagated from the source-language corpus matches the annotation assigned by the WSD system; otherwise, we discard that sense annotation.

Our semi-supervised WSD method uses a one-nearest-neighbor approach with ARES multilingual synset embeddings (Scarlini et al., 2020). We first obtain contextual word representations of each sense-annotated target translation by taking the sum of the last four layers of multilingual BERT (Devlin et al., 2019). Since ARES embeddings have twice the size of the original mBERT embeddings, we concatenate each obtained word representation with itself. We then compute the cosine similarity between the mBERT representation of the word, and the ARES representation of each synset containing the word. The synset that maximizes the similarity is taken as the output of this WSD system. To reiterate, we retain only the sense annotations from the previous step that agree with this WSD system.

4 Unsupervised Symmetric LABELSYNC

The LABELPROP method, presented in Section 3, is able to leverage existing sense annotated corpora, such as SemCor, to create comparable sense annotated corpora in other languages. However, the availability of sense-annotated corpora in other do-

Figure 2: LABELPROP propagates senses from language L1 to language L2.
mains and languages is very limited. On the other hand, large bitexts are relatively easy to obtain for many language pairs and domains.

To further reduce the dependency of WSD systems on any pre-existing annotated data, we introduce LABELSYNC, a method which annotates both sides of a given bitext. This method retains the idea of using word alignment to validate sense annotations, while eschewing the need for a sense annotated corpus. It is composed of three steps: monolingual word sense disambiguation, multilingual post-processing, and translation-based filtering (Figure 3).

4.1 Monolingual WSD
Our goal is to enrich both sides of the input bitext with sense tags. Since LABELSYNC does not assume access to any sense-annotated corpus, we employ a language-independent knowledge-based WSD system: a variant of UKB enhanced with SyntagNet (Maru et al., 2019). After each side of the bitext is annotated independently, we have two sense annotated corpora, one in each of the languages represented in the bitext.

4.2 Multi-Lingual Post-Processing
Now that both sides of the bitext are annotated independently, we leverage the lexical translation information inherent in the bitext to increase the accuracy of the sense annotations. To improve the performance of our base WSD system, we employ the SOFTCONSTRAINT method of Luan et al. (2020). This method is applicable to any base WSD system which assigns a numerical score, such as a probability, to each sense of a disambiguated word. Most modern WSD systems, including UKB, satisfy this property.

The SOFTCONSTRAINT method depends on word-level translations of each annotated word, as well as translation information from BabelNet, which is based on the hypothesis that the translation of a word token provides semantic information about its sense (Hauer and Kondrak, 2020). In our case, translation information is readily available from the bitext. As with our LABELPROP method, we use BABALIGN (Luan et al., 2020) to word align the bitext. For each sense-annotated token, the aligned word or phrase is treated as its translation.

The SOFTCONSTRAINT method can also incorporate sense frequency information, to bias the annotations toward more probable senses. However, we exclude sense frequency information from this step, as it provided no discernible benefit in our development experiments.

4.3 Translation-Based Filtering
In the final step, we aim to further reduce the noise in our sense-annotated corpora by employing a BabelNet-based filtering method, similar to the one described in Section 3.2. As before, the key idea is to impose two constraints on our sense annotations: (1) a word should only be annotated with a synset that contains the word, and (2) aligned words should be annotated with the same synset. LABELPROP initially guarantees only the latter constraint, so it has to discard some annotations to ensure the former. In contrast, LABELSYNC initially guarantees the first constraint, as UKB can only annotate a word with a synset containing it. However, since each side of the corpus is annotated independently, the second constraint may not hold. The final step of LABELSYNC is aimed at resolving this problem by synchronizing the sense annotations across both sides of the bitext.

Unlike Delli Bovi et al. (2017), who leverage embeddings of concepts to filter questionable annotations, we adopt a binary alignment-based criteria using the assumption of semantic equivalence of lexical translations. We retain only those annotations that refer to the same multilingual synset as the sense annotations of their translations. We also retain annotations if the token cannot be aligned, or if its translation is not annotated.

5 Unsupervised Asymmetric LABELGEN
Unlike LABELSYNC, our second unsupervised method, LABELGEN, assumes that the source language is English, and treats the two sides of the bitext differently. The goal is to leverage available English resources to improve WSD performance on other languages, rather than to generate English sense annotations.
5.1 English WSD
Given a bitext, we first apply a knowledge-based WSD system to the English side only, as described in Section 4.1. The lexical information for other languages is retrieved from BabelNet multi-synsets which are aligned to WordNet 3.0 synsets. This automatic candidate retrieval process is noisy, because most BabelNet lexicalizations are automatically generated from various resources. In addition, while English WordNet contains the sense frequency estimates from the manually-annotated SemCor, such information is not readily available for other languages. Hence, WSD annotations are more accurate for English compared to other languages.

5.2 Label Propagation
Having automatically sense-tagged the English side of the bitext, we propagate the labels to the non-English side using the procedure described in Section 3.1. In effect, we are applying the first part of LABELPROP, treating the English side as a sense-tagged corpus, and the other side as its translation. At the end of this process, both sides of the bitext are sense-annotated.

5.3 Re-Ranking and Filtering
We further refine the sense annotations on the non-English side of the bitext. We first apply the SOFTCONSTRAINT method as described in Section 4.2, which re-ranks the possible senses for each annotated word using the assigned WSD scores. We then apply the filtering procedure from Section 3.2, which removes any sense annotations that do not exist in the BabelNet sense inventory.

6 Evaluation
Following prior work, we extrinsically evaluate our corpus construction approaches by providing the generated annotations as training data for supervised WSD systems (reference systems), which are then evaluated on standard multi-lingual WSD benchmarks. While our methods could also be applied to low-resource languages, the current lack of evaluation datasets precludes such experiments in this work.

6.1 Reference Supervised WSD Systems
We perform experiments with two reference supervised WSD systems: (1) IMS (Zhong and Ng, 2010) with the most-frequent-sense (MFS) backoff for English, and (2) mBERT, a transformer-based method, built on multilingual BERT (Devlin et al., 2019), as described by Barba et al. (2020). We use the default parameter settings and number of training epochs. We train each model on each set of automatically produced sense annotations.

Following prior work, we use the SemEval-2007 dataset (Raganato et al., 2017) as our validation set for the English experiments. Because of the lack of standard validation sets for non-English languages, we use random samples of 1000 sentences from our training corpora. The hyperparameters of each system are held constant throughout all experiments.

6.2 Test Data
We test the reference WSD models on standard multilingual benchmark datasets: SemEval-2013 task 12 (Navigli et al., 2013), which contains data for Italian, Spanish, French, and German, and SemEval-2015 task 13 (Moro and Navigli, 2015), which covers Italian and Spanish. The SemEval-2013 datasets contain only nominal instances, while the SemEval-2015 datasets cover nouns, verbs, adjectives, and adverbs. We use the latest version of the datasets, which are annotated with synsets from BabelNet version 4.0.

For the experiments on English (Section 6.4.3), we use the standardized benchmarks of Raganato et al. (2017).

et al. (2017)\footnote{http://nlp.uniroma1.it/wsdeval}, which comprise all-words test sets from five shared tasks: Senseval2 (Edmonds and Cotton, 2001), Senseval3 (Snyder and Palmer, 2004), SemEval-2007 (Pradhan et al., 2007), SemEval-2013 (Navigli et al., 2013), and SemEval-2015 (Moro and Navigli, 2015). We also report the average results on the concatenation of all five test sets, which we refer to as ALL.

### 6.3 Semi-Supervised Approaches

This section is devoted to the empirical evaluation of the LABELPROP method from Section 3.

#### 6.3.1 Experimental Setup

We apply LABELPROP to a sense-annotated English corpus comprised of SemCor (Miller et al., 1994) and the WordNet Gloss Corpus (WNG) (Langeone et al., 2004). Following Luan et al. (2020), we translate each sentence of our English corpus with Google Translate independently into Italian, Spanish, French, and German. As described in Section 3.1, we induce word alignment by applying BABALIGN with FASTALIGN (Dyer et al., 2013) as its base aligner. Table 1 contains the statistics for the corpora created with our methods. “Sense types” indicates the number of distinct word senses in the corpus. “Failed alignments” refers to the number of English sense annotations that could not be propagated.

We compare LABELPROP to MuLaN (Barba et al., 2020), the current state-of-the-art system for semi-supervised WSD. MuLaN uses SemCor+WNG as its manually-annotated base English corpus. Specifically, we apply the same procedure to train the supervised reference system (IMS or mBERT) on the annotated data produced by each method. We train a single model for each system, using only the corpus produced by that system for each language, which limits the impact of language-specific issues. Nevertheless, due to both software and hardware variables and hyper-parameters, our MuLaN results differ from those reported in the original paper.

When reporting the results achieved with mBERT, we also include the results of two recent WSD systems: ARES, using the reported results from Scarlini et al. (2020b), and 0-Shot WSD, with results replicated using the code provided by Barba et al. (2020). Since they are not designed to create annotated training data for other WSD systems, they are not directly comparable to LABELPROP.

#### 6.3.2 Results

Table 2 presents the multilingual WSD results obtained by IMS on standard test sets. While IMS is no longer a state-of-the-art system, it is still commonly used as a benchmark for evaluating automatically generated corpora (Scarlini et al., 2019). The results demonstrate the relative quality of the generated corpora: LABELPROP is better than MuLaN on Italian and Spanish, as well as on average. The difference in performance is found to be statistically significant across all six datasets ($p < 0.05$ with McNemar’s test). Neither of the approaches outperforms the most common sense (MCS) baseline on German, which we discuss further in Section 6.3.3. The ablation results in the last two rows show that both the nearest neighbour WSD filter (NN) and the translation-based filter (KB) improve the quality of the annotations.

Table 3 presents the corresponding results using the more recent mBERT as the reference system. Our results are slightly better on average than those of 0-shot and ARES. However, only the MuLaN results are directly comparable to our LABELPROP results, as both systems produce training data for a supervised WSD reference system. LABELPROP matches or outperforms MuLaN on every dataset except German SemEval-2013, and achieves better results on average compared to the results we replicated. The difference in F-score between LABELPROP and our replicated MuLaN experiment is significant for the SemEval 2015 Italian dataset ($p < 0.05$ with McNemar’s test).

6.3.3 Error Analysis

Error analysis suggests two reasons for the relatively low results on the German data. First, English multi-word compounds often correspond to single words in German, which makes it difficult to properly propagate English sense annotations. For example, the two words in *giveaway program*, which is a translation of *Werbeprogramm*, are separately annotated with different senses. The second issue is the quality of the BabelNet translation coverage. We observe that among 69,402 BabelNet synsets, that correspond to word senses appearing in SemCor+WNG, only 40,490 synsets contain at least one German translation, compared to over 50,000 synsets in each of the other three languages.

6.4 Unsupervised Approaches

In this section, we evaluate our unsupervised methods, LABELSYNC and LABELGEN, against comparable systems.

6.4.1 Experimental Setup

We adopt UKB (Agirre et al., 2014) as the base knowledge-based WSD system used in the first step of both LABELSYNC and LABELGEN to perform the initial tagging of a bitext. (This base WSD system is not to be confused with the reference supervised WSD system that is only used for the purpose of corpus evaluation.) Following Maru et al. (2019), we use WordNet as a lexical knowledge base, enriching it with information from WNG, and syntagmatic information from SyntagNet. BabelNet is the source of multilingual lexicalization information. When applying UKB, the PPR$_{w2w}$ variant of the personalized PageRank algorithm is run separately for each word, while concentrating the initial probability mass in the senses of the context words rather than the focus word.

Both of our unsupervised methods operate on an unannotated bitext. To keep the corpus size manageable, we randomly sample 200k sentences with English, French, German, Italian, and Spanish translations from EuroSense (Delli Bovi et al., 2017) discarding its existing sense annotations. This produces four bitexts with English as one of the languages, which we align at the word level using BABALIGN. The SoftCONsTRAINT method employed by LABELSYNC to refine the initial sense annotations leverages the lexical translations. Table 1 presents the statistics of the produced corpora.

</tbody>
</table>

Table 4: WSD F-score obtained with mBERT trained on the corpora generated by LABELSYNC and LABELGEN.

The direct competitor of LABELSYNC and LABELGEN is OneSeC (Scarlini et al., 2019), an unsupervised system which produces sense-annotated data by leveraging the semantic information within Wikipedia categories. Since OneSeC can only tag nouns, any model trained on a corpus it produces will likewise only be able to disambiguate nouns. Therefore, we do not apply models trained on OneSeC to the SemEval-2015 datasets, which include verb, adjective, and adverb instances. For our multilingual experiments, we also compare to two knowledge-based WSD systems described in Section 2: UKB with SyntagNet (Maru et al., 2019), and SENSEMBERT (Scarlini et al., 2020a).

6.4.2 Multilingual Results

Table 4 presents the multilingual WSD results when using mBERT as the reference WSD system. With the consistent exception of German, the results of mBERT trained on the annotations produced by LABELSYNC are substantially better than those trained on the corpus generated by OneSeC, which is the previous state-of-the-art for unsupervised corpora tagging. Unlike OneSeC, our unsupervised methods can annotate tokens representing all parts of speech, and can therefore be applied to the SemEval 2015 datasets. LABELSYNC also outperforms both knowledge-based WSD systems, UKB+SyntagNet and SENSEMBERT, and the most common sense (MCS) baseline. LABELGEN further improves on LABELSYNC by 1.8% on average. This makes it our best performing system, which sets a new state-of-the-art on the SemEval-2013 Italian, Spanish, and French datasets.

6.4.3 English Results

In this section, we evaluate LABELSYNC on English WSD. We do not test LABELGEN on English, as it was specifically designed to tag non-English corpora. Furthermore, because OneSeC annotates only nominal instances, we conduct separate all-
7 Conclusion

We have introduced new methods to address the knowledge acquisition bottleneck in word sense disambiguation in both the semi-supervised and unsupervised settings. The methods leverage recent advances in machine translation, alignment, and contextual embeddings. Extrinsic experiments with a variety of WSD systems demonstrate that the quality of the corpora created by our methods is substantially higher compared to those produced by prior work. Our methods for automatic sense tagging can produce annotated corpora for many languages, and approach the quality of manual annotation in some cases. We make our corpora available for further research.

One advantage of our unsupervised methods is that they can be applied to annotate any bitext involving any languages. We posit that our results could be further improved by annotating corpora with broader domain coverage, or by matching the domain of the source corpus to the domain of the data to be disambiguated. We leave this as a direction for future work.

Acknowledgments

The authors of this paper are listed in alphabetical order. Yixing Luan and Arnob Mallik conducted the experiments with the semi-supervised and unsupervised methods, respectively. Bradley Hauer and Grzegorz Kondrak prepared the final version of the paper.

Abstract

In recent years, a number of studies have used linear models for personality prediction based on text. In this paper, we empirically analyze and compare the lexical signals captured in such models. We identify lexical cues for each dimension of the MBTI personality scheme in several different ways, considering different datasets, feature sets, and learning algorithms. We conduct a series of correlation analyses between the resulting MBTI data and explore their connection to other signals, such as for Big-5 traits, emotion, sentiment, age, and gender. The analysis shows intriguing correlation patterns between different personality dimensions and other traits, and also provides evidence for the robustness of the data.

1 Introduction

The notion of personality refers to an individual’s characteristic patterns of thinking, feeling, and behaving (Sherman et al., 2013). Studies have shown that personality influences an individual’s language usage (Schwartz et al., 2013b; Tucker, 1968; Hirsh and Peterson, 2009). Hence, language may reveal subtle cues about an individual’s personality. Since an individual’s personality is known to be fairly stable across long periods of time, the relation between personality and language usage is expected to be analyzable given sufficiently large amounts of textual data.

Motivation. Many people now routinely post information pertaining to their daily life, thoughts, emotions, and opinions on different online social media platforms. A number of studies have shown that such social media text may enable automated personality predictions, as reviewed in more detail in Section 2. Yet, automatic personality prediction is still a challenging problem, and there remain several unresolved issues.

First, due to privacy concerns and the high labeling cost, the number of publicly available labeled datasets is limited, and the sample size in such datasets is often rather small (especially when compared with the high dimensionality of n-gram features). Beyond this, some datasets only provide a small number of sentences per sample. These limitations make it difficult to know to what extent results in individual studies generalize across different datasets.

Second, it is non-trivial to compare results across different studies, as they adopt different feature representations and machine learning methods, and consider different personality models. Two particularly well-known personality models are Myers-Briggs Type Indicators (MBTI) and Big-5 traits, which we introduce in more detail in Section 2. In the field of personality psychology, studies have shown clear correlations between self-reported MBTI and Big-5. For instance, MBTI’s INTROVERSION–EXTRAVERSION correlates with Big-5 EXTRAVERSION, MBTI’s SENSING–INTUITION and JUDGING–PERCEIVING correlate with Big-5’s OPENNESS trait, and MBTI’s JUDGING–PERCEIVING also correlates with Big-5 CONSCIOUSNESS (Tobacyk et al., 2008).

This raises the question of whether signals from naturally occurring text exhibit similar connections, and how they relate to other psychological and demographic variables.

Goals and Contributions. The goal of this paper is thus to empirically compare personality cues at the lexical level across different datasets, personality models, and methods. In our study we focus primarily on lexical signals based on multiple MBTI datasets from heterogeneous sources, which we compare against lexical cues for Big-5 traits. Additionally, we explore connections to sentiment and emotion lexicons, as well to demographic cues.
2 Background and Related Work

Personality Models. Different models have defined different traits (sub-dimensions) of personality. Two prominent ones are the MBTI and Big-5 schemes. The Myers-Briggs Type Indicator model (MBTI) (Myers et al., 1985) consists of the following four dimensions:

1. INTROVERSION–EXTRAVERSION (I–E): where a person focuses their attention;
2. INTUITION–SENSING (N–S): the way a person tends to take in information;
3. THINKING–FEELING (T–F): how a person makes decisions;
4. JUDGING–PERCEIVING (J–P): how a person deals with the world.

Numerous concerns have been raised regarding the validity and reliability of MBTI. For instance, MBTI assumes binary categorical labels for the aforementioned four dimensions, denoted e.g. as ESTJ, although the majority of people appear to exhibit a combination of different traits along a dimension. Still, MBTI is perhaps the most widely known model, and frequently mentioned in online profiles. In contrast, the Big-5 model (Goldberg, 1990) considers continuous scores along the following five dimensions:

1. EXTRAVERSION (extroversion): describes how outgoing and social a person is;
2. AGREEABLENESS: reflects how warm, friendly, and tactful a person is;
3. OPENNESS: considers how open-minded and authority-challenging a person is;
4. CONSCIENTIOUSNESS: reflects how self-disciplined and organized a person is;
5. NEUROTICISM (emotionism): indicates a person’s ability to remain stable and balanced.

Personality Assessment. In psychological assessments, personality is typically measured by means of standardized questionnaires that evaluate particular aspects of personality. This form of personality measurement has generally been found to be fairly stable and consistent. However, a major disadvantage is that experts first need to carefully compile long lists of questions, and individuals then need to explicitly fill out the questionnaire.

This has motivated research into computational analyses of naturally occurring text with the aim of obtaining automated assessments that correlate with the professional ones. In this regard, recent studies have considered several different social media platforms and personality scales. Different models have been developed, from simple Logistic or Linear Regression ones (Arnoux et al., 2017), support vector machines (Biel et al., 2013; Kumar and Gavrilova, 2019), to more complex models such as stability selection (Plank and Hovy, 2015), Gaussian process models (Arnoux et al., 2017), and ensemble methods aggregating multiple classifiers or regressors (Kumar and Gavrilova, 2019).

Past studies have also considered different features, such as word unigrams, word n-grams (Plank and Hovy, 2015; Yarkoni, 2010; Biel et al., 2013), and word embeddings (Arnoux et al., 2017; Siddique et al., 2019). For the studies using n-grams as features, some apply TF-IDF weighting schemes (Siddique et al., 2019; Biel et al., 2013), while others use unweighted features (Plank and Hovy, 2015; Yarkoni, 2010; Kern et al., 2014).

While the above studies have mostly sought to improve the performance of personality prediction on a given dataset using a variety of different methods and features, our study focuses on assessing the contribution of individual words and n-grams as signals for personality prediction, and their relationship to other lexical cues. In previous work, a few studies have focused on broader associations between personality and aggregate word categories (Yarkoni, 2010), such as Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2001). However, this may mask the contribution of individual words in the context of an open vocabulary scenario.

Lexical Analyses. Lexicon-driven analyses have proven fruitful in areas such as sentiment analysis (Ding et al., 2008; Mohammad et al., 2013; Kiritchenko et al., 2014; Islam et al., 2020) and emotion analysis (Kulahcioglu and de Melo, 2018; Raji and de Melo, 2020; Raji and de Melo, 2021), especially when there is no labeled data, as well as in social science and digital humanities (Pennebaker et al., 2001). With this approach, a dictionary of words (or bag of words) is generated, with a positive or negative value assigned to each word, reflecting the predictive power or correlation strength between the word and the specific target label or variable. Sap et al. (2014) explored lexical cues for age and gender. In traditional personality research, psychologists have developed closed-book vocabularies by self-rating on personality trait adjectives or verbs (Ashton et al., 2004b,a).

In light of the above, exploring automatically
induced lexical cues for personality prediction is a promising endeavor, and the resulting lexical signals can also be compared with lexical cues for other variables.

3 Lexical Cue Induction

In order to determine which words and n-grams are most correlated with specific personality variables, we assume a supervised learning setup with labeled training data that allows us to train a separate linear model for each target variable and identify salient lexical cues along with their weights. We compare several different variants with different feature representations and learning algorithms.

3.1 Feature Representations

Data Preprocessing. Our study considers only the linguistic information for each sample, along with the personality type labels, ignoring multimodal signals and metadata. The text is tokenized and the following preprocessing steps are applied:
1. Lower-casing;
2. Removing English stop words, tokens consisting only of numbers, and tokens mentioning personality types;
3. Replacing URLs, hashtags, usernames with ‘@URL’, ‘@HASHTAG’, ‘@USER’.

Feature Extraction. We extract unigram, 1-2 gram (unigram + bigram), and 1-2-3 gram (unigram + bigram + trigram) feature sets for each of the datasets. Due to the combinatorial explosion of n-grams, we apply a minimum frequency threshold, dropping any n-grams appearing less than 1% in each dataset. We further exclude tokens that consist solely of numbers. For the 1-2 grams and 1-2-3 grams, we also exclude tokens with punctuation in the first character or in the middle, such as (‘!’, ‘I’), (‘today’, ‘!’, ‘I’), (‘!’, ‘today’, ‘!’).

N-gram Weighting. Weighting is often used to adjust the importance of individual features. Besides using n-grams directly, we also used three types of weightings for each n-gram:
1. Relative term frequency, \( f_{\text{rel}}(w, d) = \frac{\text{freq}(w, d)}{\text{freq}(s, d)} \), is defined as the relative term frequency (TF) of a word \( w \) within a document \( d \).
2. TF-logIDF is a common definition of Term Frequency-Inverse Document Frequency (TF-IDF) weighting that incorporates a logarithmic scaling of IDF to dampen the effect of the ratio. In general, TF-IDF representations downweight words that appear universally across many documents, as these are less likely to be sufficiently discriminative in personality prediction.
3. TF-IDF differs from the above form in that we omit the logarithmical scaling of IDF.

3.2 Learning Algorithms

Linear models have often been used to induce weighted lexicons. Sap et al. (2014) compared the formula of linear multivariate models \( y = (\sum_j w_j x_j) + w_0 \) (summing over features \( f \)) with the use of a weighted lexicon \( L \) with term weights \( w_L(t) \) that is applied to a document \( d \) with frequencies \( f(t, d) \) as \( \sum_{t \in L} w_L(t) f(t, d) \). They prove that if relative term frequency is used as the feature representation, many multivariate modeling techniques can be viewed as learning a weighted lexicon plus an intercept.

Hence, the weight of a word in a lexicon can be obtained based on the coefficients from linear multivariate models. We thus treat each personality dimension as a distinct and independent classification or regression problem. For each combination of feature and weighting, we investigate four types of learning algorithms.

Stability Selection. In stability selection (Meinshausen and Bühlmann, 2010), the training data is repeatedly resampled in a bootstrap operation, and a model is learned for each such iteration, and features selected more frequently are presumed to be more robust indicators. As the base model, we use randomized logistic regression for MBTI datasets, and Randomized Lasso for the Big-5 dataset. We run 100 resampling procedures, such that on each resampling, 75% of the samples are randomly chosen. After the step of stability selection, we apply logistic regression for MBTI (linear regression for Big-5) on the selected features (n-grams), and save their coefficients.

Penalized Ridge Classification/Regression. We further consider Ridge Regression, i.e., linear least squares regression with L1 regularization. For MBTI, we apply Ridge Classification, i.e., the target classification is mapped to \( \{-1, 1\} \) so as to cast the problem as a regression task. The L1 penalty encourages sparse features, which is well-suited for our goal of identifying salient lexical cues. We split each dataset into training set and test set randomly with a ratio of 3:1 (also using...
the same ratio for the following two approaches).

**Penalized Support Vector Classification with Linear Kernel.** Support vector machines are well-suited for high-dimensional vector representations. Considering the high dimensionality and sparsity of our feature space, we consider support vector classification/regression with a linear kernel and L1 penalty in a 10-fold cross-validation setup.

**Penalized Multi-Layer Perceptrons.** Lastly, to better account for non-linearly separable data, we consider a feed-forward neural network with a 100-dimensional hidden layer and RelU activation function, trained using Adam optimization with an initial learning rate of 0.001.

## 4 Lexical Cue Analysis

In the following, we empirically assess lexical cues induced using the aforementioned techniques.

### 4.1 Datasets

Our analysis is based on 8 MBTI datasets and one Big-5 dataset, all consisting of naturally occurring English language text annotated with personality traits. For the former, we illustrate the respective data distributions in Figure 1. In particular, kaggle refers to the Kaggle Personality Cafe MBTI dataset, which provides 8,600 samples collected from the discussion forums of the Personality Cafe website. The Twitter datasets twitter_100g, twitter_500g, twitter_2000g are obtained from Plank and Hovy (2015). Each such dataset contains 1,500 samples, but they differ in the number of tweets per sample (100, 500, or 2,000). The reddit dataset is taken from Gjurković and Šnajder (2018), and provides 9,149 rows of comments from different Reddit authors with more than 1,000 words each. Due to the computational burden of the feature computation for bi- and tri-grams, we additionally also consider splits into smaller subsets (reddit0, reddit1, reddit2), which are mainly used for analysis (see the next section for further details).

Figure 1 shows the distribution within each dimension in the different MBTI datasets. For each dimension, the first type is coded as 0, and the second type is coded as 1. For example, for I–E, INTROVERT is represented as 0, and extravert is represented as 1. Figure 1 shows that, overall, each dataset has more INTROVERT and THINKING individuals. It has been reported that INTROVERT individuals prefer online communication (Plank and Hovy, 2015; Goby, 2006), though this overrepresentation may also have other causes. Interestingly, there are some differences between users in the different datasets. The Reddit data has more INTUITIVE users, while the Twitter data has more JUDGING users. The Reddit data includes slightly more users with the THINKING trait than the Twitter dataset.

![Figure 1: MBTI distribution on each dataset, where the dimensions I–E, N–S, T–F, and J–P are each mapped from 0 to 1](image)

We only considered a single Big-5 dataset, based on YouTube video blogs (Biel et al., 2013). The texts are the manually created transcripts, and the Big-5 score is not self-reported but rather the impression score assigned by a separate group of subjects, unlike most other datasets in our study.

### 4.2 Prediction Quality of Different Models

The prediction accuracies obtained for each combination of feature, weighting scheme, and model are given in Table 1, for each dimension of MBTI. The three numbers in a given cell represent the results from the three different weighting schemes: relative frequency, TF-logIDF, TF-IDF. Note that, owing to scalability considerations for trigrams, the 1-2-3 gram feature set was only considered for stability selection.

The results suggest that 1) the accuracy is fairly similar across different weighting schemes; 2) the accuracies consistently increase from unigrams to 1-2 grams, but only modestly with 1-2-3 gram features. We additionally plot the results using 1-2 grams weighted by TF-logIDF for each method in Figure 2. Each sub-figure shows the results from one model. Within each sub-figure, different bars indicate the results for different personality dimensions. Figure 2 conveys the following two messages: First, it shows that for the three linear models with penalty, dimension N–S obtains the highest accuracy, I–E the second highest, while J–P
and T–F exhibit lower accuracies, which are close to the baseline. This is consistent with the previous literature in that word usage usually has reliable predictions along INTROVERT—EXTRAVERT and SENSATION—INTUITION scales (Plank and Hovy, 2015; Kumar and Gavrilova, 2019), while showing worse performance on JUDGING–PERCEIVING and THINKING–FEELING.

Second, we observe that the performance of ridge regression, SVMs, and MLP are fairly consistent on different datasets. They perform better with the Reddit datasets, in comparison with the last three Twitter datasets. This may be due to the fact that the Reddit datasets have more samples (3,000 for reddit0/1/2 and 9,000 for reddit), while the Twitter datasets only have 1,500 samples. Additionally, the Reddit datasets have more words for each record. The high level of performance on the Kaggle Personality Cafe dataset (with its 8,600 samples) also accords with this hypothesis.

Overall, through our experiments on different datasets, we find that applying linear models on n-gram features consistently obtain fairly reliable predictions on at least two dimensions of MBTI, namely I–E and N–S. We have also run correlation analyses between each of two lexicons for the same dimension, and the results shows good correlation across different datasets and models. With the consistent performance across different models, we can confidently proceed to procure more robust lexicons across different datasets and methods.

### 4.3 Selecting Top-Ranked Features for MBTI

For each MBTI dimension, we have ~249 n-gram coefficient sets based on different datasets, features, weightings, and models. We select a small set of top-ranked lexical cues for each such dimension:

1. First, within each such lexicon, we normalize the coefficients using z-scores (enabling us to better compare them across different models).
2. Then, we sort the n-grams with the absolute values of their z-scores, and choose the top 75% n-grams – such that we obtain a subset \( X_i \) for each original set of features.
3. For each n-gram in \( X_i \), we calculated the term frequency across all feature sets, as well as the average z-scores, and chose the n-grams that appear in at least 60% among all sets.
4. Eventually, only the n-grams retained after the last step as well as their average z-score serve as the final set of weighted lexical cues for the dimension under consideration.

With the above procedure and the two filtering steps, we select small sets of top-ranked 79, 27, 124, 85 n-grams for I–E, N–S, T–F, J–P. Note that N–S has much fewer words, so we adjusted the thresholds in steps 2 and 3 (grid search in the two dimensional space with a step of 0.01), eventually using (0.8, 0.58) to obtain 85 n-grams for N–S.

Table 2 shows the top individual words for each dimension. Interestingly, it reflects certain stereotypical characteristics of each personality type. For example, EXTRAVERT individuals have more positive words such as *lol*, *haha*, *surprise*, while IN-

TROVERT uses words expressing uncertainty such as awkward, probably, introvert. SENSING individuals focus on physical reality, while INTUITIVE individuals are driven by thoughts. Accordingly, the top words for S are concrete, such as soccer, jeans, cards, while for N they are more abstract, such as writing, science, proof. For F–T, the FEELING type has more adjectives describing feelings, e.g., wonderful, incredible, admirable, beautiful, while the THINKING type has words such as suppose, tastes, fix. For J–P, the words also reflect common stereotypes: career, passion, management, husband shows JUDGING individuals are more plan, work, and family oriented. Finally, the PERCEIVING type appears to use more words expressing feelings, such as sigh, jealous, wtf.

5 Correlation Analyses

Given the aggregated weighted lexical cues induced for each MBTI dimension, we seek to assess correlations with extrinsic lexical data covering a series of different phenomena.

5.1 Comparing Personality Models

The first interesting and straightforward comparison is between MBTI and Big-5.

First, we applied the same experiments on the YouTube dataset by Biel et al. (2013), so as to induce similar Big-5 signals, denoted as YouTube-B2013. Then, we ran Pearson correlation analyses comparing the two. We also compared our MBTI data with a well-established YouTube lexicon from Schwartz et al. (2013b), denoted as YouTube-S2013. The correlation results are given in Table 3. The analysis shows significant correlations between I–E and four dimensions of Big-5. J–P shows strong correlations with Agreeableness, Conscientiousness, Extraversiveness, Openness. T–F has a strong correlation with Agreeableness. Compared to Tobacyk et al. (2008), we have found more correlations between the two scales. In the personality literature in psychology, strong correlations have been found between Big-5 and MBTI. Most of the correlations found here can find support in psychology. The values given in brackets denote results that accord with significant correlations found in the psychology literature (Furnham, 1996).

The correlation between MBTI lexicons and our induced Big-5 lexicon (YouTube-B2013) is found to be much weaker. This is because this Big-5 lexicon is only based on one dataset (Biel et al., 2013), and that dataset has only around 400 samples.

5.2 Correlation with Emotion and Sentiment

Personality influences an individual’s emotions, opinions, and behaviours. This motivates us to study the relationship between MBTI cues and other psychological lexicons, such as sentiment and emotion ones. Little work has been conducted on the correlation between personality and emotion, but the definitions of the MBTI dimensions suggest a possible connection.

We retrieved several emotion and sentiment lexicons and computed their correlation with our data in Table 4. The first four lexicons (Mohammad, 2017) focus on four basic affective categories from the Plutchik model (Plutchik, 1980): anger, fear, joy, and sadness. Only J–P has a positive correlation with fear and sadness, while T–F has a positive correlation with joy. This suggests that the FEELING type tends to use more joy-related words, while PERCEIVING individuals tend to use more fear and sadness related words. The next three lexicons (Mohammad, 2018) are based on the PAD model (Russell and Mehrabian, 1977), which conceptualizes emotion along three dimensional axes – arousal, dominance, and valence. We observe that I–E has significant positive correlations with all three dimensions, reflecting that EXTRAVERTs focus more on outside stimuli, and tend to have more emotional reactions. J–P and N–S are negatively correlated with dominance, meaning that the JUDGING and INTUITION types exhibit higher dominance – i.e., more stability. These two types perhaps also tend to analyze and give solutions, while SENSING and PERCEIVING individuals exhibit stronger feelings, which leads to lower dominance. T–F shows positive correlation with valence – suggesting that the FEELING type may have more emotional reactions.

As personality affects an individual’s way of writing and talking, we further hypothesize that people with the same personality may tend to use expressions with similar sentiment. Thus, we also compare our MBTI data with three sentiment lexicons: Ding et al. (2008), NRC (Mohammad et al., 2013), Twitter (Kiritchenko et al., 2014), and VADER (Hutto and Gilbert, 2014). Both I–E and T–F show positive correlations with sentiment, while J–P shows a negative correlation. This suggests that EXTRAVERT, FEELING, and JUDGING types may tend to have more positive sentiment. Lin et al. (2017) developed a Big-5 personality-based sentiment classifier and argue that it performs better than an ordinary sentiment classifier, providing further corroboration for a potential correlation between personality and sentiment analysis.

5.3 Correlation with Demographic Signals

Twitter and Reddit have large user bases, including different gender and age groups. We study potential correlations between these two demographic features and the MBTI dimensions, relying on the age and gender lexicons by Sap et al. (2014), as well as the age-specific gender lexicons by Schwartz et al. (2013a). The correlations are reported in Table 5. Only J–P has a negative correlation with the age lexicons. It appears plausible that older individuals might rely more on judgement than perception.

The two general gender lexicons gender and gender (1-2-3-grams) show that I–E has a slightly negative correlation with gender, J–P has a strong correlation, while N–S and T–F have moderate positive correlations with gender. Note that for the gender lexicons, male is here treated as negative, and female as positive, and the two lexicons fail to account for other gender identities. The correlation analysis is consistent with the stereotypes that female users tend to use more words about feelings (F) and are more sensible (S) in general. However, it is interesting to see that female users are found to be more JUDGING. When we control for age group, most correlations between gender and personality disappear, and only J–P showed strong positive correlation with gender in the age group 13 to 18, and negative correlation in age group 23 to 29.

6 Conclusion

We have inferred personality predictive lexical signals, i.e., words and n-grams along with their weights, for each MBTI dimension. The data is induced based on several diverse MBTI datasets, using a variety of feature sets, weighting schemes, and learning algorithms. Our focus here is on identifying correlations with other kinds of cues, including Big-5 data, as well as emotion, sentiment, and gender-predictive lexicons. We show that naturally occurring text harbors subtle cues exhibiting correlations that largely accord with findings from psychology on self-reported personality correlations. This provides further evidence for the validity of drawing on such naturally occurring data for automated lexical cue induction.
Ethical Statement

It is important to keep in mind that all results presented here are highly dependent on the characteristics of the respective datasets and on the lexicon induction methodology. As shown in Section 4.1, different datasets provide data from different sources, leading to biases both in the kinds of textual content they provide and in the label distributions. Additionally, using automated predictors for lexicon induction tends to lead to signals reflective of particularly stereotypical cues, and linear models are unable to account for the particular context of a particular word mention. Thus, the particular word-level correlations observed in this study do not entail that such correlations also hold among people exhibiting a particular trait. Last but not least, mere correlations such as those considered in this paper do not license conclusions about particular individuals or groups of individuals, and any studies attempting to predict the personality of individuals or groups of individuals would need to consider a large number of very serious ethical and privacy concerns.

Abstract

Semantic textual similarity (STS) systems estimate the degree of the meaning similarity between two sentences. Cross-lingual STS systems estimate the degree of the meaning similarity between two sentences, each in a different language.

State-of-the-art algorithms usually employ a strongly supervised, resource-rich approach difficult to use for poorly-resourced languages. However, any approach needs to have evaluation data to confirm the results. In order to simplify the evaluation process for poorly-resourced languages (in terms of STS evaluation datasets), we present new datasets for cross-lingual and monolingual STS for languages without this evaluation data. We also present the results of several state-of-the-art methods on these data which can be used as a baseline for further research.

We believe that this article will not only extend the current STS research to other languages, but will also encourage competition on this new evaluation data.

1 Introduction

Recently, research in natural language understanding is moving beyond monolingual solutions (Wada et al., 2019; Conneau and Lample, 2019; Lin et al., 2019). However, any solution needs some kind of evaluation data. The common source of evaluation data for semantic meaning comparison are the STS tasks from SemEval workshop.

The STS task has a long history at SemEval workshops. Since 2012 till 2017 the STS task has been held annually creating a considerable amount of evaluation datasets. However, most of these datasets are in English and Spanish.

This has led us to the creation of new cross-lingual evaluation data for STS because all algorithms need verification e.g. on evaluation data.

The evaluation data consist of pairs of sentences and the degree of their semantic similarity.

This paper presents new STS datasets and thorough experiments using linear transformations for cross-lingual STS. We see four main contributions of our work:

• We show an overview of the existing cross-lingual STS datasets.
• We present newly created datasets for both cross-lingual and monolingual STS.
• We extend experiments for previously published methods replicating the results and validating the conclusions.
• We present initial experiments and provide baseline results on the new datasets.

2 Related Work

This section presents related datasets for STS with main focus on cross-lingual datasets.

Even though most of the datasets is in English and Spanish, there are also available monolingual datasets in Arabic and Czech.

The cross-lingual datasets are also quite focused on English and usually one side of the sentence pair is in English. In summary, the cross-lingual datasets are available in English paired with Arabic, Croatian, Czech, Italian, Spanish, and Turkish. More detailed overview of these datasets can be found further in this section.

In Section 3, we present datasets for both monolingual and cross-lingual STS in Czech, English, French, and German.

• SemEval 2012: Agirre et al. (2012) introduced the shared task competition in English. They provided five datasets (paraphrase sentences MSRpar, video descriptions MSRvid,
automatically translated sentences MTnews and MTeuroparl, and gloss pairs OnWN) consisting of 2234 training sentence pairs, 3108 testing sentence pairs, and 6 trial pairs. Gluvaš et al. (2017) translated one side (750 sentences each) of two English monolingual datasets (MSRvid and OnWN) from SemEval 2012 task 6 to Spanish, Italian, and Croatian.

• SemEval 2013: Agirre et al. (2013) continued with English STS core task. The whole dataset contains 2250 test and 20 trial new sentence pairs from four datasets (news Headlines, mapping of lexical resources OnWN and FNWN, machine translation evaluations SMT). They also introduced typed similarity task for predefined types (e.g. author, location, subject and description).

• SemEval 2014: Agirre et al. (2014) divided the task into two subtasks one for English (3750 sentence pairs) and the other for Spanish. The English data contains image descriptions (Images), news headlines (Headlines), gloss pairs (OnWN), news title and tweet comments (Tweet-news), discussion forum and news (Deft-forum and Deft-news). The newly introduced Spanish dataset contained 480 sentence pairs from Wikipedia, 324 sentence pairs from Google News and 65 trial sentence pairs.

• SemEval 2015: Agirre et al. (2015) continued with both English (3000 test pairs, 70 trial pairs) and Spanish (751 pairs) subtasks and newly introduced an interpretable STS subtask. The interpretation is evaluated on the alignments of sentence pairs. The English dataset contains image descriptions (image), news headlines (headlines), student and reference answers (answers-students), answers from exchange forums (answers-forum), and discussion forum comments (belief).

• SemEval 2016: Agirre et al. (2016) proposed two Spanish-English datasets in SemEval 2016 task 1. One consists of news headlines News (301 sentence pairs) and the other contains sentences from multiple sources including news headlines, question-answering, plagiarism detection, etc. Multi-source (294 sentence pairs). Gluvaš et al. (2017) translated Spanish sentences from both datasets to Italian and Croatian.

• SemEval 2017: Cer et al. (2017) introduced four cross-lingual datasets and three monolingual datasets. Each dataset contains 250 sentence pairs and the data source is Flickr30k image captions (Young et al., 2014), except Track4b which is based on data from WMT 2014 quality estimation task (Bojar et al., 2014). The cross-lingual dataset contains the following language pairs: Spanish-English (Track4a and Track4b), Arabic-English (Track2), and Turkish-English (Track6). The monolingual dataset consists of English (Track5), Spanish (Track3), and Arabic (Track1).

• Czech STS: Svoboda and Brychcín (2018) translated the English Images and Headlines parts of the dataset from SemEval 2013 - 2015 resulting in a dataset of 575 pairs of news headlines and 850 pairs of image descriptions. However, the links to the English dataset were not preserved leaving us only with a Czech monolingual dataset.

Table 1: Number of tokens for each dataset.

We used the English monolingual dataset (Track5) from SemEval 2017 task 1 (Cer et al., 2017) to create new evaluation data for Czech, French and German.

We translated (using Google Translate) and then manually checked both sides of 250 pairs from the English STS dataset from SemEval 2017 (Track5) into Czech, French, and German.

The translations were manually checked by two upper intermediate (B2) level speakers of the given language in case of French and German and native speakers of Czech. We also asked them to preserve the meaning of the translation as much as possible in relation to the semantic similarity score.

We assume that the translated pairs preserve the same semantic similarity score. The resulting
dataset thus contains monolingual and cross-lingual datasets for all language pairs.

Table 1 shows number of tokens in a dataset per side (part) of the evaluation pair.

The dataset consisting of 2000 sentences is available for research purposes at https://gitlab.com/tigi.cz/cross-lingual-sts.

Each file contains one sentence per line. The STS evaluation pair consists of the first and second part (sentence) each stored in a separate file. The semantic similarity score is located in the gold score file. The lines in all files correspond with each other. To get the evaluation data for e.g. EN-CS load the file STS.2017.input.track5.EN.first.txt and STS.2017.input.track5.CS.second.txt and the gold standard in file STS.2017.gs.track5.first-second.txt.

This new resource consists of four monolingual datasets and twelve cross-lingual datasets.

4 Experiments

We follow Brychcín (2020) who used bilingual dictionaries and a new transformation for word level semantic representations which reduces hubness in semantic spaces. He also evaluated his methods on several STS datasets including cross-lingual.

The transformations of semantic spaces and combinations of word representations are too complex and beyond the scope of this short paper, for a thorough description of these methods please refer to the original publication.

In the replicated experiments on new datasets we use monolingual semantic spaces transformed into a unified space using bilingual dictionaries. STS performance is measured by the Pearson correlation between automatically estimated scores and human judgments.

Our experiments start with building monolingual semantic spaces for each of tested languages, namely, Czech (CS), German (DE), English (EN), and French (FR). For all languages we use character-n-gram-based skip-gram model (Bojanowski et al., 2017) pre-trained on Wikipedia1.

For each language, we construct the vocabulary from 300k most frequent words. We estimate IDF weights on the Wikipedia corpus for every language. Each Wikipedia article represents a document.

The bilingual dictionaries between each pair of languages are created from the 20k most frequent words in the corpus using Google translate.

The global post-processing techniques for semantic spaces used by Brychcín (2020) consist of two steps column-wise mean centering and word vector normalization to unit vectors. This guarantees that all word pairs in the dictionary contribute equally to the optimization criteria of the linear transformation. We always apply this post-processing for both semantic spaces before the linear mapping.

4.1 Linear Transformations

We experiment with the following five techniques for linear mapping to transform the semantic spaces. For detailed description of these methods please see (Brychcín, 2020).

- Least Squares Transformation (LS)
- Orthogonal Transformation (OT)
- Canonical Correlation Analysis (CCA)
- Ranking Transformation (RT)
- Orthogonal Ranking Transformation (ORT)

4.2 Word Combinations

Semantic textual similarity is estimated by combining word representations by Linear Combination (LC), Principal Angles (PA)2, and Optimal Matching (OM)3. We evaluate both uniform weighting (for mutual comparison with original methods) and IDF weighting in all three STS approaches.

RT and ORT require special settings to work properly we use the same settings as Brychcín (2020).

4.3 Results

Table 3 shows the mean Pearson correlations for each linear transformation combined with different STS techniques on the created cross-lingual STS datasets. We can state our results support the claims by Brychcín (2020). ORT outperformed other transformations independently of STS technique. IDF weighting boosts the correlations in all cases and together with OM yields the best performance.

In Tables 2, and 4 we show correlations achieved by the best settings, i.e., OM with IDF weighting. In table 2 we compare our results with the top performing system ECNU (Tian et al., 2017) and

</table>

with SemEval baseline (Cer et al., 2017). Note that the EN-EN is equal to the one achieved by Brychcín (2020) and thus validates our implementation.

In Table 4 we can see the mean Pearson correlations over language pairs. The worst results were achieved on DE-Fr and CS-Fr which is not surprising as they are distant language families (Slavic-Romance and Germanic-Romance). In general, French appears to be the most difficult to understand the meaning compared to other language combinations in this dataset.

The linear mapping techniques are sorted by their performance e.g. OT outperforms LS and CCA. The best performing setting is Orthogonal Ranking Transformation and Optimal Matching with IDF weighting.

5 Conclusion and Future Work

In this paper we presented new STS datasets for both cross-lingual and monolingual STS and provided them to the research community. We extended experiments of previous work on STS using linear transformations to create cross-lingual semantic spaces, by conducting initial experiments on the newly created datasets. We confirmed the findings of Brychcin (2020) by replicating three (previously published) approaches to combine information from word representations.

The used STS system does not require sentence similarity supervision and the only cross-lingual information is a bilingual dictionary. In the future, we intend to investigate the use of unsupervised methods to create the bilingual dictionary.

Abstract

The number of biomedical documents is increasing rapidly. Accordingly, a demand for extracting knowledge from large-scale biomedical texts is also increasing. BERT-based models are known for their high performance in various tasks. However, it is often computationally expensive. A high-end GPU environment is not available in many situations. To attain both high accuracy and fast extraction speed, we propose combinations of simpler pre-trained models. Our method outperforms the latest state-of-the-art model and BERT-based models on the GAD corpus. In addition, our method shows approximately three times faster extraction speed than the BERT-based models on the ChemProt corpus and reduces the memory size to one sixth of the BERT ones.

1 Introduction

The amount of biomedical documents is increasing rapidly. The documents contain valuable knowledge, such as chemical compound names and their relations. However, the current knowledge extraction is considerably manual. Therefore, a demand for extracting knowledge automatically from large-scale biomedical text data is increasing.

Biomedical relation extraction (RE) models based on BERT (Devlin et al., 2019) have shown great performance (Lee et al., 2019; Beltagy et al., 2019). The methods using BERT models pre-trained on biomedical corpora achieved state-of-the-art (SOTA) performance on several biomedical RE datasets. However, BERT models require a huge amount of computational resources and generally need a long time for extraction processes. By processing data in parallel with multiple computational resources, we can process larger text as compared with a single resource. However, a high-end GPU or a distributed environment for efficient computation is not available in many situations. Even if we can utilize such computational resources, substantial energy consumption becomes a problem (Strubell et al., 2019). Therefore, more lightweight and accurate RE models are expected.

In this paper, we construct a biomedical RE model by combining word embeddings obtained from multiple lightweight models. The RE model can be executed in a wide range of environments, such as a CPU and a middle-class GPU, by reducing memory consumption during the learning process or the inference process. During the inference process of our proposed model, the amount of calculation can be suppressed and the model can process documents at high speed. Since the calculation in each lightweight model is small scale, memory consumption can be suppressed. Furthermore, by selecting whether or not to utilize each word embeddings, we can customize the model to be suitable for the computer environment. Hence, our model can process faster than the BERT-based models in the inference process.

We adopt more lightweight pre-trained models: ELMo (Peters et al., 2018) and Contextual String Embeddings (CSE) (Akbik et al., 2018). ELMo is contextualized word-level embeddings from the language model (LM) based on multiple layers of bidirectional long-short term memories (Bi-LSTMs) (Hochreiter and Schmidhuber, 1997). On the other hand, CSE is character-level embeddings of each input word from LM based on single-layer Bi-LSTM. Subword information of words plays an important role in the estimation of kinds and features of chemicals since chemical names tend to contain characteristic sub-word patterns such as prefixes and suffixes. Therefore, we propose RE models that combine ELMo and CSE to utilize both word-level and character-level features effectively.

We investigate the effectiveness of our RE mod-
els in terms of not only the accuracy but also the processing speed and the memory size. The contributions of this paper are as follows:

- We apply the strategy that feeds the complementary features from pre-training models to RE tasks in the biomedical domain: GloVe, ELmo, and CSE.
- The proposed model outperforms the latest SOTA F1 score on the GAD corpus. As a case study, we show that BERT-based models do not always produce the best performance.
- Our model performs approximately three times faster extraction speed than BERT-based models on the ChemProt corpus and reduces the memory size to one sixth of the BERT ones.

## 2 Related Work

Beltagy et al. (Beltagy et al., 2019) have proposed a method with pre-trained the BERT model called SciBERT. They pre-trained the BERT model on the large scale computer science and biomedical corpora. They constructed a new vocabulary of the BERT model for the tasks of science and biomedical domains. The SciBERT model with their vocabulary achieved SOTA performance on several benchmark tasks on the domains. Lee et al. (Lee et al., 2019) have proposed a model called BioBERT. They pre-trained the BERT model on a large scale biomedical corpus containing 4.5 billion words. They applied the model to biomedical NER, RE, and question answering tasks and achieved high performance on the benchmark tasks. For the RE tasks, they utilized the sentence classifier of the original version of BERT, which uses a [CLS] token for the classification of relations. They used pre-defined strings such as @GENE$ and @DISEASE$ to express a pair of target entities. For instance, a sentence with two target entities (gene and disease in this case) is represented as **Example 1**.

**Example 1** Serine at position 986 of @GENE$ may be an independent genetic predictor of angiographic @DISEASE$.

Zhou et al. (Zhou et al., 2016) have proposed a relation classification model with an attention-based Bi-LSTM model. They used pre-defined indicator tags to express a pair of target entities. For instance, a sentence with a pair of target entities is represented as **Example 2**.

**Example 2** <e1> Flowers </e1> are carried into the <e2> chapel </e2>.

Entity pairs were anonymized using the predefined strings in the method of Lee et al. (Lee et al., 2019). In contrast, this model can predict a relation class using surface information of the target entity pair. Sub-word information such as prefixes and suffixes plays an important role in estimations of kinds and features of chemicals. Therefore, we express the entity pair using tags in our method.

BERT is constructed by multiple layers of multi-head self-attention layers and requires large-scale computational resources. More lightweight pre-training LM models have also been proposed. Jin et al. (Jin et al., 2019) have proposed models for biomedical NLI tasks using ELMo pre-trained on large-scale in-domain text data. ELMo is an LM based on multi-layer Bi-LSTMs for aiming at obtaining contextualized word-level embeddings. CSE is generated by a character-level LM. The LM is lightweight since it is constructed with a single layer of Bi-LSTM. Sharma et al. (Sharma and Daniel Jr, 2019) have proposed a biomedical NER method with CSE generated from the LM pre-trained on a biomedical corpus. Watanabe et al. (Watanabe et al., 2019) have proposed a method with a multi-task learning model using CSE. Their method achieved SOTA performance on the biomedical NER task. Sharma et al. and Watanabe et al. evaluated the effectiveness of CSE on the biomedical NER tasks. However, they did not evaluate the effectiveness of CSE on the biomedical RE task. We evaluate the effectiveness of ELMo and CSE on the biomedical RE tasks.

## 3 Proposed Method

Figure 1 shows an overview of our method. We incorporate three types of word embeddings into the RE model: GloVe (Pennington et al., 2014),
CSE, and ELMo. First, we train a character-level LM for CSE and a word-level LM for ELMo using large-scale biomedical corpora. Then we obtain GloVe, CSE, and ELMo vectors corresponding to each word in a sentence as shown in the middle of Figure 1. Next, we construct an RE model as shown in the top of Figure 1. We explain the pre-training procedure for the GloVe embeddings and the language models for ELMo and CSE vectors in Section 3.1. Then, we explain the RE model based on the combinations of multiple word embeddings in Section 3.2.

### 3.1 Pre-Training

We obtain word embeddings by concatenating GloVe, CSE, and ELMo vectors for training and extraction. We use the GloVe embeddings trained on general domain corpora (the Wikipedia and the Gigaword corpus). For pre-training the CSE language model, we use the PubMed, the PMC, and the ChemRxiv datasets. The data from PubMed, PMC, and ChemRxiv contain 190K, 270K, and 300K biomedical papers, respectively. We use the ELMo embeddings trained on the PubMed corpus.

### 3.2 Relation Extraction Model

For the RE task, we apply a Bi-LSTM with an attention model (Zhou et al., 2016). The relation extraction model outputs a predicted class label. Here, we express the stacked embeddings as \( X = x_1, x_2, ..., x_n \). The predicted class label is computed as follows:

\[
\begin{align*}
\overrightarrow{h_i} &= LSTM(x_i, \overrightarrow{h}_{i-1}) \\
\overleftarrow{h_i} &= LSTM(x_i, \overleftarrow{h}_{i+1}) \\
h_i &= [\overrightarrow{h_i}; \overleftarrow{h_i}]
\end{align*}
\]

where \( x_i \) is the i-th input vector. \( \overrightarrow{h_i} \) and \( \overleftarrow{h_i} \) are hidden states of the forward LSTM and backward LSTM, respectively. \([::]\) indicates concatenation of two vectors. We calculate a weight \( a_i \) for each hidden state \( h_i \) as follows:

\[
\begin{align*}
m_i &= \omega^T \tanh(h_i) \\
a_i &= \frac{\exp(m_i)}{\sum_{j=1}^{n} \exp(m_j)}
\end{align*}
\]

where \( \omega \) is a vector of trainable parameters. We obtain the final hidden state \( h^* \) as follows:

\[
\begin{align*}
r &= \sum_{i=1}^{n} a_i h_i \\
h^* &= \tanh(r)
\end{align*}
\]

Then, the model calculates a predicted label \( \hat{y} \) as follows:

\[
\hat{y} = \arg \max_{y} P(y|X)
\]

During training, we use the loss function:

\[
Loss_{RE} = -\frac{1}{N} \sum_{i=1}^{N} \log(p(y_i|X))
\]

where \( N \) is the number of class labels.

We use an SGD optimizer (Bottou, 1991). We set parameters as follows: a learning rate is 0.1, a batch size is 32, and the number of hidden units is 256.

### 4 Experimental Settings

#### 4.1 Dataset

We use the Genetic Association Database (GAD) (Bravo et al., 2015) and the Bio-Creative VI Chemical-Protein RE dataset (ChemProt) (Islamaj Doğan et al., 2017) as RE datasets to evaluate our model. Table 1 shows the statistics for each dataset.

result shows the effectiveness of LMs pre-trained on the biomedical corpora.

For the GAD dataset, the Proposed3 showed the best performance. It outperformed SciBERT, BioBERT, and E-SVM. For the ChemProt dataset, although this method also outperformed SPINN, the previous SOTA method, it did not reach the scores of SciBERT and BioBERT.

Another approach to improve the accuracy is to incorporate a BERT model with our combination models. We also attempted to incorporate the BERT embeddings generated by the BioBERT model into our model although the result is not documented in Table 2. However, all the methods combining BERT embeddings (GloVe+BERT, GloVe+ELMo+BERT, GloVe+CSE+BERT, and GloVe+ELMo+CSE+BERT) resulted slightly lower performance than BioBERT. In addition, the models with BERT embeddings lead to vanishment of the effectiveness and motivation, namely construction of a lightweight model.

### 5.2 Evaluation on Processing Speed

Table 3 shows the extraction time of the proposed methods, SciBERT, and BioBERT for processing the test set of ChemProt. The F1 score of the Proposed3 was approximately 6 points lower than BioBERT. However, the extraction speed was 2.85 times faster than that of BioBERT. Although the F1 score of the Proposed1 was approximately 8 points lower than the Proposed3, the extraction speed was 2.76 times faster than that of the Proposed3. We can see a trade-off between the F1 scores and the extraction speed. If users need the extraction speed for the application, our method is useful although the accuracy is comparatively sacrificed.

### 5.3 Evaluation on Memory Size

In the experiment, we used NVIDIA Tesla V100 GPU with 32GB memory. This is the high-end GPU for data center use at present. We observed the maximum memory consumption during the learning execution of BioBERT and the proposed method. BioBERT consumed approximately 12GB of memory. It indicates that BioBERT needs high-end GPUs to execute the learning. On the other hand, our method consumed approximately 2GB of memory. The memory consumption of our method was lower than that of BioBERT (1/6). In addition, considering the memory consumption, we believe that our model can be executed even on a middle-class GPU.

### 6 Discussion

We showed the effectiveness of our method in the previous section. In this section, we discuss our method from various perspectives, including some negative results. First, we discuss a comparison between the BERT-based models and the proposed method in Section 6.1. Then, we discuss the experimental settings of the proposed method in Section 6.2 and 6.3.

#### 6.1 Datasets and Model Performance

For the GAD dataset, our method outperformed the BERT-based models. However, for the ChemProt dataset, the precision, recall, and F1 scores were lower than the scores of the BERT-based models. In the GAD dataset, the number of the negative samples is almost the same as the number of positive samples as shown in Table 2. On the other hand, in the ChemProt dataset, the number of negative samples is three times more than the number of positive samples. We analyzed the classification errors of our method for the positive samples of the ChemProt dataset. About 92% of the misclassifications were positive samples classified into the negative class, not into the other positive classes. It seems that the data imbalance affects our model.

---

*We did not evaluate the extraction time for the GAD dataset because the dataset size is small. However, it seems that there is no large difference between the average time per sample for the GAD and the time for the ChemProt.*

6.2 Effects of Pre-Training Corpora

We used the CSE pre-trained on the PubMed, PMC, and ChemRxiv corpora in Proposed3. We evaluated the effectiveness of each corpus for the pre-training. Table 4 shows the results for the ChemProt. The F1 score of the model pre-trained on the PubMed + ChemRxiv was lower than the model pre-trained on the PubMed. On the other hand, the F1 score of the model pre-trained on the PubMed + PMC was higher than the model pre-trained on the PubMed. The F1 score of the model pre-trained on the PubMed + PMC + ChemRxiv was the best score. The combination of PubMed, PMC, and ChemRxiv was effective although introducing ChemRxiv alone provided no benefit to the pre-training.

6.3 Effects of Target Entity Pair Indicators

We used the indicator tags to express a pair of two target entities. On the other hand, Lee et al. (Lee et al., 2019) replaced the target entity pair with pre-defined strings. In this section, we compare the methods using the indicator tags with the methods using the entity pair replacement. For the GAD dataset, we replaced diseases and genes with pre-defined strings @DISEASE$ and @GENES$, respectively. For the ChemProt dataset, Lim and Kang (2018), replaced chemicals and proteins with pre-defined strings “bc6entc” and “bc6entg”, respectively. We used the same pre-defined strings that were used in Lim and Kang.

For instance, 1-aminoadamantane and Fos in Example 4 are replaced with “bc6entc” and “bc6entg” respectively as shown in Example 5.

Example 4 Amantadine (1-aminoadamantane) induced Fos expression in the central, dorsal-medial and ventral-medial part of the striatum.

Example 5 Amantadine (bc6entc) induced bc6entg expression in the central, dorsal-medial and ventral-medial part of the striatum.

We evaluated the proposed3 using each of the indicator tags and the entity pair replacement. Table 5 shows the experimental results for the GAD and ChemProt datasets. As a result, the use of the indicator tags was effective as compared with that of the replacement approach. We can use the surface information of the target entity pair by using indicator tags. Therefore, the result shows the effectiveness of the surface information of the entity pairs.

7 Conclusions

In this paper, we reported the effectiveness of lightweight and high-performance RE models for the biomedical domain. Our method used the combination of word embeddings generated by the pre-trained LMs (the ELMo model and the CSE model). The ELMo model is a word-level LM and the CSE model is a character-level LM. We proposed RE models that combined ELMo and CSE to utilize
both word-level and character-level features effectively.

We evaluated the proposed methods on the biomedical RE datasets. We compared our methods with BERT-based methods (BioBERT and SciBERT) and the SOTA methods. We also evaluated the model performance and the inference time. Experimental results showed the effectiveness of the combinations of the LMs. For the GAD dataset, we obtained the SOTA score. For the ChemProt dataset, our model showed approximately three times faster extraction speed than BioBERT. In addition, our model reduced the memory size to one sixth of the BERT-based models. However, the F1 score of our model was lower than that of BioBERT for the ChemProt dataset. In future work, we analyze the causes of the high extraction speed and the low performance of our model for the ChemProt dataset in terms of the parameter size and architectures.

Discussion Structure Prediction Based on a Two-step Method

Takumi Himeno and Kazutaka Shimada
Department of Artificial Intelligence, Kyushu Institute of Technology, Japan
t_himeno@pluto.ai.kyutech.ac.jp, shimada@ai.kyutech.ac.jp

Abstract
Conversations are often held in laboratories and companies. A summary is vital to grasp the content of a discussion for people who did not attend the discussion. If the summary is illustrated as an argument structure, it is helpful to grasp the discussion’s essentials immediately. Our purpose in this paper is to predict a link structure between nodes that consist of utterances in a conversation: classification of each node pair into “linked” or “not-linked.” One approach to predict the structure is to utilize machine learning models. However, the result tends to over-generate links of nodes. To solve this problem, we introduce a two-step method to the structure prediction task. We utilize a machine learning-based approach as the first step: a link prediction task. Then, we apply a score-based approach as the second step: a link selection task. Our two-step methods dramatically improved the accuracy as compared with one-step methods based on SVM and BERT.

1 Introduction
Meetings are often held in laboratories and companies to come up with new research ideas and management strategies. A summary is vital to grasp the content of a discussion for people who did not attend the discussion. Summaries are suitable for understanding the main points in discussions. Assume that a summary is illustrated as a discussion structure. The summary is more powerful and helpful to understand the main points in the discussion because users can immediately capture the flow of the discussion by using links between utterances. For this purpose, we need to predict the discussion structure of each discussion.

Argument mining is one of the tasks to construct a structure of sentences (Stab and Gurevych, 2017a). It automatically derives the structure of argumentation from unstructured documents such as essays. It consists of four subtasks as follows: component identification, component classification, relation identification, and relation classification. Component identification is a task that extracts argument components from a given document. Argument components denote sentences and paragraphs related to the discussion structure. Component classification is a task that assigns a label, e.g., claim, to each argument component. Relation identification is a task that predicts whether each pair of argument components is related or not. Relation classification is a task that assigns a label, such as “attack” and “support,” to the related pairs of argument components.

In this paper, we deal with relation identification for constructing a discussion structure in a multi-party conversation. In other words, we construct a link prediction model for nodes consisting of some utterances. Methods in previous work often predicted the discussion structures by using machine learning approaches, such as neural networks. Himeno and Shimada (2020) have reported that such machine learning models tended to over-generate links between nodes. Here we focus on some rules in discussion structures; e.g., a child node has one parent note. We incorporate score-based selection rules with the machine learning model as post-processing to improve the accuracy. We introduce top-down and bottom-up approaches for selecting edges. The result shows that the proposed methods are more accurate than the method without the selection.

2 Related Work
In recent years, argument mining is attracting attention in natural language processing. Argument mining is a task to construct the structure of a document. It is applied to many natural language processing tasks such as document summarization (Barker
and Gaizauskas, 2016; Peldszus, 2014), the automatic scoring of essays (Ghosh et al., 2016), the paper writing support (Stab and Gurevych, 2017b; Nguyen and Litman, 2016), the information retrieval (Stab et al., 2018) and so on. Stab and Gurevych (2014) have tackled the relation identification for essays written by students. They created some features capturing the characteristics of the essay and then predicted links between argument components. The essay is usually formalized, such as the form of a claim followed by premises. However, multi-party conversations are not always formalized because many people freely speak to assert their opinions.

Discussion structures can be regarded as a kind of graph structure. In fact, some studies handled the selection of edges of argument structures as the shortest path problem of graphs (Dijkstra et al., 1959; Gabow and Tarjan, 1985). The shortest path problem is an optimization problem to find the path with the minimum weight among the paths connecting two given nodes in a weighted graph. In the shortest path problem, the method usually optimizes the entire path from parent nodes to multiple terminal nodes. We also apply this idea to our task, namely relation identification. However, it is not always suitable to adapt our task directly because there are some conditions in discussions: e.g., only one parent node for a child node. In this paper, we propose a link selection method for local utterance pairs to handle the characteristics of the discussions.

In addition, many studies have focused on the visualization of discussions (Chamberlain et al., 2018; Lugini et al., 2020). In this paper, we also visualize predicted links to understand the result easily.

### 3 Dataset and Task

#### 3.1 Dataset

In this paper, we use the AMI corpus, a multi-party conversation corpus (Carletta et al., 2005). It contains various useful annotations, such as the argument structure and time information, to predict a link between nodes. Each node consists of one or more utterances. We use scenario meetings that are held with the discussion points given in advance. In the discussion setting, four employees in different roles in a company discuss developing a new TV remote control that replaces an old-style TV remote control for consumers on the market. One discussion is held four times. Each utterance in the AMI corpus contains speaker ID, time information, and a dialog act.

In this paper, we use the annotated data based on the Twente argument schema (TAS) to contain the link between nodes (Rienks et al., 2005). TAS is an annotation schema created to clarify the discussion structure which arises from the scenario meeting of the AMI corpus. The discussion structure in TAS consists of two elements. One is a node, and the other is an edge. The node in TAS contains parts of, or even complete, speaker turns. The edge in TAS represents the type of relation between the nodes. In TAS, unit labels that represent the role of the node are also annotated. The details of the unit labels are shown in Table 1. In addition, TAS defines “discussion” as segments in the meeting (“Dialog”). One dialog consists of one or more discussions. One discussion consists of some nodes. One unit label is assigned to each node.

#### 3.2 Task

Figure 1 shows an example of relation identification in this paper. In Figure 1, the dialog contains two discussions: discussion1 and discussion2. The two discussions contain three nodes and two nodes,

![Figure 1: Relation identification. We handle all combinations of node pairs in each discussion for the relation identification task. The task is to classify each pair into “linked” or “not-linked.”](http://groups.inf.ed.ac.uk/ami/download/)

4 Proposed Method

In this section, we explain our method with two steps: link prediction and link selection. Figure 2 shows an overview of our method. The first step (link prediction) is based on machine learning techniques. We compare two models; one is Support Vector Machines (Vapnik, 2000) with word embeddings and selected features, and the other is BERT (Devlin et al., 2019). However, the models tend to over-generate links between nodes in this task. Hence, we introduce link selection approaches as the second step: top-down and bottom-up approaches.

4.1 Link prediction

4.1.1 SVM

We apply Support Vector Machines (SVMs) to the link prediction task. Figure 3 shows the outline of the SVM-based model. It learns the link prediction model with two embeddings of two nodes and eight features. As the word embedding, we use word2vec (W2V) published by Google. We generate the vector space as follows:

\[ V_{node_i} = \sum_{x=1}^{m} v_x \]  

where \( v_x \) denotes the word vectors of \( node_n \) and \( m \) denotes the size of the \( node_n \). For example, assume that we predict the relation between \( node_i \) and \( node_j \) consisting of some word embeddings \( (v_x) \). We obtain two summed word embedding vectors, namely \( V_{node_i} \) and \( V_{node_j} \) from \( node_i \) and \( node_j \). Finally, SVMs learn and predict the relation by using concatenated \( V_{node_i} \) and \( V_{node_j} \).

We also utilize eight features as follows:

- Number of words in node pair
  - If a speaker supports and attacks another speaker’s claim, the size of the node tends to be larger. In a similar way, the node also tends to be larger if the speaker wants to convey much information to the other speakers.

Figure 3: The link prediction model with SVM.
On the other hand, the size of a node becomes smaller if the node consists of short utterances, such as back-channel feedback. Thus, the size of each node is one of the important characteristics. To capture this feature, we use the number of words in each node.

- **Number of common words in node pairs**
  If two nodes are related to a common topic, words in them are frequently overlapped. Therefore, we count the number of common words that appear in each node as the feature.

- **Speaker information**
  Agreement or negative statements to an opinion from a speaker tends to be uttered from another speaker. Besides, the situation that the same speaker gives a positive opinion to his/her own claim or points out a problem of his/her claim is very rare. Therefore, the speaker information of each node has an important role in the relation between two nodes. We use the speaker ID of each node as the feature.

- **Time information**
  If the discussion is active, the time interval between nodes tends to become shorter. As another example, a link between a node in the early stage and a node in the last stage in a discussion is rare. In other words, far-flung nodes usually do not possess a link. Thus, time information between nodes has an important role. To capture this feature, we focus on time information in the corpus. We compute the time information by using the end time of node \( i \) and the start time of node \( j \) as the feature.

- **Distance between nodes**
  Assume that the discussion is stagnant. In this situation, the distance between nodes becomes short because the number of nodes in the stagnant situation becomes small\(^5\). Thus, the distance, namely the number of nodes between two nodes, is one important feature. Therefore, we sort the nodes in a discussion in terms of the timestamps and use the distance between nodes as the feature.

- **Dialog act**
  Dialog act tags are important information for the prediction model. For example, if a node contains an “Inform” tag, the node tends to connect with nodes containing “Backchannel” and “Assess” because of the nature of discussions. On the other hand, a node with an “Elicit-inform” tag does not usually connect with an “Inform” tag because the “Elicit-inform” tag is used by a speaker to request that someone else give some information while the “Inform” tag is used by a speaker to give information. Therefore, we use the distribution of 15 types of dialog acts in each node as the feature.

- **Unit label**
  The unit labels described in Section 3.1 also have an important role in the prediction of the link between nodes. They contain three types of labels related to questions: “Open Issue,” “A/B Issue,” and “Yes/No Issue.” If a node contains such tags, the node tends to connect with nodes that express positive/negative opinions. Besides, nodes with such tags do not generally connect with nodes about questions because it is a question-question pair. Therefore, we use the unit label of each node as the feature.

- **Polarity of node pair**
  Emotional information is also one of the characteristics of conversations. For example, a speaker may emotionally argue while claiming his/her opinion in a discussion. In a similar way, when a speaker may emotionally argue when he/she agrees or disagrees with another speaker’s question. To capture the information, we use Stanford CoreNLP (Manning et al., 2014). We compute the score (1 to 5) of each utterance by using CoreNLP. Then we compute the average score from the score of the utterances in each node. We use the average polarity score of each node as the feature.

### 4.1.2 BERT

The second model is BERT (Devlin et al., 2019). BERT is a Transformer-based machine learning model that is pre-trained by a large corpus. It can fine-tune the target tasks. BERT is known to perform well in various natural language processing.
4.2 Link selection

The link prediction models in Section 4.1 tend to over-generate links. In this section, we introduce two types of selection approaches: bottom-up and top-down.

4.2.1 Bottom-up approach

In this approach, first of all, each model (SVM and BERT) predicts the relation of each node: “link” or “not-link.” Figure 5 shows an overview of the bottom-up approach. In this figure, we obtain the link prediction result; e.g., node1 is linked to node2, node3, and node4. Then, we prune links on the basis of a cost parameter in the case that a child node has two or more parent nodes; e.g., node5 has two parents (node2 and node3). We employ the value of decision_function on scikit-learn for SVM. For BERT, we employ the value of the softmax function.

We select the node pair with the highest value as the final result if a child node has some parent nodes. In Figure 5, node5 has two parents with values (node2 with 0.8 and node3 with 0.9). The bottom-up approach selects node5 as the final link. We apply this bottom-up approach to the SVM model in Section 4.1.1 and the BERT model in Section 4.1.2 as the post-processing step, namely the selection process.

4.2.2 Top-down approach

Figure 6 shows an overview of the top-down approach. Firstly, in this approach, we assume that the first node in each discussion is the first parent node. Then, we predict the presence of the link between the parent node and each node in a discussion. In Figure 6, the solid line denotes that a link prediction model judged “the two nodes contain the link.” On the other hand, the dashed line denotes that the model judged “no link between the two nodes.” For example, the model judges that node3 and node5 are linked with node1 (the first parent node). Next, we set new parents by using the result; i.e., node3 and node5 are new parents. We repeat the process for the new parents. We select the final link in the case that two or more parent nodes have one child node. In Figure 6, node4 has two parents, namely node3 and node5. In other words, the model predicts that node3 is linked to node4 and node5 is also linked to node4. In a similar way with the bottom-up approach, we select the node pair with the highest value as the final result if a child node has some parent nodes: e.g., node5 in Figure 6.

The top-down approach needs a higher computa-

5 Experiment

5.1 Experimental Settings

For the SVM model, we use LiBSVM (scikit-learn) for the implementation (Chang and Lin, 2011). The kernel function was the RBF function, and the cost parameter was 100. The other parameters were default values on scikit-learn. The setting was determined from the training data with a grid search on scikit-learn.

For the BERT model, we used the BERT-Base as the pre-trained model. The text has been lowercased. The batch size for the training was 16, and the batch size for the development and test was 8. The number of epochs was 3. We used cross-entropy as the loss function. The optimizer was Adam, and the learning rate was 0.00002.

We used 219 discussions from 92 dialogs of the AMI corpus. In this experiment, all nodes in each discussion were given, and we used oracle unit labels in the corpus for the feature extraction. We divided the AMI corpus into 201 discussions from 84 dialogs for the training data, 13 discussions from 4 dialogs for the development data, and 12 discussions from 4 dialogs for the evaluation data. As explained in Section 3.2, we generated all combinations of two nodes in each discussion. The distribution, such as the number of linked pairs and not-linked pairs, was shown in Table 2.

Table 2 said that the experimental data were imbalanced; the linked pairs were just 3850 as against 38530 not-linked pairs. Models generated from imbalanced data tend to become a weak classifier. Therefore, we reduced the imbalance of the training data. For all models, we randomly selected 3850 not-linked pairs from the original training data. Then, we generated each model, namely SVM and BERT, from the downsized and balanced training data.

5.2 Experimental Results

We compared the effectiveness of our two-step methods. Table 3 and Table 4 show the experimental result of SVMs and BERT, respectively. $T_{down}$ and $B_{up}$ denote the top-down and bottom-up approaches for each model, respectively. The boldface denotes the best score for each criterion, namely Precision, Recall, and F1-score, in the table. On the F1-score, the two-step methods with the bottom-up outperformed the methods without the link selection. The top-down approach on SVM improved the precision rate although the F1-score was lower than $SVM$ without selection. These results show the effectiveness of our two-step methods, namely the introduction of the link selection approach.

5.3 Discussion

The link prediction models obtained high recall rates for the class “link” (0.84 on SVM and 0.65 on BERT) while the precision rates were low. In other words, the outputs contained many mistakes: child nodes with some parent nodes. The problem was remedied by introducing link selection models, especially the bottom-up. On the other hand, the improvement of the top-down approach was limited. The reason is that the top-down approach sequentially predicts a link of two nodes and selects the link from the top node. Although it can hold the relation between two nodes, it is not suitable to hold the relation of the whole discussion. As a result, the result was not sufficient. Moreover, in the top-down approach, the mistakes of the link prediction in the early stage lead to a negative impact on the later stage accumulatively. To obtain higher
accuracy by the top-down approach, we need additional rules and conditions in the link selection process: e.g., appearance order in the discussion.

We visualized discussion structures from the predicted results. Figure 7 shows an example of the correct discussion structure of a discussion. Figure 8 and Figure 9 show the visualized structures of SVM and SVM with the bottom-up approach, respectively. Figure 10 and Figure 11 also show the visualized structures of BERT only and BERT with the bottom-up approach, respectively. In each figure, solid blue lines denote correct links, and dashed red lines denote incorrect links. From the figure, our method dramatically improved the discussion structure prediction task. In particular, the output of the BERT model was obviously refined, namely the deletion of dashed red lines, because the precision rate of the original BERT model was extremely low. For the SVM model, the output from our method reduced mis-prediction as a whole.

The parameters of this experiment were determined from the training data. Therefore, the parameters are not always the best parameters in the experiment. Moreover, we just evaluated our methods with one setting in Table 2. We need to investigate the best parameters and the effectiveness of our method through cross-validation. In addition, we used word2vec for the embeddings for SVM although we can currently obtain embeddings from BERT as a stronger embedding. The BERT embeddings might lead to the improvement of the accuracy of the SVM-based model. The replacement of word embeddings for SVMs is one future work.

In our previous work (Himeno and Shimada, 2020), link prediction models tended to over-generate links between nodes. In this experiment, the bottom-up approach was effective for both SVM and BERT. Therefore, we believe that our two-step method is versatile and effective for relation identification tasks of argument mining. However, we evaluated our method with only the AMI corpus. Applying our method to other corpora and evaluating the effectiveness of our method in relation identification tasks are important future work.

6 Conclusions

In this paper, we proposed two types of discussion structure prediction methods. They were based on a two-step architecture: link prediction and link selection. For the link prediction, we evaluated two machine learning models, namely SVM and BERT. These models tended to over-generate links be-
between nodes. To solve this problem, we introduced top-down and bottom-up approaches to the link selection task. Our methods outperformed SVM and BERT without the link selection approaches (0.53 vs. 0.66 on F1 for SVM and 0.24 vs. 0.41 on F1 for BERT). In the experiment, the bottom-up approach was better than the top-down approach. We visualized the discussion structures from the outputs. From the visualized data, we can see qualitatively that our methods dramatically improved the discussion structure prediction.

To obtain higher accuracy, the recall rate of the link prediction model is the most important factor. It was indicated by the results of SVM: the higher recall rate led to the best performance, as compared with the BERT-based model. Therefore the important future work is to improve the link prediction models by machine learning, especially the recall rate.

Abstract

We use a deep bidirectional transformer to extract the Myers-Briggs personality type from user-generated data in a multi-label and multiclass classification setting. Our dataset is large and made up of three available personality datasets of various social media platforms including Reddit, Twitter, and Personality Cafe forum. We induce personality embeddings from our transformer-based model and investigate if they can be used for downstream text classification tasks. Experimental evidence shows that personality embeddings are effective in three classification tasks including authorship verification, stance, and hyperpartisan detection. We also provide novel and interpretable analysis for the third task: hyperpartisan news classification.

1 Introduction

The vocabulary we use in everyday language is a rich source of information about our beliefs, thoughts, and personalities (Pennebaker et al., 2015). Many efforts in text analysis provide compelling evidence that our everyday language carries psychological cues (Gottschalk and Gleser, 1979; Stone et al., 1966; Weintraub, 1989; Pennebaker et al., 2015). With this study, we seek to determine the personality of a given text’s author as defined by the Myers-Briggs Type Indicators or MBTI (Myers and Myers, 1995). Myers-Briggs uses four binary dimensions to classify people (Introvert–Extrovert, Intuitive–Sensing, Thinking–Feeling, Judging–Perceiving), which gives 16 different types, such as INTJ and ENTJ. This work uncovers novel insights into the personality space of authors from their online writings.

The personality signal carries the fingerprint of the individual’s psyche and, even though noisy, can be useful (as shown in this work) for a variety of downstream NLP tasks, such as authorship verification, stance, and hyperpartisan detection. Personality prediction does not only benefit commercial applications and psychology but also is advantageous in health care. Recent works link personality types and social media behavior with depression and posttraumatic stress disorder (Preotjiuc-Pietro et al., 2015). This is significant because it opens new avenues for prevention care as certain personality types can anticipate mental illness and schizophrenia. (Mitchell et al., 2015).

This problem poses a non-trivial challenge because a good solution must be capable of capturing the complexity and the depth of the human psyche as expressed through text. Anything short of that will result in task-specific pattern-matching. It follows that the main technical difficulty presented by the task at hand is the discrepancy between the corpora concerning their distributions, which results in the domain shift. This is where our work becomes relevant as it aims to bridge the gap by transfer learning and universal language understanding.

The problem is also challenging because the human psyche is complex in its nature. The labels are fuzzy as the label distribution changes from population to population and the ground truth is not derived by an objective method; rather, it is a set of ideas generally agreed upon by specialists and society. Furthermore, high quality curated datasets constructed by professional psychologists are difficult to obtain due to privacy reasons.

Models have only recently reached the capacity required. Our approach uses transfer learning through language understanding for personality prediction. We create a unified dataset from the collection of user inputs of three available MBTI datasets (Gjurković and Šnajder, 2018; Mitchell, 2017; Plank and Hovy, 2015) originating from social media platforms including Reddit, Twitter, and Personality Cafe forum. We investigate how transfer learning with pretrained transformers con-
tributes to personality prediction under a multi-label multi-class classification strategy. We analyze the relationship between personality types with the three specific tasks of stance, authorship, and hyperpartisan news classification. The results on the unified dataset show that transfer learning along with pretrained bidirectional transformer models effectively changes the Hamming loss, F1, and Jaccard similarity for multi-label personality prediction. The contributions of our paper are listed below:

- We propose to use the flow of sentiments across a document as a proxy for Myer-Briggs personality type and use a transformer-based model to predict personality type.
- We show the usefulness of personality traits on three downstream text classification tasks: authorship verification, stance, and hyperpartisan detection. The technical novelty is on transfer learning of our pretrained personality model to improve NLP downstream tasks.
- We give an in-depth statistical analysis of the effect of using personality information in the task of hyperpartisan news classification.

In the following sections we introduce and evaluate the personality model, then analyze its application in the three text classification tasks (mentioned above) using transfer learning.

2 Related Work

Personality prediction from text is a challenging task (Štajner and Yenikent, 2021; Yang et al., 2020) and many personality prediction approaches rely on crafted features which can range from simple ones, such as TF-IDF of word or character n-grams to the ones produced by tools such as Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2015), which extracts anything from low-level information such as Part Of Speech tags and topical preferences to psychological categories. These features are often supported by various psycholinguistic word lists that aim to detect emotions and sensory experiences (Preoțiuc-Pietro et al., 2017).

Our work uses a bidirectional transformer to predict MBTI personality types using a large collection of data obtained from three existing personality datasets. Utilization of the pretrained word embeddings (Mikolov et al., 2013; Pennington et al., 2014) in many deep learning models indicates that leveraging knowledge obtained from unsupervised learning boosts the performance. Recently, language models pretrained on a large amount of raw text were shown to provide representations applicable to a wide variety of tasks with minimal fine-tuning (Radford et al., 2018; Howard and Ruder, 2018; Peters et al., 2018a). These models can be effectively generalized to many downstream tasks and adapted to different domains. Below are the three representative studies on utilizing online user-generated text for personality prediction. They are annotated with self-reported MBTI personality types of users.

Reddit9K dataset is a large-scale dataset constructed from the posts and comments of 9K Reddit users. It is labeled with MBTI indicators and covers a wide variety of topics (Gjurković and Šnaidjer, 2018). The authors extract user activity and linguistic features including word and character n-grams, LIWC word categories (Pennebaker et al., 2015), and two Psycholinguistic dictionaries (Preoțiuc-Pietro et al., 2017; Coltheart, 1981). Support Vector Machine (SVM), Logistic Regression (LR), and multi-layer perceptron are used to identify personality types and prove to be discriminative for personality prediction. Twitter dataset is a large corpus of 1.2M tweets of 1.5K users (Plank and Hovy, 2015). Experiments performed by the dataset creators show that linguistic features are reliable representatives for two out of four personality dimensions. We hypothesize that the cause of the discrepancy is the difference between the distribution of personality types in social media users and the general U.S. population. Finally, Kaggle dataset collects the user posts of the Personality Cafe\textsuperscript{1} forum and covers 8.6K different people with 16 MBTI personality types (Mitchell, 2017).

3 Dataset

We use Reddit9k, Twitter, and Kaggle Myers-Briggs personality type datasets to train and evaluate our proposed model for automatic personality type prediction. In all datasets, the annotation process relies on self-reported personality types, and no questionnaire is given to the users. Previously, MyPersonality created from Facebook user data was a questionnaire-based dataset. However, it is not available to the public anymore. We make a unified dataset from the collection of the three available MBTI personality datasets and remove

\textsuperscript{1}https://www.personalitycafe.com
the non-English contents. We find that the new dataset is highly skewed towards two out of four personality dimensions. There are a few reasons for that. i) According to Plank and Hovy (2015) the distribution of personality types among the United States population is not balanced. ii) Users from some specific personality types tend to participate in social media platforms and express their personality types more than others. Our experiments also show that the class imbalance highly affects training, generating poor results for small classes, among evaluation methods. To alleviate the skewness of the data in training we take two (standard) steps: add class weights concerning their size in loss computation and make a balanced subset of the original dataset. We notice that the former does not improve the performance significantly, but the latter does. Hence, we create a balanced version of the dataset by over-sampling the small and under-sampling the large classes such that their final sizes become equal to the original average size of the 16 MBTI personality types before sampling. Table 1 reports the unified personality dataset statistics after balancing.

4 Personality Embedding

We build a general model to predict four MBTI personality dimensions and to infer personality embedding. The MBTI dimensions are expressed as Booleans (0/1). The personality dimensions are IE, or Introversion (I)/Extroversion (E); NS, or iNtuition (N)/Sensing (S); FT, or Feeling (F)/Thinking (T); and JP, or Judging (J)/Perceiving (P). Under this scheme, each instance can have multiple labels with four classes. The combination of these four classes gives $2^4 = 16$ MBTI personality types. We consider multi-labeling classification to learn the personality dimensions together. Our experiments show that sub-sampling creates a small training set with poor final results while over-sampling creates a huge dataset with hundreds of redundant examples. So, the models cannot differentiate the 16 classes (personality types) with the under-sampled small training data or they fail to predict the unseen examples of minority classes correctly in the over-sampled dataset as they get over-fitted by the redundant examples. Finally, we find that by converting the 16 classes into four in the multi-labeling scheme and applying over-sampling and sub-sampling simultaneously we can better overcome the class imbalance. The following section describes the proposed personality prediction model.

4.1 PersBERT Model

The use of pretrained language models and transformers shows significant improvements in various NLP problems. The bidirectional based transformer models such as BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019) overcome previously published language models trained on one direction (e.g. ULMFiT) (Howard and Ruder, 2018) or the shallow concatenation of left and right direction of text input (e.g. ELMo) (Peters et al., 2018b) in various text classification tasks. We use BERT architecture as the basis of our personality prediction model. BERT takes position, segment, and token embedding as input to compute the importance of a token in a sequence. For personality classification purposes, we take into account the sentiment of sentences in an input sequence aside from the standard BERT input. According to (Tausczik and Pennebaker, 2010), the level of emotion and sentiment expression by people in their opinions and the way they express their emotions define how people feel about the world. People’s everyday language is a rich source of their beliefs, thinking patterns, and personality. Because personality speaks of stable differences in characteristic patterns of thinking, feeling, and behaving, it is connected with emotion and sentiment (Corr and Matthews, 2009). In this regard, some tools such as LIWC are designed to organize the words in psychologically meaningful categories and to identify emotion in language. They are also widely used in Psycholinguistic studies (Tausczik and Pennebaker, 2010). The connec-
tion between language, emotion, and personality elevates opinionated user generated content into a valuable resource for mining people’s personalities.

In our approach we split the input sequence into linguistic sentences.\(^2\) The sentiment of each sentence is one of positive, negative, or neutral; it can be inferred using any sentiment analysis tool. We give the utilized tools in Section 4.3. The sentiments of input tokens are embedded using a \(3 \times k\) matrix that is randomly initialized, where \(k\) is the size of the hidden states of the model. Then, these sentence-wise sentiment embeddings are accumulated with the three standard embeddings of the BERT model \((E_t^\text{token}, E_t^\text{position}, E_t^\text{segment})\) to form the input embedding \((E_t\) for token \(t)\). So, \(E_t = E_t^\text{token} + E_t^\text{position} + E_t^\text{segment} + E_t^\text{sentiment}\).

Figure 1 shows the model architecture. The input embeddings are given to the BERT sentence classification model that takes a sequence of linguistic sentences as one single input compared to the sentence-pair model that takes two inputs (e.g. a question and its answer). A fully connected layer forms a classifier that squeezes the pooled output \((x)\) of the BERT model to four personality dimensions \((I/E, N/S, F/T,\) and \(J/P)\). The hidden state of [CLS] token \((h_{\text{[cls]}})\) is used as the input of the pooling layer. So, \(x = \tanh(W_p h_{\text{[cls]}} + b_p), \logit = W^c x + b^c\) where \(W^c, W^p, b^p,\) and \(b^c\) are the layers’ parameters. Similar to other multi-label multi-class problems, the loss is the overall binary cross entropy among all classes, \(L = \frac{1}{N} \sum_{i \in N,c \in C} y_{c,i} \log \sigma(y_{c,i}^\prime) + (1 - y_{c,i}) \log (1 - \sigma(y_{c,i}^\prime))\).

where \(N\) is the number of examples, \(C\) number of classes, \(\sigma\) sigmoid function and \(y, y^\prime\) are true labels and logits (input of probability function) respectively. We refer to the proposed model as PersBERT for the rest of the paper.

4.2 Multi-class Multi-label Baselines

We mentioned earlier that personality is connected to emotion and sentiment (Tausczik and Pennebaker, 2010; Corr and Matthews, 2009). Also, automatic prediction of MBTI personality is being considered under a multi-label setting. Thus, we choose baselines with various architectures that are widely used in sentiment analysis or multi-label classification. They are listed as follows: Kim-CNN & XML-CNN are two CNN-based neural network models. The former is one of the initial and successful applications of Convolutional Neural Network (CNN) for text classification (Kim, 2014). And the latter is designed for extreme multi-label text classification where the number of labels can exceed even a few thousand (Liu et al., 2017). Its architecture inherits Kim-CNN’s model specification with an additional dynamic max-pooling layer that highlights important information across different parts of a document. XML-CNN was able to beat most of the deep learning baselines in six benchmark datasets. DocBERT is the BERT model with a fully connected layer that converts the hidden state of the BERT pooling layer to \(C\) activations for \(C\)-class classification (Devlin et al., 2019). The pooling layer pools the model by taking the hidden state corresponding to the classification token ([CLS]) of the input sequence through non-linearity (tanh). We fine-tune DocBERT for classification and initialize it with pretrained BERT-base-uncased weights. Lastly, Hierarchical Attention Network (HAN) is a recurrent neural network model that mirrors the hierarchical structure of the English language (Yang et al., 2016). Applying attention mechanisms in word and sentence-level enables this model to find crucial parts of the document for the downstream classification task. The model outperforms its competitive baselines in sentiment analysis of user reviews dataset including Yelp, Amazon, and IMDB.

4.3 Evaluation

We train the models on 30 epochs with the batch size of 16 or 32. Training is controlled by early stopping with patience = 5, which will be stopped after 5 consequent epochs of no improvement of the highest F1 score gained. The test set is evaluated using the model with the best F1 of the dev set. We use Google News (GNews) (He et al., 2020; Liu et al., 2015) and FastText token embedding in our experiments for the two CNN-based (Kim-CNN & XML-CNN) and LSTM-based baselines (HAN) (Mikolov et al., 2018). However, DocBERT and PersBERT models’ parameters are initialized with their corresponding BERT-base-uncased model weights. The BERTAdam optimizes these two models with the learning rate of \(2e - 5\) recommended in (Devlin et al., 2019). We set the sequence length = 256 for all models. Similar to DocBERT, all parameters of PersBERT are updated during backpropagation. Training PersBERT with more than \(5K\) examples (Table 1) takes

\(^2\)we use NLTK sentence tokenizer (Loper and Bird, 2002).

5 days on a TITAN RTX GPU with batch size=16.

For evaluating multi-label personality prediction, we use Jaccard Similarity, Hamming loss, Macro-F1, and Micro-F1 scores. For more information about the measures the reader is directed to (Wu and Zhou, 2017). We use scikit-learn library (Pedregosa et al., 2011) for evaluation measures and other statistical methods. We utilize VADER, a rule-based model for the general sentiment analysis task, to infer the sentiment of sentences (Hutto and Gilbert, 2014). VADER gives us a compound sentiment score between -1 and +1. The scores between -1 and -0.05 indicate negative, the ones greater than 0.05 show positive sentiment, and the scores between -0.05 and +0.05 have a neutral sentiment. Each token inherits the sentiment of the sentence in which the token appears. For the two classification ([CLS]) and separator [SEP] tokens, we use neutral embedding. Although VADER is a token-based sentiment tool, we use sentence-wise sentiment instead of token-wise for two reasons: i) our intuition is to let the model learn the transition of sentiment across sentences and not tokens; this follows from the assumption that the change of sentiment from sentence to sentence may indicate one’s personality. ii) BERT uses sub-words units known as Word-pieces and each VADER lexicon may be composed of multiple Word-pieces. Thus, we must assign the sentiment of an entry in VADER lexicon to all its Word-pieces. For example, the sentiment of ‘huggable’ must be assigned to its three sub-words in our model: ['hug', '##ga', '#ble']. Also, our experiments on the dev set show that token-wise sentiment avoids learning the transition of sentiments and does not improve the model performance as much as sentence-wise sentiment.

Experimental results of multi-label MBTI personality prediction on the unified dataset (Table 1) are provided in Table 2. They indicate that PersBERT trained on 256 tokens of input sequence achieves the best results among baselines in all multi-class-multi-label evaluation measures. An F1 improvement of +0.5% and −0.52% Hamming loss reduction on ≥ 159K test instances compared to DocBERT shows that adding sentiment embedding of sentences to the input distinguishes the personality types more accurately. Apart from that, both transformer-based models, DocBERT and PersBERT, show significant improvement over the two CNN models with two different pretrained embeddings as well as the HAN (about +40% in Jacc. and −30% in Hamming loss). We believe that the two masking and next sentence prediction techniques used in BERT’s pretraining enable the model to better understand the relationship between the words of a sentence in both directions, as well as the relationship between the sentences. This leads to an enriched language model and a remarkable improvement in identifying personality signals from individuals’ language compared to other baselines.

5 Transfer Learning

We aim to study if the knowledge gained from our personality prediction model, PersBERT, helps opinion-oriented problems. Personality is closely connected with opinions and how people form opinions; hence, we choose three tasks, i.e., hyperpartisan news detection, authorship verification, and stance detection (Hosseinia et al., 2020), that are designed around opinion mining. We create our transfer learner named DocBERT + PersBERT by connecting the pretrained personality model, PersBERT, to DocBERT (Figure 2). Empirical results show that these transformer models achieve the best results among the baselines introduced in Section 4.2. We share a fully connected layer, classifier layer, between the DocBERT and PersBERT models. The layer takes the concatenation of the
Table 3: Hyperpartisan news dataset

</tbody>
</table>

output vector of pooling layers and converts them to $C$ classes. Recall that in DocBERT and PersBERT, the pooling layer pools the model by taking the hidden state corresponding to [CLS] token of input sequence using a non-linear activation (tanh). Hence,

$$a_{\text{PersBERT/DocBERT}}^{\text{[cls]}} = \tanh(W_{p/d}^{\text{[cls]}} + b_{p/d}),$$

$$z = W_{c}[x_{\text{DocBERT}}; x_{\text{PersBERT}}] + b_c$$

where $W_{p/d}, b_{p/d}$ are the parameters of PersBERT or DocBERT pooling layers. $[; ;]$ denotes concatenation, $W_{c}$ is the $2 \times k \times C$ classifier weight matrix and $k$ is the size of the pooled vectors (hidden state). Finally, the classifier output, $z$, is normalized with a Softmax function for downstream $C$-class classification tasks. Next, we introduce the three text classification problems for our evaluations.

5.1 Hyperpartisan News Detection

The term “hyperpartisan news” is used to define the extremely biased news in favor of the right or the left political spectrum. SemEval2019 task 4 proposes hyperpartisan news detection and has released only the training and dev sets of two versions of the hyperpartisan news dataset. In the first version, “news by-publisher”, all articles are labeled by the overall bias of the publisher as provided by BuzzFeed or MediaBiasFactCheck.com while in “news by-article” dataset documents are labeled manually by the agreement of the journalists (Kiesel et al., 2019). Because the test set is not released yet, we use SemEval dev set as test and split its training set into new training and dev sets with no publishers in common. Likewise, we create new sets for the “news by-article” dataset. Our topic modeling analysis on the “news by-publisher” training set reveals that it is highly imbalanced in terms of news classes. We use Non-negative Matrix Factorization (NMF) to estimate topic distribution in news. For some topics, top documents belong to only one class. To avoid the models to learn topics but hyperpartisanship we sample from the training set so that the resulting set includes an equal number of unique examples per topic. We only apply sub-sampling on the training set and keep the dev and test set intact. This process increases the F1 score of DocBERT model by 5% on the dev set. Table 3 provides the dataset statistics.

5.2 Stance Detection

Stance detection identifies if an opinion supports an idea or contradicts it. We use the new version of Procon dataset (Hosseinia et al., 2019) in our evaluation. The dataset covers the argumentative opinions of different controversial issues, ranging from education and immigration to birth control. The dataset has 4,264 instances and we split it into (70%, 10%, 20%) for training, dev and test, respectively. As each instance in Procon dataset is a pair of a question about an issue and an opinion about it, we use the BERT sentence-pair model for both DocBERT and DocBERT + PersBERT models. Thus, the input of the two BERT-based models is formed as [CLS] question [SEP] opinion [SEP] where [CLS], [SEP] are reserved tokens used by BERT for classification and separation of the two input parts respectively (Devlin et al., 2019).

5.3 Authorship Verification

Authorship Verification (AV) identifies whether a pair of documents are written by the same author. It has applications in plagiarism detection, forensic analysis, and sockpuppet detection, to name a few. We examine our model on three standard PAN AV datasets. Each dataset contains one training and one test set. We split the original training set into (70%, 30%) for training and dev, and evaluate on the original test set. Similarly, each instance in the AV dataset is a pair of documents, so, we use the BERT sentence-pair model for both DocBERT and DocBERT + PersBERT models. The input is formed as [CLS] first document [SEP] second document [SEP] where documents are written by one or two unknown author(s) and may contain several (linguistic) sentences.

5.4 Results and Analysis

The settings, training strategy, and baselines are the same as PersBERT’s (Table2, Section4.3) for the three aforementioned opinion-oriented clas-

The experiments reported above show that the proposed approach is not useful in identifying hyperpartisanship in the “news by-publisher” dataset. However, we anticipate there are some connections between personality and hyperpartisanship as opinion forms a bridge between these two concepts. We design the following experiments to investigate the hidden connection. Articles of the large “news by-publisher” dataset (Table 3) cover a wide variety of topics. So, we investigate whether personality types vary in mainstream and hyperpartisan classes for separate news topics. We first model topics of the news training set using the Non-negative Matrix Factorization (NMF) algorithm for 20 topics. Then, we choose distinct articles for each topic and induce MBTI personality dimensions using PersBERT (Section 4.1). We select these two topics to minimize the influence of per-topic-personality distribution. Later in this section, we measure the relationship between personality distribution and the PersBERT model is trained on social media data while news data is formal and usually follows its publisher’s strict writing regulation. It may lead to hiding the author’s informal writing and personality features. This difference between the language of news and social media data challenges the effect of transfer learning between the two domains. Secondly, it is expected that personality distribution differs between mainstream and hyperpartisan classes for different news topics, similar to what we observed in stance detection. The following section provides additional experiments for hyperpartisanship detection.

5.4.1 A Deeper Look into Hyperpartisanship

Despite the improvements of F1 in “news by-article” results using personality information, we do not see the same effect on hyperpartisan “news by-publisher” results. There is a reduction by \(-5.17\%\) of F1 in “news by-publisher” when personality information is added. We hypothesize that there are two main reasons for this behavior: first,
news topics using entropy. As noted before, a tuple of four dimensions gives us an MBTI personality type. We plot 16 MBTI personality types versus two news classes for the two selected topics (Figure 4). According to the figure, there is a remarkable difference between several personality types of the two news classes for the topic “econ.” 100% of personality types 7 and 10 are from hyperpartisan and mainstream news classes, respectively; about 80% of personality type 4 belongs to the mainstream, while 70% of type 8 forms hyperpartisan news. However, the plot of topic “life” shows less difference in news distribution among personality classes. We report average entropy of the two news classes across all personality types to measure the difference of personality distributions between the two news classes (Table 5).

\[
\text{entropy} = \frac{1}{|T|} \sum_{t \in T} \sum_{i \in I} -p_{i,t} \log_2(p_{i,t})
\]

Where \( T \) is the set of all personality types, \( I = \{\text{Hyp., Main.}\} \), \( |\cdot| \) denotes the size, and \( p_{i,t} = \frac{n_{i,t}}{\sum_{i \in I} n_{i,t}} \) is the proportion of news class if in personality class \( t \). The smaller the entropy, the more the two news classes have different distributions among the 16 personality types. We train both DocBERT and DocBERT+PersBERT on about 500 articles from topic “life” and “econ,” separately and evaluate it on the original test set. According to Table 5, training on topic “econ” with lower entropy results in higher balanced accuracy of DocBERT+PersBERT with an improvement of > 5% for the sequence length = 256. It shows that topic-based sub-sampling gives us a more distinctive representation of personality types that contributes to better hyperpartisan news detection. On the other hand, training on the data with higher entropy (topic “life”) results in lower accuracy of DocBERT+PersBERT compared to DocBERT indicating that adding unbiased personality features makes the differentiation between the two news classes harder. Moreover, we sub-sampled the whole training data such that the average entropy does not exceed the low amount of 0.1. The sampling gives us 111,614 training examples for \( \text{entropy} \leq 0.1 \). Results in Table 6 reveal that training on data with unbalanced personality distribution of news classes results in remarkable improvements for both models with higher F1 of DocBERT+PersBERT.

6 Conclusion

We believe that this work lays the foundation for leveraging personality signals in a variety of opinion-oriented tasks. We first proposed a novel model, PersBERT, that jointly models the sentence-specific sentiment and personality information building upon the BERT architecture to predict the MBTI personality dimensions. Our pretrained personality transformer improves BERT results and other baselines in benchmark datasets on the personality task. Further, our proposed model was
used on different downstream NLP tasks providing major improvements showing that the subtle signals of user sentiment and their connection with personalities captured by our model are useful in real-world NLP tasks. It is worthwhile to note that the performance comes from training using only short sequences of online user posts (i.e. noisy data for personality). We believe the improvements of our model can be more pronounced if trained upon large-scale gold standard personality datasets (e.g. curated using controlled experiments which is a potential future work). We find that personality signals are more distinctive in authorship verification and stance detection than hyperpartisan news detection where the data is sourced from formal and more supervised writings. However, our personality embeddings can still be used for an effective sub-sampling even in hyperpartisan news detection. Our architecture allows for novel analysis and insights that were previously unknown and have the potential to improve various other NLP tasks which we defer for future exploration.

Abstract

Concept normalization of clinical texts to standard medical classifications and ontologies is a task with high importance for healthcare and medical research. We attempt to solve this problem through automatic SNOMED CT encoding, where SNOMED CT is one of the most widely used and comprehensive clinical term ontologies. Applying basic Deep Learning models, however, leads to undesirable results due to the unbalanced nature of the data and the extreme number of classes. We propose a classification procedure that features a multiple-step workflow consisting of label clustering, multi-cluster classification, and clusters-to-labels mapping. For multi-cluster classification, BioBERT is fine-tuned over our custom dataset. The clusters-to-labels mapping is carried out by a one-vs-all classifier (SVC) applied to every single cluster. We also present the steps for automatic dataset generation of textual descriptions annotated with SNOMED CT codes based on public data and linked open data. In order to cope with the problem that our dataset is highly unbalanced, some data augmentation methods are applied. The results from the conducted experiments show high accuracy and reliability of our approach for prediction of SNOMED CT codes relevant to a clinical text.

1 Introduction

The task of automatic encoding of clinical text with standard medical classifications and ontologies is with high importance for healthcare organizations and medical research. Truly, more than 80\% of clinical documents are stored in free-text format. This paper presents a research effort in solving the problem of automatic encoding of textual description of medical diagnoses with one of the most widely used (Lee et al., 2013) and comprehensive ontologies – the Systematized Nomenclature of Medicine – Clinical Terms (SNOMED CT)\textsuperscript{1}. One of the most important characteristics of SNOMED CT, which makes it significantly different from the rest of the standard medical classifications, is that it is based on compositional grammar\textsuperscript{2}. Another aspect of popularity and importance of SNOMED CT for health information is interoperability, that is discussed in (Peterson and Liu, 2020). SNOMED CT is well known for being one of the most comprehensive medical ontologies, which makes the task of automatic encoding an extreme scale classification task with more than 360,000 medical codes. Currently, this task has not been solved with sufficient accuracy for all possible classes. Usually the developed solutions cover restricted terminology from 10 to a couple of thousands terms (Gaudet-Blavignac et al., 2021). The compositional nature of the SNOMED CT codes gives us the opportunity to address the problem either with classical approaches for classification tasks or with specific solutions that benefit from the compositional grammar’s structure. As a product of our research,

\textsuperscript{1}https://www.snomed.org/
\textsuperscript{2}https://confluence.ihtsdotools.org/display/DOCS/Compositional+Grammar+-+ Specification+and+Guide
the developed service for automatic encoding with SNOMED CT codes will be used mainly for Electronic Health Records (EHR) processing for patients with oncological diseases and certain rare diseases. Most of these diseases are well known to have a huge number of related diseases. Thus, our study will not be restricted only to the diseases of interest but will have a much broader scope. We propose an adaptation of the approach proposed by (Chang et al., 2020) and demonstrate the entire process from training dataset construction to classification model design and training.

2 Related Work

The problem of automatic encoding of EHR with SNOMED CT codes was investigated by many researchers since the very beginning of the ontology development. Different solutions cover broad range of SNOMED CT codes from 10 to a couple of thousands, usually the main obstacle for scalability is the availability of sufficient volume of annotated training data. Basaldella et al (Basaldella et al., 2020) present COMETA - manually annotated corpora by experts that contain 20k English biomedical entities encoded with SNOMED CT.

The most popular approaches for automatic encoding, include hybrid methods combining regular expressions and vector space models (Ruch et al., 2008) with top precision 0.823 and mean avg precision 0.45 for 1239 MEDLINE citations. Some approaches take in consideration compositional structure (Liu et al., 2012) of SNOMED CT.

Recent research is based on deep learning techniques, and the most promising solutions are using transformers like BERT (Devlin et al., 2018). Pattisapu et al (Pattisapu et al., 2020) apply word embeddings, graph embeddings and BERT derivatives transformers and achieve the highest accuracy 0.83 for two benchmark datasets CADEC and PsyTAR.

Kraljevic et al (Kraljevic et al., 2021) propose MedCAT with Macro F1: 0.841–0.860 across different clinical domains and tasks. MedCAT is based on Word2Vec embeddings, and there is also MedCAT BERT version based on clinicalBERT (Alsentzer et al., 2019), and latter model shows a little bit lower performance than the former one.

A recent systematic review (Gaudet-Blavignac et al., 2021) shows that only few of the developed services for automatic encoding with SNOMED CT, are provided as open source - The clinical Text Analysis and Knowledge Extraction System (cTAKES) (Savova et al., 2010) and MetaMap (Aronson, 2001). Both of them are rule-based.

3 Data

One of the key factors that plays a role in the automatic encoding of SNOMED CT codes is the data. In our project, we do not have annotated data which can be used to train the developed models. Thus, we use certain public data and linked open data in order to automatically generate annotated corpora that can serve as a training dataset.

3.1 Data Sources

In our research, we will consider only a subset of the available SNOMED CT codes, namely those related to disorders, clinical findings and procedures. The relevant medical ontologies, standard classifications, and vocabularies for the project, which are used to enrich the SNOMED CT descriptions with additional alternative textual descriptions, are the Human Disease Ontology3, the International Classification of Diseases, 10th revision (ICD-10)4, the International Classification of Diseases, 9th revision (ICD-9)5, the International Classification of Diseases for Oncology, 3rd Edition (ICD-O-3)6, the Medical Subject Heading (MESH)7, the Mondo Disease Ontology (MONDO)8, the Orphanet Rare Disease Ontology (ORDO)9, and the Unified Medical Language System (UMLS)10. Benefiting from the resources provided by the linked open data cloud (LOD)11, we can identify some of the mappings between the ontologies listed above using Bioportal12. Some general equivalence mappings are provided for ICD-10 and ICD-913 as well as rules for mappings between SNOMED CT and ICD-1014. In addition, the ICD-10 CM Alphabeti-
cal Index\textsuperscript{15} is used. All these resource and official mappings between them provide valid encoding of the textual descriptions of diseases with SNOMED CT codes.

3.2 Data Integration

As we alluded above, in order to increase the size of the corpus of SNOMED codes with textual descriptions (and hence boost the predictive power of our neural network by ensuring a richer training set), we extract mappings between SNOMED CT and other medical ontologies, standard classifications, and vocabularies. Then, we use these mappings to link SNOMED CT codes to descriptions native to the aforementioned resources.

Following this guiding principle, but applying it to different subsets of SNOMED CT codes and allowing different degrees of description transitivity (stay tuned), we constructed four distinct datasets, the last two of which allowed for a high classification accuracy.

Table 1: Dataset Evolution

We can conceptualize the overarching principle behind the construction of the different datasets as follows: First, we choose a certain subset of SNOMED CT codes whose elements will serve as labels in the classification procedure. Second, we consider the medical codes from the above ontologies, classifications, and vocabularies that are linked to our chosen SNOMED CT subset through an "exact-match" type predicate.\textsuperscript{16} Third, we build a graph whose vertices are all of the chosen SNOMED CT codes and their "exact-match" neighbors; and whose edges are precisely these "exact-match" mappings. Fourth, we prescribe a degree of description transitivity. That is, we specify whether medical codes in connected components will share all textual descriptions associated with that component or simply the descriptions associated with their immediate neighbors. Finally, we extract a corpus of SNOMED CT codes along with the natural language descriptions that these codes acquired from the mapping graph.

Version 1 of our dataset reflected the naïve idea of considering a graph with full description transitivity. Of course, this approach of total transitive search between ontologies is largely misguided since the mappings between SNOMED CT codes and outside resources are rarely one-to-one. Indeed, these mappings prescribes similarity rather than identity – a circumstance that caused the graph generated by the V1 SNOMED CT subset to contain a connected component encompassing more than 90\% of the vertices. Thus, the majority of the relevant SNOMED CT codes became indistinguishable for our classification procedure.

For the second version of our dataset, we considered an even larger subset of SNOMED CT codes, which we further split into three categories – Procedures, Findings, and Disorders – respecting the official SNOMED CT organization. We used these three subsets to generate three distinct mapping graphs following the above procedure. Again, we prescribed full mapping transitivity on the individual graphs, but we forbade communication between graphs. This new strategy decreased the edge density of the graphs considerably, but large connected components were still present, which led to poor classification performance.

Consequently, we decided to narrow down the generating subset of SNOMED CT codes and to...
allow description-sharing only among immediate "exact-match" neighbors. Thus, for Dataset V3, we considered solely the SNOMED CT codes which exactly matched the following widely encountered procedures, findings, and disorders related to oncological diseases, certain rare diseases, and digestive, neurological, and respiratory diseases.

The lack of description transitivity in V3 caused the majority of the considered SNOMED CT codes to have unique description clusters. This circumstance allowed us to observe high classification accuracy for the first time. However, many SNOMED CT codes were now matched to a single single-word textual description, and the augmentation strategies discussed in the next subsection failed to meaningfully increase the description clusters of such codes.

For that reason, the official verified SNOMED CT ontology mappings used in V3 were supplemented with additional mappings excavated from Wikidata\(^\text{17}\). Then, full description transitivity was applied, and thus Dataset V4 came to be.

Table 2: Additional Data

### 3.3 Data Augmentation

Our data integration strategies resulted in a one-to-many mapping of SNOMED CT codes to synonymous natural language descriptions. This mapping, however, featured a significant number of SNOMED CT codes with less than four textual descriptions. In order to address this circumstance, which would have otherwise interfered with the precision of our neural network, we employed several data augmentation techniques aimed at synthetically increasing the set of descriptions so that each SNOMED CT code could get mapped to at least four descriptions.

Our augmentation strategies were motivated by considerations of what synonymous textual descriptions could arise in the work of medical professionals.

#### 3.3.1 Random Swap and Random Synonym Insertion

We adapted some of the code developed for Easy Data Augmentation\(^\text{(Wei and Zou, 2019)}\) for the purposes of random word swapping and random synonym insertion. The Random Swap transformation works by selecting two random indices in a list of multiple words, and then, swapping the words with the corresponding indices. Only one swap is performed per transformation, which guarantees that novel descriptions are produced after the augmentation. The Random Synonym Insertion transformation works by shuffling the words in a sentence and looping over the shuffled sequence of words until a word with a WordNet\(^\text{18}\) synonym is selected. Once such a word is found, a random synonym is pulled from its list of synonyms and inserted at a random place in the initial sentence. If no synonyms are found, nothing happens.

**Examples:**

- **Random Swap:** Fear of thunderstorms → Fear thunderstorms of.
- **Random Synonym Insertion:** Complete loss of teeth due to trauma → Complete loss of hurt teeth due to trauma.

#### 3.3.2 Typographical Augmentation

Since medics work in tense environments, they are susceptible to making errors while typing medical records, as they are subjected to a lot of stress, strain, and lack of sleep. We have developed the following augmentations mimicking potential typos:

- **Swap adjacent character:** Syndrome → Synrdome.
- **Remove character:** Syndrome → Syndome.
- **Change character with corresponding adjacent keyboard-key character:** Syndrome → Syndrone.
- **Insert adjacent keyboard-key character to a word:** Syndrome → Syundrome.

All these augmentations are applied on a randomly selected character of a randomly selected word.
3.3.3 Manual Augmentation

At certain places, where the above strategies could not be naturally applied, synonymous natural language descriptions were manually crafted.

Example:

3-PGDH deficiency $\rightarrow$ 3-phosphoglycerate dehydrogenase deficiency.

4 Text-Based Encoding with SNOMED CT Codes

If we have an unbalanced dataset, or if we want to split our problem into sub-problems, we can group our labels into clusters and train a model to predict to which of the clusters each sample belongs. After that, another model can refine (map) every predicted cluster to a specific label.

The proposed approach of text-based SNOMED CT classification is the following (see Fig. 2):

- Data Augmentation
- Label Clustering
- Sampling
- Train Multi-Cluster Classification Model
- Train Model for Clusters to Labels Refinement

4.1 Data Augmentation

The data augmentation techniques used in this step are described in detail in the previous section. The following parameters are used:

$$\text{augment probability} = 40\%$$
$$\text{minimum samples} = 5,$$

where augment probability refers to what portion of the current description’s words will be augmented and minimum samples refers to the minimum number of description samples every class should contain after the augmentation.

4.2 Label Clustering

Label clustering is widely used in extreme scale classification problems because datasets are mainly unbalanced and there are vast numbers of classes or because we want the classification task to be performed with less granularity. Our approach for clustering the dataset labels into groups is done by label embeddings, used in (Khandagale et al., 2020), and by applying clustering algorithm to it. Label embeddings for specific labels can be produced by summing all sample embeddings for which it is active. So, if we denote $X$ to be the matrix holding the embeddings of all samples’ descriptions, $X = [\text{samples} \times \text{embeddings}]$, and $Y$ to be the matrix holding multi-hot encoding of samples’ classes, $Y = [\text{samples} \times \text{labels}]$, Label embeddings (matrix $L$) is calculated using dot product between $X$ and $Y$. This matrix $L$ gives us information on how each label relates to each sample in our data, $L = Y^T X = [\text{labels} \times \text{embeddings}]$. For encoding the input samples’ descriptions, we applied the pre-trained BioBERT model (Lee et al., 2020). Clustering is done by a K-Means algorithm, with selected number of clusters of 100. This specific number is selected by manual analysis of data distribution over different number of clusters. The desired number of clusters is the smallest number that produces the minimum number of labels contained in more than one cluster, as well as best distribution of the labels for each cluster.
4.3 Sampling
Since our dataset is highly unbalanced because of the specifics of the domain, there are classes with only 5 samples and there are classes with more than 800 samples. The naïve sampling of random data splitting to train/dev/test sets will not work because this will result in all samples of some classes to be included entirely into one of the splits, which will lead to reduced accuracy. So, we developed a custom sampling strategy, which extracts distributed number of samples by a random manner into the dev and test split, which will result specific classes included into the dev and test splits to be included into the training corpus. For example, if class \( N \) has only 5 samples, its samples will be distributed as follows: train/dev/test = 3/1/1.

4.4 Train Multi-Cluster Classification Model
After label clustering is applied on the data, the next step is training a model for classification of the produced clusters. This can be formulated as binary, multi-class or multi-label classification. Since our dataset is very complex, and one class can be included into one or multiple clusters, we modified the official BioBERT implementation to perform a multi-label classification using Area Under the Curve (ROC AUC) as a scoring function. As an input, we have transformed our dataset using the produced clusters instead of the original labels, and we have fine-tuned the BioBERT weights on it.

4.5 Train Model for Clusters to Labels Refinement
The goal of the last step in the pipeline is finding to which label every sample belongs based on the already predicted cluster. There are a lot of possible solutions for mapping the sample’s predicted clusters to their labels, and a classical one is for each label to look into all instances which is too expensive, discussed in (Chang et al., 2020). Another approach is training multiple models. A model for every label including the subset of all instances included into the predicted clusters (Chang et al., 2020), which will lead to the number of models equal to the number of classes. Since we are dealing with an extreme scale classification task with more than 10k classes, we think that this is not practical for applying it in real applications. We have trained linear one-vs-rest classifiers (Support Vector Classification (Platt, 1999), (Chang and Lin, 2011)) for every cluster including all its instances with BioBERT sample embeddings as an input. This approach results in 100 SVC trained models for clusters-to-labels refinement using Area Under the Curve (ROC AUC) as a scoring function. Our contribution:
- Proposed augmentation techniques matching data distribution specifics;
- Proposed sampling strategy dealing with unbalanced data;
- Multi-class cluster classification is replaced with multi-label cluster classification, increasing the task’s level of complexity;
- Cluster to label refinement is compressed to model per cluster, which is more suitable for extreme scale classification tasks;

5 Experiments and Results
5.1 Dataset V1
On version 1 of our dataset, we initially attempted a classical multi-class classification approach by using pretrained BioBERT (Lee et al., 2020). The results were close to random guessing, so we tried another approach. We used some standard community detection algorithms (like Louvain (Blondel et al., 2008), (Dugué and Perez, 2015), (Traag et al., 2011) and Leiden (Traag et al., 2019)) to group SNOMED CT codes into classes in order to train a cascade of hierarchical BioBERT classifiers. This grouping was necessary because 95% of Dataset V1 forms a dense graph (see Figure 5). After analyzing the results, we concluded that by this grouping a lot of important connections were removed. For this reason, we have left this approach aside.

5.2 Dataset V2
On the new version of the dataset, we tried to solve the problem by a multi-label classification approach using pretrained BioBERT again. After comprehensive training iterations, our model reached Area Under the Curve (ROC AUC) of 0.60 (Figure 6) which was not high enough for solving the problem.

5.3 Dataset V3
The proposed approach described in section 4 is applied on this third version of our dataset. We have fine-tuned the BioBERT weights for the multi-cluster classification task (Step 4 of our pipeline),
Figure 3: Cluster classification BioBERT model is dealing with multi-label data

Figure 4: Refinement maps every sample with its corresponding labels based on the sample’s predicted cluster

Figure 5: Dataset V1 - Dense Graph

and after 7 epochs of training, it reached Area Under the Curve (ROC AUC) of 0.99653. Training

Figure 6: Dataset V2 - ROC curve

SVC for every cluster (100 SVC models) produces Area Under the Curve (ROC AUC) of 0.83273.

5.4 Dataset V4

The proposed approach described in the previous section is applied on this fourth version of our dataset. The Vocabulary is based on BioBERT v1.1, trained over PubMed. Some of the characteristics of Dataset V4 are presented in Table 3.

Table 3: Dataset V4 Characteristics

We have fine-tuned the BioBERT weights for the multi-cluster classification task (Step 4 of our pipeline), and after 25 epochs of training, it reached Area Under the Curve (ROC AUC) of 0.977.

Training SVC for every cluster (100 SVC mod-
els) produces Area Under the Curve (ROC AUC) of 0.804.

5.5 Discussion
The comparison (see Table 4) of the bioBERT multi-label classification with bioBERT clustering and label refinement, show that the proposed approach significantly improves the accuracy for SNOMED CT encoding task. The experiments are performed for trained models for 7 epochs for Dataset V2 - disorders subset.

<table>
<thead>

</tr>
<tr>
<td>bioBERT clusterings + label refinement (final approach)</td>
<td>0.97</td>
</tr>
</tbody>
</table>

Table 4: Comparison of the bioBERT models for Dataset V2- disorders

The proposed approach shows high accuracy and scalability. The additional steps for label refinement do not cause significant slow down of the learning process of the model. The obtained accuracy of the given method shows a significant improvement of the evaluation, compared to other solutions in the literature of the same problem, that report accuracy in the range from 0.83 (Pattisapu et al., 2020) up to 0.86 (Kraljevic et al., 2021). Moreover, the presented results of the experiments and the evaluation are for a larger dataset and a wider range of SNOMED CT codes.

6 Conclusion and Further Work

We demonstrated how can be generated annotated dataset with SNOMED CT codes. The proposed approach demonstrates high accuracy and scalability. In comparison with other state-of-the-art approaches the achieved accuracy for the proposed model is relatively high and more over for wider coverage of SNOMED CT.

Our further work includes training of Multilingual BERT to solve the multilingual problem. Possible increase of the Area Under the Curve (ROC AUC) scores can be achieved through grid search applied to the selection of the K-Means clusters number, until finding the optimal number, based on the distribution of the data.

Abstract

Existing text style transfer (TST) methods rely on style classifiers to disentangle the text’s content and style attributes for text style transfer. While the style classifier plays a critical role in existing TST methods, there is no known investigation on its effect on the TST methods. In this paper, we conduct an empirical study on the limitations of the style classifiers used in existing TST methods. We demonstrate that the existing style classifiers cannot learn sentence syntax effectively and ultimately worsen existing TST models’ performance. To address this issue, we propose a novel Syntax-Aware Controllable Generation (SACG) model, which includes a syntax-aware style classifier that ensures learned style latent representations effectively capture the syntax information for TST. Through extensive experiments on two popular TST tasks, we show that our proposed method significantly outperforms the state-of-the-art methods. Our case studies have also demonstrated SACG’s ability to generate fluent target-style sentences that preserved the original content.

1 Introduction

Text Style Transfer (TST) is an increasingly popular natural language generation task that aims to change the stylistic properties (e.g., the sentiment of text) of the text while retaining its style-independent content (Hu et al., 2020). Due to the difficulty in obtaining training sentence pairs with the same content and differing styles, most existing methods are designed to perform TST in an unsupervised manner; the models only have access to non-parallel, but style-labelled sentences.

A popular TST approach is to leverage an adversarial learning autoencoder framework where a style classifier or discriminator is pre-trained to first disentangle the content and style latent representations, before using a decoder to generate the output sentence in the target style (Shen et al., 2017; Zhao et al., 2018; Fu et al., 2018; Chen et al., 2018). Another line of work proposed attribute-controlled generation methods where the style attribute latent vector is learned and combine with the latent representation of the text to generate output sentences in target style (Hu et al., 2017; Dai et al., 2019; Zhang et al., 2018a). Similar to the adversarial learning approach, the learning of the style attribute latent vector is guided using a pre-trained style classifier.

A common key component in the two aforementioned TST approaches is the usage of a style classifier. However, little is known about the effects of the style classifier on these models. For instance, is the style classifier effective in learning the style in the text? What aspects of the text style has the existing style classifier learned? Can the style classifiers distinguish text’s syntax? Can the style classifier guide TST models to generate syntactically correct sentences and in the target style? This paper investigates these questions by conducting an empirical analysis of the style classifiers used in TST models. Extending from our empirical study, we propose the Syntax-Aware Controllable Generation (SACG) model, which includes a syntax-aware style classifier that ensures that the learned style latent representations effectively capture the syntax information for TST. Through extensive experiments with two popular TST datasets and human evaluation, we demonstrated SACG’s ability to outperform the state-of-the-art baselines in the TST tasks.

2 Related Work

In recent years, studies on text style have attracted not only the linguist’s attention but also that of many computer science researchers. Specifically,
computer science researchers are investigating the Text Style Transfer (TST) task that aims to change the text’s stylistic properties while retaining its style-independent content. The recent comprehensive survey (Hu et al., 2020) summarizes the existing TST approaches.

Among these approaches, a popular line of research aims to infer a latent representation for an input sentence and manipulate the generated sentence’s style based on this learned latent representation. Two techniques are commonly used to learn and manipulate the text’s style latent representations: (1) adversarial learning and (2) attribute-controlled generation. Shen et al. (2017) leverages an adversarial training scheme where a classifier is used to evaluate if an encoder is able to generate a latent content representation devoid of style. The text content latent representation is subsequently used to generate a specific style sentence using a style-dependent decoder. Similar works have been proposed where a classifier is pretrained to enable the adversarial learning process in TST models (Zhao et al., 2018; Fu et al., 2018; Chen et al., 2018; Logeswaran et al., 2018; Yin et al., 2019; Lai et al., 2019; Vineet et al., 2019).

Hu et al. (2017) proposed an attribute-controlled generation text style transfer model that utilized a Variational Autoencoder (VAE) (Kingma and Welling, 2013) to learn a sentence’s latent representation $z$ and leverage a style classifier to learn a style attribute vector $s$. Subsequently, $z$ and $s$ are input into a decoder to generate a target style sentence. Similar attribute-controlled generation methods have been proposed for the TST task (Dai et al., 2019; Zhang et al., 2018a; Li et al., 2019).

In the aforementioned methods, pretrained style classifiers played a vital role in guiding the TST task. However, these style classifiers are often pretrained without considering the syntax of sentences. We postulate that syntax is an important aspect of text style, especially in text formality style transfer. This paper empirically demonstrates the importance of modeling syntax in the TST task and proposes a novel syntax-aware TST method that outperforms state-of-the-art TST methods.

### 3 Empirical Study

Before presenting our proposed method, we first conduct an empirical study on the style classifiers used in existing TST methods. The goal is to examine the style classifiers’ ability to learn the syntax style information in a given text.

TextCNN (Kim, 2014), RNN (Cho et al., 2014), and Transformer (Vaswani et al., 2017) are popular style classifiers used in many TST models (Dai et al., 2019; Vineet et al., 2019; Luo et al., 2019; Li et al., 2019; Zhang et al., 2018b). In this study, we train the three style classifiers on GYAFC (Rao and Tetreault, 2018), which is a popular formality transfer dataset used in many TST studies. We first train and test the classifiers using the original GYAFC training and test set. Next, we perturb the sentence structure of the text in the GYAFC test set by disordering the sentences’ word order. The underlying intuition is that there should be syntax differences between formal and informal sentences, and the style classifiers should be able to learn the syntactic style information. Therefore, perturbing the test set’s sentence structure should worsen classification accuracy as the syntactic information in the text is corrupted.

The empirical experiment results show that syntax plays a crucial role in text’s formality. Table 1 shows the results of our empirical experiments. We observed a small 2.9% decrease in style classification accuracy in the disordered test set compared to the original GYAFC test set. We further examined the style classifiers’ performance in different classes. We noted that the classification accuracy for formal sentences sharply decreased as we disordered the test sentences’ word order. However, such observations are not made for informal sentences; the classification accuracy remained fairly constant even when word order was disrupted in informal sentences. From the observations, we postulate that the style classifiers may have focused on the attribute words to predict the style of sentences while neglecting the syntactic information in their style predictions. Furthermore, the style classifiers may have regarded the perturbed sentences as in-
formal ones. Nevertheless, the syntax of informal sentences should be different from the perturbed sentences. The similar classification performance on perturbed sentences demonstrated the style classifiers’ ineffectiveness in capturing different formality styles’ syntax information. More importantly, the style classifier’s inability to learn syntax information could misguide the TST model’s decoder to generate fragmented sentences, especially when transferring sentences to the informal style.

4 Methodology

This section proposes the Syntax-Aware Controllable Generation (SACG) model, which addresses the ineffectiveness of existing TST methods in handling sentence structure when transferring text style. We first introduce Graph Convolutional Networks (GCNs). Subsequently, we explain how the GCNs are utilized to extract sentence structure information in our syntax-classifier and syntax-encoder, which are the two main components in our proposed SACG model. Finally, we describe the learning process of our SACG model.

4.1 GCN and Sentence Structure Representation

As a variant of convolutional neural networks (LeCun et al., 1998), graph convolutional networks (GCNs) (Kipf and Welling, 2017) is designed for graph data and it has demonstrated effectiveness in modeling text data via syntactic dependency graphs (Marcheggiani and Titov, 2017). Consider a graph $\mathcal{G} = \{V,E\}$ where $V$ (where $|V| = n$ is the number of vertices in $\mathcal{G}$) is the set of graph node and $E$ is the set of graph edges. Given a feature matrix $X \in \mathbb{R}^{n \times d}$, where row $x_i \in \mathbb{R}^d$ corresponds to a feature for vertex $i$, the propagation rule of a GCN is given as

$$H^{(l+1)} = \sigma(AH^{(l)}W^{(l)}),$$ (1)

where $H^{(l)} \in \mathbb{R}^{n \times d_l}$ is the feature matrix of the $l$-th layer and $d_l$ is the number of features for each node in the $l$-th layer. $H^{(0)} = X$, $W^{(l)}$ is the weight matrix between the $l$-th and $(l+1)$-th layers, $A \in \mathbb{R}^{n \times n}$ is the adjacency matrix associated with the graph $\mathcal{G}$, and $\sigma(\cdot)$ is a non-linear activation function, such as ReLU or Leaky ReLU. In essence, a GCN takes in a feature matrix $X$ as an input and extract a latent feature matrix $H^{(L)}$ as the output, where $L$ is the number of layers in GCN.

Figure 1 shows the architecture of our proposed syntax-aware style classifier. Our goal is to extract and utilize sentence structure information to guide our SACG model to generate more plausible sentences. The syntactic relations between words in a sentence can be represented using dependency trees (Marcheggiani and Titov, 2017). A dependency tree can be regarded as a directed graph, and the GCNs can be used to extract the latent representation of sentence structure from the dependency trees. Previous studies have attempted to use GNCs to learn syntactic representation from dependency trees (Marcheggiani and Titov, 2017; Bastings et al., 2017). However, many of these existing techniques are over-parameterized, especially on huge datasets. To overcome this limitation, we employ a simpler approach where an adjacency matrix incorporated with directions is used to represent a sentence’s structure. Specifically, the adjacency matrix $A$ is used to represent the dependency relations of all words in the sentence. The column words are head words, and the row words are dependents. We set the element $A_{ij}$ to 1 if there is a dependency between the $i$-th word (head) and the $j$-th word (dependent). Similar to (Marcheggiani and Titov, 2017), we add a self-loop for each node in the graph, where all diagonal elements of $A$ are set to 1.

4.2 Syntax-Aware Style Classifier

In this subsection, we propose syntax-aware style classifier $D$ to encode the syntactic information from the dependency trees better.

Figure 1 shows the architecture of our proposed syntax-aware style classifier. We first encode the to-
Figure 2: Framework of the Syntax-Aware Controllable Generation (SACG) model.

kens in a sentence of size \( n \) as \( s = \{w_1, \ldots, w_n\} \) in the word embedding layer, where \( w_i \) is the \( i \)-th step input of Bi-LSTM. GCN has a limitation in capturing dependencies between nodes far away from each other in the graph. Therefore, instead of performing the graph convolution on the static word embeddings, we perform the GCN operations on top of the Bi-LSTM hidden states (Marcheggiani and Titov, 2017). As such, the GCN will only need to model the relationships for fewer hops. The Bi-LSTM states \( H_{lstm} = \{h_{lstm,1}, \ldots, h_{lstm,n}\} \) serve as input \( x_i = h_{lstm,i} \) to GCN, where \( h_{lstm,i} \) is the concatenation of the forward and backward hidden states. We feed the hidden states into a \( L \)-layer GCN to obtain the hidden representations of each token, which are directly influenced by its neighbors no more than \( L \) edges apart in the dependency tree. Formally, the hidden representation of node \( i \) at the \((l + 1)\)-th layer of GCN is computed by the following equation:

\[
    h^{(l+1)}_i = \sigma \left( \sum_{j=1}^{n} A_{ij} W^{(l)} h^{(l)}_j + b^{(l)} \right) 
\]

where \( A \) is the adjacency matrix of dependency tree, \( W^{(l)} \) and \( b^{(l)} \) are the model parameters, and \( \sigma \) is an activation function. We obtain the hidden representation \( h^{(L)}_i \) of node \( i \) after \( L \) GCN layers.

We noted that some node representations are more informative by gathering information from syntactically related neighbors through GCN. Thus, we utilize scaled dot-product attention (Vaswani et al., 2017) and averaging to aggregate the node representations to sentence representation:

\[
    \text{Attention}(Q, K, V) = \text{softmax}\left( \frac{QK^T}{\sqrt{d_k}} \right)V
\]

where \( Q, K, V \) represent queries, keys, and values, respectively, \( \frac{1}{\sqrt{d_k}} \) is the scaling factor. In practice, we feed the output \( H^{(L)} \) of GCN to \( Q, K, V \). Finally, we obtain the style prediction by feeding the sentence representation into a fully connected neural network followed by the softmax operation.

4.3 Syntax-aware Controllable Generation

Figure 2 shows the framework of our proposed Syntax-Aware Controllable Generation (SACG) model. For each input sentence \( s \) with attribute \( y_o \) and the corresponding adjacency matrix \( A \), the syntax-aware encoder \( E \) encodes \( s \) to a latent representation \( z = E(s, A) \). \( E \) is designed to extract sentence structure using the feature extractor of our proposed syntax-aware classifier. Subsequently, a decoder \( G \) decodes transferred sentence \( \tilde{s} = G(z, y_t) \) or input sentence \( s = G(z, y_o) \) based on the attribute controlling code \( y_t \) or \( y_o \). We employ the Stanford neural dependency parser Stanza (Zhang et al., 2020) to generate the dependency tree for transferred sentences, and the corresponding adjacency matrix \( \tilde{A} \). The transferred sentence \( \tilde{s} \) and the corresponding adjacency matrix serve as the input of the syntax-aware classifier \( D \), and the classifier will evaluate if the transferred sentence has the desired style.

We train the SACG model with classification loss \( L_{cla} \) and reconstruction loss \( L_{tree} \).

Classification Loss \( L_{cla} \): The classification loss ensures the transferred sentence is in the target style. To this end, we apply the pretrained syntax-aware classifier to guide the updates of related parameters such that the output sentence is predicted to be in the target style:

\[
    L_{cla} = -\mathbb{E}_{(s, y_o) \sim D}[\log P(y_t | G(\tilde{s}), \tilde{A})] 
\]

where \( G(\tilde{s}) \) denotes a soft generated sentence based on Gumbel-Softmax distribution (Jang et al., 2017a) and the representation of each word is
defined as the weighted sum of word embeddings with the prediction probability at the current timestep. \( A \) denotes the corresponding adjacency matrix of transferred sentence \( \hat{s} \).

**Reconstruction Loss** \( L_{rec} \): The reconstruction loss attempts to preserve the original content information in the transferred sentences. Specifically, the loss function constrains the model to capture informative features to reconstruct the original sentence using the learned representations. Formally, we define \( L_{rec} \) as follows:

\[
L_{rec} = -\log P(s|z, y_o) \tag{5}
\]

Where \( z \) denotes the hidden representation extracted by our syntax-aware encoder, and \( y_o \) denotes the original style of input sentence \( s \).

**Putting them together**, the final joint training loss \( L \) is as follows:

\[
L = L_{rec} + \lambda L_{cla} \tag{6}
\]

Where \( \lambda \) is a balancing hyper-parameter to ensure that the transferred sentence has the target style while preserving the original content.

5 Experiments

5.1 Experiment Setting

**Datasets.** We evaluate our model on two popular style transfer tasks: (1) Sentiment transfer, and (2) formality transfer. The representative Yelp \(^2\) restaurant reviews dataset (Shen et al., 2017) is selected for the sentiment transfer task. Following the same data preprocessing steps proposed in (Shen et al., 2017), reviews with a rating above 3 are considered positive, and those below 3 are negative. We adopt the same train, development, and test split as (Shen et al., 2017). Rao et al. (2018) released the GYAFCC \(^3\) (Grammarly’s Yahoo Answers Formality Corpus) dataset to facilitate the formality style transfer task. We adopt the Family&Relationship (F&R) domain data for our experiments. Although it is a parallel dataset, the alignments are only used for evaluation and not for model construction. Table 2 shows the training, validation, and test splits of the Yelp and GYAFCC datasets used in our experiments.

**Baselines.** We benchmark SACG against 12 state-of-the-art TST models: \( \text{ARAE} \) (Zhao et al., 2018), \( \text{DualRL} \) (Luo et al., 2019), \( \text{DAST}, \text{DAST-C} \) (Li et al., 2019), \( \text{PFST} \) (He et al., 2020), \( \text{DRLST} \) (Vineet et al., 2019), \( \text{DeleteOnly}, \text{Template}, \text{Del}&\text{Retri} \) (Li et al., 2018), \( \text{DIRR} \) (Liu et al., 2021), and \( \text{HPAY} \) (Kim and Sohn, 2020).

**Training.** The experiments were performed on an Ubuntu 18.04.4 LTS system with 24 cores, 128 GB RAM, and Nvidia RTX 2080Ti. The word embeddings of 300 dimensions are learned from scratch. We use a single Bi-LSTM layer followed by 2 GCN layers. The hidden dimension of the latent representation \( z \) is set to 500, and the learnable vectors with 200 dimensions represent the style labels. The decoder is initialized by a concatenation of the latent representation \( z \) and attribute controlling code \( y \). The syntax-aware style classifier is pretrained for evaluation and guiding the decoder’s generation. After pretraining, the parameters of the classifier are fixed. We use the Gumbel-softmax to back-propagate the loss through discrete tokens from the classifier to the encoder-decoder model (Jang et al., 2017b). We empirically set the learning rate to \( 1 \times 10^{-5} \) and the balancing parameter \( \lambda \) to 1.

5.2 Automatic Evaluation

We evaluate the proposed model and baselines on three criteria commonly used in TST studies: transfer strength, content preservation, and fluency.

**Transfer strength.** A TST model’s transfer strength or its ability to transfer text style is commonly measured using style transfer accuracy (Hu et al., 2020). A syntax-aware style classifier is first pre-trained to predict the style label of the input sentence. The classifier is subsequently used to approximate the style transfer accuracy of the sentences’ transferred style by considering the target style as the ground truth.

**Content preservation.** To quantitatively measure the amount of original content preserved after the style transfer operation, we employed four metrics used in previous work (Fu et al., 2018; Vineet et al., 2019; He et al., 2020):

- **BLEU:** The BLEU score (Papineni et al., 2002) is used to compare the style transferred sentences with the human references provided.

\[\text{Table 2: Dataset statistics for Yelp and GYAFCC.}\]

\[
\begin{array}{|c|c|c|c|c|}
\hline
\text{Dataset} & \text{Attributes} & \text{Train} & \text{Dev} & \text{Test} \\
\hline
\text{Yelp} & \text{Positive} & 267K & 38K & 76K \\
& \text{Negative} & 176K & 25K & 50K \\
\hline
\text{GYAFCC} & \text{Informal} & 51K & 2.7K & 1.3K \\
& \text{Formal} & 51K & 2.2K & 1K \\
\hline
\end{array}

Table 4: Performance of models on Yelp dataset (Sentiment Transfer Task).

in the GYAF dataset.

• **self-BLEU**: The self-BLEU score is adopted by comparing the style transferred sentence with its original sentence. This metric is used when human reference is not available.

• **Cosine Similarity**: Fu et al. (2018) calculated the cosine similarity between original sentence embedding and transferred sentence embedding. The two sentences’ embeddings should be close to preserve the semantics of the transferred sentences.

• **Word Overlap**: Vineet et al. (2019) employed a simple metric that counts the unigram word overlap rate of the original and style transferred sentences.

**Fluency.** Generating fluent sentences is a common goal for most natural language generation models. GPT-2 (Radford et al., 2019) is a large-scale transformer-based language model that is pre-trained on large text corpus. We fine-tuned GPT-2 on the GYAF and Yelp datasets and use the model to measure the perplexity (PPL) of transferred sentences. The sentences with smaller PPL scores are considered more fluent.

**Geometric Mean (G-Score)**: We compute the geometric mean of ACC, self-BLEU, BLEU, CS, WO and 1/PPL. Notably, we take the inverse of the calculated perplexity score because a smaller PPL score corresponds to better fluency.

### 5.2.1 Automatic Experiment Results

Table 3 shows the performance of the proposed SACG model and baselines on the formality transfer task. SACG has achieved the best G-Score, outperforming the state-of-the-art baselines. Nevertheless, we noted that none of the TST models could score well on all evaluation metrics. Many of the baselines can only perform well on transfer strength or content preservation, but not on both evaluation criteria. SACG has outperformed the baselines in G-Score, and achieve 84.1% transfer accuracy and 21.1 average BLEU score. The GYAF dataset also provided the performances of four human references performing the formality transfer task on the test set. The BLEU score of

Each human reference is calculated with the other three human references. Interestingly, we observe that SACG’s performance on the three TST evaluation criteria is comparable and close to human references’ performance.

Similar results were observed for the sentiment transfer task. Table 4 shows the performance of the proposed SACG model and baselines on the Yelp dataset. We computed the self-BLEU scores as no human references are provided for the Yelp test set. Similarly, SACG outperformed the baselines in G-score. We observe that the average style transfer accuracy in Yelp is 86.3%, which is significantly higher than GYAFC’s average score of 66.0%. The difference in the average style transfer accuracy highlights the challenge of the formality transfer task. We also noted that most models performed better in this task compared to the formality transfer task. Nevertheless, the trade-off phenomenon between transfer strength and content preservation is still observed in the sentiment transfer task.

5.3 Human Evaluation

To further evaluate SACG’s performance in generating syntactically correct sentences in target style, we conducted a human-based evaluation study. Specifically, we first randomly sampled 200 sentences from the GYAFC dataset. Next, we perform text style transfer for the sampled sentences using SACG and four competitive baselines. Finally, we recruited two linguistics researchers (i.e., participants) to evaluate the style-transferred sentences generated by the TST models. The participants are asked to evaluate the generated sentences on the three criteria discussed in the earlier section. Specifically, for Transfer Strength, participants are asked to indicate if the generated sentences are in the target style (i.e., a binary true/false indicator). For Content Presentation, the participants are asked to rate the amount of content preserved in the generated sentences using a 6-point Likert scale. 1: no content presented, and 6: all content are preserved. Similarly, for Fluency, the participants are asked to rate fluency in the generated sentences using a 6-point Likert scale. 1: too many grammatical errors, and 6: perfect and fluent sentence.

To minimize biases, we do not display the models’ names and we shuffled the order of the models when displaying their generated sentence. Therefore, the participants do not know which model generates a particular sentence.

5.3.1 Human Experiment Results

Table 5 shows the human evaluation results. For the transfer style, we compute the models’ style transfer accuracy using the binary feedback from the participants. We compute the models’ average 6-point Likert scores for content preservation and fluency criteria. SACG is observed to outperform the baselines in all three criteria. SACG is also rated to generate more syntactically sound and fluent sentence compared to the baselines. To check for participant bias, we compute the inter-annotator agreement between the participants. The Cohen’s kappa coefficients on style transfer strength, content preservation, and fluency are 0.54, 0.76, and 0.72, respectively. The participants have substantially high agreement on the content presentation and fluency. However, the participants’ agreement for style transfer strength is moderate as text formality is subjective, and the participants are only asked to perform binary indication.

5.4 Syntax Evaluation

As human references are available in the GYAFC dataset, we compare the syntax of the sentences generated by the TST models with the human references. Specifically, we compute the constituency tree edit distance (TED) to measure the syntactic similarity between generated sentences and human references. The intuition is that the TST model that could generate sentences with similar syntactic structure as the human references would likely have learned the syntactic information associated with the text formality style. To compute the constituency TED, we parse the sentences using Stan-
ford CoreNLP and compute the TED between constituency parsing trees.

Table 6 shows the syntax evaluation results. We noted that SACG outperformed the baseline in generating sentences that are syntactically similar to human references. This superior performance in both the formality transfer task and syntax evaluation suggests that SACG is able to learn the syntax information of formal and informal text to perform better text formality transfer.

5.5 Ablation Study

We also conducted an ablation study to further examine the importance of syntax-aware classifier and encoder in the SACG model. Table 7 shows the results of our ablation study. In the “w/o syntax-aware encoder” setting, we replace the syntax-aware encoder with a one-layer GRU (Cho et al., 2014). We noted a small decrease in performance for both formality transfer and sentiment transfer tasks when the encoder is replaced. In the “w/o syntax-aware encoder & classifier” setting, we further replace the syntax-aware classifier with a TextCNN (Kim, 2014) classifier. Interestingly, we observe a sharp decrease in performance for both formality transfer and sentiment transfer tasks. In particular, the absence of the syntax-aware encoder and classifier greatly worsens the fluency of the sentences. Our ablation study noted that the syntax-aware encoder and classifier play vital roles in ensuring SACG generates fluent target-style sentences that preserve the original content.

5.6 Case Study

We conduct some case studies by presenting randomly sampled examples and the corresponding style transferred output of SACG and the top three baselines ranked by G-Score. Table 8 shows the example outputs on the GYAFC and Yelp datasets. For the Yelp dataset, we observe that DualRL, PFST, and SACG are able to transfer the sentiment of the source sentence correctly. The generated sentences are also fluent and have preserved the original content (i.e., going back to a venue). The formality transfer task is observed to be more challenging, as we noted that most of the baselines could not generate acceptable output sentences. The baselines have generated output sentences with grammatical errors, making it harder to judge if the style has been successfully transferred. Albeit the difficulty of the task, SACG is able to generate a fluent sentence that preserved the original content.

6 Ethical Considerations

TST algorithms have many real-world applications. For example, these algorithms can improve target marketing messages’ persuasiveness and integrate into writing tools to improve users’ writing style. However, TST algorithms inherently run the risk of being misused for document forgery, impersonation, and sock-puppeting. To mitigate these risks, we will add access control to our code repository, and we would share our codes after the requester has acknowledged our ethical disclaimer.
7 Conclusion

In this paper, we empirically examined the style classifier used in existing TST models and demonstrated that the existing style classifier could not learn the text syntax effectively. We proposed SACG, a novel deep generative framework that considers syntax when learning style latent representation. We conducted extensive experiments on two benchmark datasets and benchmarked SACG against competitive TST models. The automatic and human-based evaluation experiment results showed that SACG outperforms state-of-the-art methods. Our case studies also demonstrated that SACG is able to generate fluent target-style sentences that preserved the original content. For future work, we will continue to explore other methods to improve the structural representations of text and incorporate them to perform better TST.

Abstract

Nowadays, named entity recognition (NER) achieved excellent results on the standard corpora. However, big issues are emerging with a need for an application in a specific domain, because it requires a suitable annotated corpus with adapted NE tag-set. This is particularly evident in the historical document processing field.

The main goal of this paper consists of proposing and evaluation of several transfer learning methods to increase the score of the Czech historical NER. We study several information sources, and we use two neural nets for NE modeling and recognition.

We employ two corpora for evaluation of our transfer learning methods, namely Czech named entity corpus and Czech historical named entity corpus. We show that BERT representation with fine-tuning and only the simple classifier trained on the union of corpora achieves excellent results.

1 INTRODUCTION

Recently, named entity recognition (NER) achieved outstanding results on standard NER corpora. Particularly on English CONLL-2003 corpus 90% F-measure has been overcome, which is sufficient for several real applications.

However, big issues are emerging with a need for an application in the specific domain which requires an appropriately annotated corpus including adapted NE tag-set. This issue is particularly evident in the case of historical documents in Czech language on which we focus on the project “Modern Access to Historical Sources”1. Manual annotation of this corpus is very expensive and time consuming. Moreover, the presence of a linguist is necessary. We will use the information about named entities as additional metadata for information retrieval and knowledge extraction.

Transfer learning targets at reusing information obtained from one corpus to improve the results of a model learned on an analogous task with few resources. To overcome this issue, we propose and evaluate several transfer learning approaches to improve the results of the Czech historical NER when the annotated resources are limited. The following information sources are considered and studied for this task:

- pre-trained fastText2 word vectors;
- pre-trained word2vec3 word vectors;
- pre-trained Slavic BERT4 contextual text representation;
- Czech contemporary NE corpus from different domain.

We employ two neural based models, namely recurrent Bidirectional long short-term memory (BiLSTM) (Graves et al., 2005) and Bidirectional encoder representations from transformers (BERT) model (Devlin et al., 2019) with a simple perceptron for NER modelling and recognition. We use two corpora for evaluation of our experiments.

Note that, to the best of our knowledge, this is the first attempt to employ transfer learning in the field of Czech historical NER.

2 RELATED WORK

Rodriguez et al. (Rodriguez et al., 2018) presented reproduction paper focused on transfer learning for entity recognition. They compared seven new corpus pairs results and other researches that were

1http://www.portafontium.eu/
2https://fasttext.cc/
3https://code.google.com/p/word2vec/
4https://github.com/deepmipt/Slavic-BERT-NER
published previously. They showed that if there is a small labelled target dataset, the simpler approaches work better in compare to neural transfer approaches that work better for larger labelled target data set. They reached an F1 score of 71.81% for the period 1814–1817 and 70.35% for the period 1685–1691.

In term of NER in historical texts, different methods have been applied for English so far; rule-based NER (Grover et al., 2008), Maximum entropy Markov model and Conditional random fields (Packer et al., 2010). Different tools for NER (Rodriguez et al., 2012) as OpenNLP, Stanford NER, AlchemyAPI and OpenCalais are available. NER for historical newspapers was researched by Mac Kim and Cassidy (2015) (English), Neudecker Neudecker (2016) (Dutch, French, German) and Kettunen et al. (2016) (Finnish). In case of historical newspapers, Stanford NER (Finkel et al., 2005) was applied to the 155 million OCRed articles from historical Australian newspapers by Sung hwan and Cassidy (Mac Kim and Cassidy, 2015) and they described how the data can be exploited using a clustering method. Moreover, Neudecker (Neudecker, 2016) created an open corpus for NER in Dutch, French and German based on OCRed historical newspapers as part of the Europeana Newspapers project.6 using Stanford NER for German. Similarly, (Kettunen et al., 2016) evaluated NER tools for Finnish using OCRed Finnish historical newspaper collection Digi. Transfer learning for NER was implemented by Lee et al. (Lee et al., 2018), similarly, for historical German NER by Riedl and Padó (2018) and Schweter and Baiter (2019).

Transfer learning for NER was implemented by Lee et al. (Lee et al., 2018) using artificial neural nets for two different datasets of patient note de-identification. They demonstrated that an ANN model trained on large labeled data set could be transferred to get state-of-the-art results on the datasets with small number of labels. Transfer learning for historical NER was investigated by Riedl and Padó (Riedl and Padó, 2018). They compared different NER models and methods for both contemporary German (large datasets) and Historic German (small datasets). They concluded that the best performance has BiLSTM model with a CRF as a top layer if enough data is available. On the other hand, the BiLSTM model using transfer learning showed that it is more effective for small data. They trained the model with large datasets of contemporary German and then they tuned on small historical ones. More recently, Schweter and Baiter (Schweter and Baiter, 2019) applied the contextual string embeddings (Akbik et al., 2018) (Flair) for German Historic NER. They also used synthetic masked language modelling (SMLM) that randomly adds noise during the training in comparison to the masked language modelling in BERT by Devlin et al. (Devlin et al., 2019). They showed that pre-trained models on specific datasets can reach state-of-the-art results in the case of Historic German. However, the SMLM approach showed the second best results. They also experimented with pre-trained fastText embeddings.

Recently, NER for contemporary Czech was researched by Štraka et al. (2019) using BERT (Devlin et al., 2019) and Flair (Akbik et al., 2018). Similarly, Arkhipov et al. (2019) presented multilingual NER for Russian, Bulgarian, Czech and Polish.

In term of NER for contemporary Czech, Štraka et al. (Straka et al., 2019) recently presented their sequence-to-sequence model to evaluate BERT (Devlin et al., 2019) and Flair (Akbik et al., 2018) and their combination on Czech named entity corpus (CNEC) versions 1.1 and 2.0. For CNEC 1.1, they reached 87.62% F1-score using Flair, 89.85% using BERT and 89.91% using both of them. For types of CNEC 2.0., they achieved 81.65% F1-score for Flair, 86.23% for BERT and 85.52% for both.

Moreover, Arkhipov et al. (Arkhipov et al., 2019) presented multilingual named entity recognition in Russian, Bulgarian, Czech and Polish (Asia Bibi datasets from BSNLP 2019 Shared Task) using BERT model and additional word-level CRF layer. This approach reached state-of-the-art results: 93.9 F1 score for Czech, 87.3 for Russian, 87.2 for Bulgarian and 93.2 for Polish, respectively.

In the case of text embeddings, Akbik et al. proposed a pre-trained model of contextual string embeddings (Flair) for NER that considers words as sequences of characters. They experimented with a BiLSTM-CRF model proposed by Huang et al. (Huang et al., 2015) and different approaches to word embeddings. They extended the model by adding a concatenation of pre-trained static word embeddings with contextual ones and a concate-

5http://www.europeana-newspapers.eu/

6https://ufal.mff.cuni.cz/cnec
nation of task-trained character features with contextual string embeddings. They reached 93.09% F1-score for English and 88.32% for German with this model configuration for CoNLL2003 shared task.

3 CORPORAS

We experimented with two corpora: Czech named entity corpus (CNEC) and Czech historical named entity corpus (CHNEC). CNEC corpus contains almost 9,000 sentences and more than 35,000 occurrences of the Czech named entities. The corpus uses two-level NEs annotation scheme and the first-level contains 10 main NE types and the second-level is composed of 62 NE subtypes. To be able to map NEs from CNEC to CHNEC, we use only five NE types from the first annotation level which are same for both corpora.

CHNEC\(^7\) contains 73,647 tokens and 4,017 named entity occurrences. The corpus was created from Czech historical newspaper Posel od Čerchova from second half of 19th century and distinguishes five NE types: Personal names, Institutions, Geographical names, Time expressions and Artifact names/Objects. The corpus is encoded in IOB format (Ramshaw and Marcus, 1995), where \(B\) represents one-token entity or the beginning of multi-token named-entity, \(I\) inside tokens of multi-token named-entity and \(O\) stands for all tokens that are not a named-entities.

4 METHODS

4.1 Models and Representations

4.1.1 BiLSTM with Word-level Embeddings

The first approach uses BiLSTM model with word-level representation of the sentences. We used similar network structure and similar hyperparameters as presented by Hubková et al. (2020) (Table 1) with two different word representation methods: fastText and word2vec.

Note that we use BiLSTM model with randomly initialized word embeddings as a baseline. This approach does not consider any transfer because the embeddings are learned during the training of the network only of the available training data.

4.1.2 BERT with Perceptron

The second method uses BERT model (Devlin et al., 2019) for representation of the text and a simple single-layer perceptron (SLP) with only one softmax layer is used for NE recognition. The main advantage of this approach in comparison with the previous one is that BERT considers the different word meaning when used in the different context.

This model uses unlabeled data to pretrain deep bidirectional representations by jointly conditioning on both left and right context in all layers. Sequences of word tokens (or subtokens) in the sentence are used as an input and the outputs are class probabilities among the classes.

4.2 Transfer Learning

4.2.1 Transfer from Embedding Word Vectors

The first transfer learning approach is focused on the embedding vectors. Our embedding vectors are built using different models, and thus they kept different information. FastText considers word and also sub-word units, therefore it should encode semantic and syntactic information as well. However, word2vec is trained properly using word tokens, hence it includes mostly semantic information.

The initial embeddings are learned on huge unlabeled text corpora coming from different domains and containing different language (contemporary Czech instead of historical one). For that reason, we assume that the further fine-tuning of these embeddings on the target data should improve the final NE recognition score. Therefore, in this approach, we compare fastText and word2vec and embeddings with two scenarios. The first one uses only static embeddings without a subsequent training and the second one tries to adjust these vectors into our task during network training.

4.2.2 Transfer from BERT Representation

The second approach is based on the transfer from BERT representation. In order to have as much precious representation as possible, we use pre-trained Slavic BERT proposed by Arkipiov et al. (2019). This model is based on a multilingual BERT model and fine-tuned with Czech, Russian, Bulgarian and

\(^7\)http://chnec.kiv.zcu.cz/
Polish data. We assume that the further fine-tuning of this representation on the target data will still improve the final NE score. Therefore, in this approach, we perform another fine-tuning by training on our historical data.

4.2.3 Transfer from Different Corpus
The third approach assumes that different NER corpora (see Section 3) should include complementary information and the usage of these together will improve the final score of the target task. The following scenarios are considered, evaluated and compared:

- training only on CHNEC corpus (to show the impact of the approaches below);
- training only on CNEC corpus (to show the results when the target annotated data are not available);
- union of both corpora and training on this large dataset;
- initial training on the CNEC corpus and fine-tuning on the target one (CHNEC).

4.3 Cross-corpus Method
As a cross-corpus method we mean that we trained BiLSTM or BERT model with CNEC training data set (source corpus) and models and we tested on CHNEC test data (target corpus). This approach showed if bigger corpora for contemporary language itself can be used for tagging a smaller historical texts.

We experimented with token classification PyTorch module for NER by Wolf et al. (2019) and we used pre-trained Slavic BERT model.

BERT token classification method has a linear layer on top of the hidden-states output and this model is available through PyTorch module. Pre-trained Slavic BERT is based on BERT model by Devlin et al. (2019) and extended by word-level CRF layer. The model is tuned on four Slavic languages Russian, Bulgarian, Czech and Polish.

5 Evaluation and Results
Table 2 and Table 3 show the results of our experiments. We use the standard precision, recall and macro-averaged F1-score (Powers, 2011) metrics for evaluation. In all cases, we calculate the final score on the testing part of CHNEC corpus. Qualitative analysis in Section 5.1 is based on the observed linguistics phenomena in both development and test data sets.

The first part of Table 2 presents the results of our approaches dealing with the transfer of embedded word vectors. BiLSTM model trained only on CHNEC corpus is used for NE recognition. The results show that fastText representation brings significantly better results than word2vec one. These results further illustrate that the fine-tuning of the embeddings has only a positive impact in the word2vec case, and unfortunately, it does not bring any improvement in the case of the fastText representation. This behaviour should be justified that fastText word representation corresponds better to our task, and our training data are too small and differ from the testing set for the further improvement of the model. Based on these results, we will use for the following experiments only fastText fixed embeddings.

The second part of the table shows the experiments using BiLSTM model with different approaches for training. These results show that it is possible to obtain F-measure 45% using only the different corpus (any additional annotation is not required). Moreover, it has been demonstrated that the transfer from CNEC into CHNEC does not bring any positive impact on the final NER.

The last part of Table 2 shows the results of our transfer learning approaches using BERT representation with the simple single-layer perceptron as a classifier. The impact of the different training approaches is also considered. These results show clearly that BERT representation with fine-tuning and only a simple classifier brings significantly better results that all the approaches evaluated previously. This should be explained by the fact that word context representation is much more accurate than the word-level one. This experiment further illustrates that the additional data coming from another NER corpus is beneficial to improve the final NER score by 2%.

Another observation is that the values of the precision and recall are balanced, however in the previous series of experiments, these values differ significantly.

The previous experiment does not consider the individual NE types. However, this information could be very interesting for further improvement of the training strategy and the model itself. We assume, that the size of the training data and the

</table>

The learning approaches on the randomly selected sample containing about 100 randomly selected sentences per model and approach.

If we train BiLSTM model only with CNEC data, the model showed that this method correctly tagged especially geographic names and personal names, e.g.: names of towns such as Prahy or Horšovský Týn; names of persons such as Vojtěcha Bittmara or Petr Bedřich Florian. The time expressions were tagged correctly in case that the format of the time in CNEC was similar to format in CHNEC, e.g. 20 . února 1775 (“20th February 1775”). Similarly, the named entity Sokol (name of a sport institution) was tagged correctly as this named entity occurs in both CNEC and CHNEC. However, the other NE types were rather erroneous.

On the other hand, if we compare these results with a basic BiLSTM model that was trained only on in-domain historical data, we can see that the specific language expressions that occur in historical CHNEC texts are not tagged. CHNEC corpus contains a number of abbreviations, e.g. 26 . června t . r . (“26th June this year”) or c . k . okresní finanční ředitelství v Plzni (“Imperial-Royal District Financial Directorate in Pilsen”). More-
over, using dots in the named entities in this corpus is inconsistent, it means that it contains both 29. June and 29. June or name of person Jos. Kralovec.

Then, we analyze the results of the approaches which use BERT representation. Generally, BERT improves the results with its ability to correctly tag NEs that do not occur in the training data. As we fine-tuned the Slavic BERT model using the combination of CNEC and CHNEC, the model overcomes the problems with abbreviations mentioned above. However, some false positive cases occur as well, e.g. c. k. okresní hejtman ("Imperial-Royal district governor") was tagged as Institution.

Geographical names that occur more frequently in CHNEC than most other NE types reached 0.92 F1-score in comparison to Institutions that occur only 286 times in the whole CHNEC and reached 0.59 F1-score.

Next to the pure occurrences in the corpora, the names of the Institutions differ between historical and contemporary language a lot as many institutions do not exist in the present anymore, e.g. spořitelný kr. města Domažlic ("savings bank of the royal town of Domažlice"). From this point of view, Time expressions or Personal names are more stable in time. The Institution are also usually long multi-word expressions (e.g. "všeobecné úvěrní a obchodní banky" ("general credit and commercial bank") in contrast to shorter and more consistent Time expressions and Personal names. This fact also complement the previous justifications of the lowest recognition score for the class Institutions.

6 Conclusions

In this paper, we proposed and evaluated several transfer learning approaches in order to improve the results of the Czech historical NER. We considered and studied the following information sources: pre-trained fastText and word2vec word representations, pre-trained Slavic BERT contextual text representation and another NE corpus from different domain. We used two popular models, namely recurrent BiLSTM and BERT with a simple perceptron for NER modelling and recognition. We have shown that fastText representation gives significantly better results than word2vec model. It has been also demonstrated that the transfer from CNEC into CHNEC with BiLSTM model does not improve the final NER score. We have further presented that BERT representation with fine-tuning and only the simple classifier trained on the union of corpora brings the best results (F-measure 82%). Based on the analysis of the errors, we can also conclude that the combination of the different models/approaches would not bring any further improvement.

Abstract
Feature engineering is an important step in classical NLP pipelines, but machine learning engineers may not be aware of the signals to look for when processing foreign language text. The Russian Feature Extraction Toolkit (RFET) is a collection of feature extraction libraries bundled for ease of use by engineers who do not speak Russian. RFET’s current feature set includes features applicable to social media genres of text and to computational social science tasks. We demonstrate the effectiveness of the tool by using it in a personality trait identification task. We compare the performance of Support Vector Machines (SVMs) trained with and without the features provided by RFET; we also compare it to a SVM with neural embedding features generated by Sentence-BERT.

1 Introduction
Data scientists and computer scientists working on natural language processing (NLP) problems are occasionally confronted with tasks in languages they do not know well. Technical linguistic issues that may be well known to researchers and language practitioners familiar with the language can be quite important to effective language engineering, and can take a lengthy career to master.

The Russian Feature Extraction Toolkit (RFET) unites a suite of tools for Russian language processing that would allow a programmer unfamiliar with the language the ability to get started quickly in common text classification tasks such as sociolinguistic factor classification, sentiment classification, and emotion analysis. Additionally, this toolkit provides those advanced in Russian NLP convenient accessibility of features and feature combinations to quickly iterate through multiple experiment scenarios.

Deep learning approaches are showing great promise, and feature extraction is less commonly utilized in these approaches. Still, there are existing systems in production which harness classical machine learning techniques. RFET, and tools like it for other languages, could improve performance of these systems without a complete redesign. Further, there are many languages in which deep learning approaches still lack pre-trained models or even a sufficient quantity of text examples to create them. The methodology presented in this paper could be used to design Feature Extraction Toolkits for these languages, in these cases.

This toolkit does not replace feature extraction functions in libraries like NLTK (Bird, 2006) or scikit-learn (Pedregosa et al., 2011). These systems can produce language-independent statistical measurements on text that could be used as features. It also does not seek to replace toolkits for basic NLP pipeline elements, such Natasha,¹ though there is some overlap between the tools. This toolkit focuses on uniting Russian language resources that provide linguistically-informed features that are distinctive of the Russian language or otherwise not adequately represented in features used in text analytics or corpus linguistics, with a focus on social media Russian. The toolkit includes 70 features.

In order to validate the toolkit’s utility, we evaluate its efficacy in a challenging task with little prior work in Russian: namely, the identification of personality traits from user-generated social media text. This task is further described in Section 2.2.

Section 3 describes RFET’s collected features in more detail; Section 4 describes the dataset and other methodological details of the task and our results. Other sections outline larger context and limitations of the study.

2 Related Work

2.1 Language-specific Feature Extraction

Structured Programming for Linguistic Cue Extraction (SPLICE) (Moffitt et al., 2012) is a tool for English language feature extraction. SPLICE offers (via API\(^2\)) a variety of lexicons and other features relevant to credibility assessment and deception detection, including lexicons for deference, positive and negative self-evaluation, affect and sentiment (from SentiWordNet). SPLICE’s features include part of speech, verb tense and passive voice (for immediacy), spoken word counts for hedging and disfluency, and a variety of readability scores. It offers a mechanism for users to submit their own lexicons.

The Arabic Data Science Toolkit (ADST) (Rodrigues et al., 2018) is a Python toolkit for analyzing Arabic, particularly social media Arabic. It addresses features both in Modern Standard Arabic and Egyptian Colloquial Arabic, and focuses on features that highlight emotion, such as laughter and emoji, and informal expressions of intensity, such as elongated words. It also includes several language-specific lexicons, such as honorifics, polite and pious expressions, abusive language, and transitional phrases. Its coverage of emotional language is somewhat incomplete, focusing more on positive emotions such as happiness and humor than negative emotions.

Linguistic Inquiry and Word Count (LIWC) (Pennebaker, 1993; Pennebaker et al., 2007, 2015) is a collection of vetted lexicons focused mainly on lexical features of psychological interest, though it also covers more general linguistic categories as well. All categories are vetted multiple times by human judges. The 2015 version has been updated and expanded to include “netspeak” language found in social media and SMS, including some common informal abbreviations and emoticons. Developed originally for English, it has been ported to 12 languages, including Russian. It is available only under paid license (even for non-commercial academic use) and (for Russian) only as a stand-alone program. The API only supports English.

Another tool, Empath (Fast et al., 2016), might be characterized as a partially automated extension of LIWC, with a framework for further extensibility. Empath uses a combination of human-generated seed words, semantic embedding-based term discovery to grow topic lexicons (categories) from these seed terms, and crowd-powered filtering to validate these categories. Unlike most embedding-based models, it is trained largely on fiction works in the public domain, which are claimed to offer more general coverage than other domains. It offers many more topics and categories than LIWC, but novel categories are largely unvetted. The pre-validated models currently available are (to the best of our knowledge) only available in English.

Natasha and DeepPavlov\(^3\) (Burtsev et al., 2018) are NLP pipeline toolkits specifically built for Russian. They bring together NLP tools such as word token and sentence segmentation, word embeddings, morphological syntactic tools, and NER. Natasha adds fact extraction; DeepPavlov various conversational agent functions. As general purpose tools, they complement RFET, which has a more specific focus on social media text.

2.2 Personality Trait Identification

While several personality taxonomies exist, the most well researched set of personality traits is called the Five Factor Model, Big Five, or OCEAN (Openness, Conscientiousness, Extraversion, Agreeableness, and Negative Emotionality or “Neuroticism”), which is typically measured via a 60-item self-report questionnaire, the Big Five Inventory-2 (BFI-2) (Soto and John, 2017). The BFI-2 has been translated into Russian and validated with samples of students and internet users (Shchebetenko et al., 2020).

Golbeck et al. (2011a,b) were among the first to examine the efficacy of inferring personality from user-generated social media text (from Twitter and Facebook). Since that time, a number of studies have followed suit. Farnadi

\(^2\)http://splice.cmi.arizona.edu/

\(^3\)https://deeppavlov.ai/
et al. (2016) conducted a comparative analysis of computational methods on English social media text from three separate platforms: Facebook, YouTube, and Twitter. While most work in social media personality trait identification has focused on English, other European languages have also been examined. For example, the PAN research group organized a shared task in 2015 with Twitter data from four languages: English, Spanish, Italian, and Dutch (Rangel Pardo et al., 2015).

Only a few studies have attempted personality trait inference from Russian social media text. Stankevich et al. (2018) learned a three-way (low, medium, high) classification of the five factors from a dataset of 165 VKontakte profiles. However, due to the sparseness of usable, user-generated text in their dataset, they were unable to use lexical features, but only very basic features on the text (such as average numbers of words and sentences, use of punctuation and uppercase). Their reported F1 scores range from 36% for Conscientiousness to 53% for Agreeableness.

Similarly, Ignatiev et al. (2019) used both SVM and Random Forest approaches for a two-way (highest quartile, lowest quartile) classification of five factors traits from their dataset of 1,020 VKontakte profiles. They used lexical features, an aggression lexicon, user profile information, and a repost matrix, and reported F1 scores ranging from 61.75% on Openness to Experience to 73.75% on Extroversion.

Litvinova et al. (2015; 2016) and Vybornova et al. (2011) infer personality traits from other genres of Russian text (besides social media such as VKontakte). They propose several and test linguistic correlates to personality, such as content/function words, readability indices, lexical diversity and usage of first-person singular pronouns.

3 RFET Features

3.1 Morphological

Morphological features are generated using PyMorphy2, a Russian morphological analyzer and inflection engine (Korobov, 2015).\(^4\) The morphological analyzer is able to detect the following morphological features: part of speech, animacy, verbal aspect, dictionary citation forms, case, gender, involvement, mood, number, person, tense, transitivity and voice. Because PyMorphy2 evaluates on the token level, without looking at the context, syntax level features are not captured by the toolkit.

The toolkit leverages the output of PyMorphy2 to calculate the frequencies of these features within the text, but we added extensions to produce additional linguistic features for RFET. We diverge from PyMorphy2 where the tool conflates logically different phenomena. For example, PyMorphy2 determines gender of nouns and adjectives by word ending; however, some borrowed nouns and acronyms are indeclinable and thus may not show any cues for gender. Not all such nouns are neutral, so assigning a default gender risks inaccuracies (Wang, 2014). Inevitably, some lexical items will be missing from PyMorphy2’s lexicons and thus have undetermined gender so far as PyMorphy2 is concerned.

Additionally, not all Russian parts of speech inflect for gender. The toolkit expands the tag set from 4 tags (masculine, feminine, neuter, null) to 5 tags (masculine, feminine, neuter, undetermined, non-gendered-pos) to differentiate between those words of specific parts of speech that are not gendered in Russian (i.e. conjunctions, comparatives, gerunds, adverbs, particle, infinitives, prepositions and predicatives) with those parts of speech that can have gender, but are not determined by PyMorphy2.

RFET also utilizes PyMorphy2’s OpenCorpora Dictionary (Открытый корпус), to identify the ratio of words in the text that are not found in its lexicon. This ratio may indicate usage of new words, slang, typos, URLs and other Out Of Vocabulary (OOV) items. The ratio of OOV items can be a useful feature for classification to sociolinguistic targets.

3.2 Laughter, Emoticons and Emoji

While laughter appears in informal text across languages, the characters and patterns used

\(^4\)https://github.com/kmike/pymorphy2. At the time of RFET’s design, PyMorphy2 seemed to be the most widely cited specifically Russian morphological parser and was integrated into DeepPavlov. UDpipe’s Russian lemmatizer may have been a reasonable alternate choice. A Russian lemmatizer for SpaCy was not available until February 2021, as documented in the SpaCy blog. (https://explosion.ai/blog/spacy-v3). A comparison of lemmatizers is out of scope for this paper.
to represent laughter differ. RFET returns frequency features on Russian-specific laughter and emoticons found on social media, as well as language-agnostic emoji features. These features could be utilized in an author attribution system, sentiment analysis, or emotion classification system.

RFET returns frequency information on type, number of times used and length of laughter or emoticon within the text. RFET tracks the following types of laughter (in featurename (example) pairs): haa (xaha), haah (xahaaxaax), haahaa (xahaaxa), ha-ha (xa-xa), hehe (hehhehee), hihi (xihxihxhi), hi-hi (xih-xih), Lol (xol), Lolol (xolol), phaha (pahaaxa), HAHAXA-RAHAH, hoho (xhoxo), HIHI (XIXHI), HEEHEE (XEXEXE), HOHO (XOXO), HA-HA (XA-XA), HIIHI (XHI-XHI), as well as Russian happy face parenthesis (“))))
5 and sad face parenthesis (“((“)). These are implemented as templated regular expressions that match and report the length of variants.

RFET also has a feature which returns the frequency of emoji usage and leverages Cal Henderson’s emoji-data package.6

3.3 Sentiment and Emotion Features

Sentiment analysis is one of the most popular commercial applications of NLP, and RFET makes it easier for a nonnative speaker to implement a system in Russian. Currently RFET utilizes one emotion/sentiment lexicon and can easily be extended to allow for others.

The NRC Emotion Lexicon (Mohammad and Turney, 2013), also known as EmoLex, is a lexicon translated into 104 languages. Each lexical entry is coded for Positive and Negative sentiment and the emotions Fear, Anger, Sadness, Joy, Disgust, Surprise, Trust and Anticipation.7 RFET reports the emotions present in the text by using PyMorphy2 to resolve the dictionary citation form of each token in the text and reporting the emotion(s) and sentiment orientation associated with that form in the lexicon, if available. If the token is present in the lexicon but is not coded as positive or negative, the token is coded as neutral. Similarly, RFET reports whether a token is not found in the lexicon. RFET uses these resources to return a dictionary of sentiment (positive, negative, neutral) and emotion (fear, sadness, joy, disgust, surprise, trust, and anticipation) or “token_not_in_lexicon” and the count of tokens representing these.

3.4 Lexical Diversity

According to Litvinova et al. (2016, 2017), a lack of lexical diversity was associated with individuals with a greater likelihood of self-destructive behavior, which may be useful to author profiling or personality identification systems.

Litvinova et al. (2017) described lexical diversity through a variety of features, including type to token ratio, an index of formality, an index of lexical density, the ratio of function words (particles, prepositions, conjunctions, etc) to total tokens, the ratio of content words (nouns, verbs, infinitives, adjectives, adverbs, etc.) to total tokens, the ratio of personal pronouns to total tokens, and the proportions of the 100 most frequent Russian words in the document to all tokens.

RFET implements these key lexical diversity features replicating Litvinova’s descriptions; in addition to extracting the proportion of the top 100 most frequent Russian words (unigrams), it also tracks usage of the top most frequent bigrams, trigrams, and 4-, 5-, and 6-grams in the Russian National Corpus (RNC).8

3.5 Other Lexical Features

Other Russian specific features that RFET extracts and quantifies are punctuation, digits, diacritics, other languages, and other scripts. The punctuation, diacritics, and quotation scripts include Russian specific unicode characters (i.e. «, », „ and “) in addition to the punctuation that is shared across languages. The punctuation feature does overlap with the emoticon features.

7https://github.com/iamcal/emoji-data

N-grams are found at e.g., https://ruscorpora.ru/old/1grams.top.html.
The ratio of code switching or borrowings from Western languages may be indicated by the ratio of Latin characters to total characters in the text, and this is reported by RFET as an additional feature. Another feature utilizes a language identification package\(^9\) to determine the language of the text, in order to identify instances of non-Russian text within a corpus of presumed Russian documents, including languages such as Bulgarian, Macedonian, and Ukrainian that also use Cyrillic.

4 Inferring Personality Traits

4.1 Dataset

The dataset for evaluating the personality trait inference task was collected by the authors during 2020. It consists of 149K VKontakte posts from 288 consenting participants, with a total of 3.8M word tokens. (This corpus was filtered from a larger collection by excluding posts containing URLs, ASCII art, duplicate posts, and posts that appeared to be auto-generated. It includes only those participants with at least 1200 tokens in their VK posts after this filtering process.) Each of the 288 participants took the Russian version of the BFI-2 inventory (Soto and John, 2017; Shchebetenko et al., 2020). The labels (personality trait scores) were rescaled from the raw inventory scores to the interval \([-5, 5]\). The dataset was partitioned by author into train and test sets (with 80% of author accounts comprising 79% of the total word tokens in train and the rest in test).

4.2 Baselines

We created two sets of baseline models for personality ID, one using classical machine learning methods, and one using neural embeddings.

The first set of baseline models created for the five personality traits used a standard bag-of-words approach using term frequency–inverse document frequency (tf*idf) and included language-independent features of “lexical richness” such as Yule’s (2014) \(K\), Sicil’s (1975) \(S\), Honoré’s (1979) Measure, Brunet’s (1978) Measure, Maas’s (1972) \(a^2\), and Rubet’s \(k\) (Dugast, 1979). None of these features require specific knowledge of the target language. Because of the size of the \(tf*idf\) data, principal component analysis (Jolliffe and Cadima, 2016) was used to reduce the number of features. In total, 73 features were kept from the \(tf*idf\) data, which corresponded to keeping 85% of the total variance, as well as the six lexical richness features.

The second set of baseline models created for the five personality traits used Sentence-BERT (SBERT) (Reimers and Gurevych, 2019) in combination with Russian-specific language model Sentence RuBERT (rubert-base-cased-sentence)\(^{10}\), a fine-tuned version of RuBERT (Kuratov and Arkhipov, 2019) for sentence embedding. Sentence-BERT produces fixed-sized embeddings by pooling the output of a language model. These fixed-sized embeddings are convenient to use in combination with classification algorithms for sentence classification tasks. We used Sentence-BERT’s highest performing pooling strategy to produce these embeddings by taking the mean of all output language vectors and Sentence-BERT’s default maximum sequence length of 128 WordPieces.\(^{11}\)

4.3 Method

We used a standard implementation of a support vector machine (SVM) to train personality identification regression models from a corpus of Russian VKontakte text labeled for Big Five personality traits, varying the features supplied to each system. Each feature set we utilized was used to train and test against the five traits-Openness (O), Conscientiousness (C), Extraversion (E), Agreeableness (A), and Negative Emotionality (N) traits. A linear kernel was used for all traits, and the regularization parameter \(C\) was tuned separately for each trait.

The target data are scaled to the interval \([-5, 5]\) for each trait, and we report the root

\(^9\)https://pypi.org/project/langdetect/, which is a Python port of Shuyo Nakatani’s (2010-2014) language-detection Java language ID package.

\(^{10}\)https://huggingface.co/DeepPavlov/rubert-base-cased-sentence

\(^{11}\)Preliminary experiments suggested that using a maximum sequence length of 512 WordPieces did not meaningfully improve performance accuracy, while adding significant time requirements. The average post in our training corpus, when tokenized to the rubert-base-cased-sentence lexicon, was 50 WordPieces. There were 4719 posts longer than 128 WordPieces, about 4.5% of our training corpus, which means with a maxlength of 128, only 4.5% of our samples were clipped.
mean square error (RMSE). Across all experiments, the same training and testing splits were used on the data.

Our goal is to predict all five personality traits, so this problem can be treated as a multi-target regression problem. Since there is evidence in our dataset and other literature that personality traits are correlated (Gosling et al., 2003), the target trait of one model may be useful as a feature when predicting another trait. Because of this, predicted values for some traits were fed back in as features for other models, called “stacked single target” (SST) chains (Spyromitros-Xioufis et al., 2016). Similar work has been done for other multi-target regression problems with positive results (Melki et al., 2017). It is possible for this process to be optimized, standardized, or generally improved. We look to investigate this in future work. For the experiments reported in Table 1, the trait that was predicted the most accurately was the one chosen as a feature for the next round of models. Each trait was added in as a feature exactly one time, such that the final database consisted of all the raw data, plus five new features (one for each trait). Thus each of the five traits is predicted using the stacked single targets (i.e., trait value predictions from previous iterations of the model) for the four other traits as features.

4.4 Results

Table 1 shows root mean squared error (RMSE) (lower is better) and \( R^2 \) (higher is better) for our bag of words classifier with and without the RFET features. Each post was treated as a unique entry, and the data was fed into a support vector regression model. To prevent overfitting, both the test-train split and cross validation splits were done on the participant level. The model never saw any data from any participants in test or validation sets. The inclusion of RFET features produced a more accurate model based on both RMSE and \( R^2 \) values. We believe these features add significant value to modeling personality traits and likely other tasks as well.

Our Sentence-BERT neural baseline results for post-level predictions of a post author’s personality traits, as well as comparable predictions for the BoW+RFET model, can be found in Table 2. Unlike our SVM baseline and SVM with RFET features results in Table 1, neither Sentence-BERT nor the SVM with RFET features shown here utilize SST as input to help improve the performance. We found that the SVM with SST and SVM with RFET features (with or without SST) outperformed the Sentence-BERT neural baseline.

Comparing the two BoW+RFET columns in Tables 1 and 2, we can see that the SST chains do improve the BoW+RFET model’s accuracy for all features but Negative Emotionality, but of course this comes at the cost of speed, as the five traits can no longer be trained or decoded in parallel (and training requires several more iterations).

5 Discussion

For the personality trait identification task on this social media dataset, we see that a classic SVM baseline using RFET features outperforms a similar SVM without the RFET features. We likewise see that the SVM with RFET features outperforms a model using a transformer model pre-trained on Russian text.
One trait where the advantage of the RFET features is particularly large is the Agreeableness trait. One possible explanation for this may be differences in participants’ use of emoji, emoticons, and/or emotional words correlating with their Agreeableness trait values. RFET includes features specifically developed for emoji, emoticons, and emotional words, and even the SVM BoW model may be somewhat sensitive to them; the pretrained model, on the other hand, may be ignoring emoji and emoticons, since such “words” may not have appeared in its original training data.

Another advantage the standard machine learning methods have over neural models is interpretability. Since a SVM was used with a linear kernel, it is possible to extract feature importance from each model, and gain insights into where the strongest correlations lie. To do this, we employed the R package e1071 (Meyer et al., 2021). Every model is trained independently, and so produces different feature weights, but in general, these features appeared as the most important for our machine learning models:

- content, function word to token ratios;
- NRC emotional lexicon tokens;
- number frequency (singular vs. plural)
- frequency of morphological features: grammatical number, animacy, case, verbal mood
- frequencies of top 100 (RNC) unigrams

6 Limitations and Future Work

Neural NLP models that follow the BERT architecture, like Sentence RuBERT, grow in memory requirements quadratic to the sequence length. Because of this, the models are limited to a sequence length (often 512 WordPieces, but 128 here) with the remaining WordPieces in a post ignored and left unprocessed. VK posts longer than 128 WordPieces are clipped in our Sentence-BERT experiments, while the full posts serve as input to the SVM bag of words and RFET feature extraction systems. Model architectures have been released catering to long form English text, such as Big Bird (Zaheer et al., 2020) and Longformer (Beltagy et al., 2020), but models using these architectures are not yet available for Russian.

Lastly, RuBERT was trained on Wikipedia and books. Our experiments were on social media text, which RFET was designed to address. This genre mismatch (and RuBERT’s resulting limited coverage for WordPieces specific to social media) may have limited Sentence RuBERT’s effectiveness for this task.

One possible weakness in the RFET model (as trained on these training data) is sparsity of certain features. Certain RFET features may be overfitting to particular participants. Idiosyncratic uses of words from a few people with unusual personality trait values or a large volume of posts may be inappropriately generalized as signals for those trait values.

One possible mitigation, of course, is the collection of data from a much larger set of individuals. In these experiments, we apply a more local mitigation strategy: combining different kinds of laughter into a single feature. One strength of RFET is the flexibility of combining or splitting apart features according to the need of the task. For example, personality trait (or other attribute) detection may benefit from combining features; author identification or verification may benefit from keeping very specific features split apart.

Future feature extractors include frequency of Russian diminutives through the usage of suffixes and infixes, ratio of other language scripts being used in the text and usage and frequency of filler words and phrases. Additional information about sentiment and prevalence of emojis will be incorporated from the Emoji Sentiment Ranking (Kralj Novak et al., 2015), which provides usage statistics and associated sentiment for each emoji. An expanded list of emoticons will also be added to reflect the frequency and usage of more emoticons.

Future iterations of RFET may utilize RuSentLex (Loukachevitch and Levchik, 2016), a Russian emotion lexicon with 16,057 entries. Each entry includes a description of its syntactic category, a lemmatized version, the sentiment valence, and source of the valence (opinion, feeling, or fact). Ambiguous entries in RuSentLex (with more than one possible value for valence or source) are also elaborated with examples. We anticipate these features will provide better coverage of sentiment than the

12http://kt.ijs.si/data/Emoji_sentiment_ranking/
7 Conclusion

This paper introduces the Russian Feature Extraction Toolkit, an API for feature extraction on the Russian language. Each feature in the toolkit utilizes linguistic knowledge of the Russian language. It is designed to get a Russian non-speaker up and running quickly on Russian NLP tasks, and to speed up the workflow of Russian speaking NLP programmers. We have shown that it improves performance on a Big Five personality trait inference task relative to a SVM baseline with only language-independent features and, more surprisingly, to a pre-trained transformer baseline using Sentence RuBERT. This suggests that RFET's features specific to social media can be very useful for enhancing state-of-the-art methods for certain genres or domains.

Licensing: We plan to release RFET for non-commercial research and education. A public API will be made available for demonstration purposes. For commercial licenses, contact the University of Maryland’s Office of Technology Commercialization.  

Ethical Considerations

No novel data collection was done specifically for developing RFET; RFET features depend on pre-collected corpora such as the Russian National Corpus (RNC). Data collection for the evaluation of RFET’s efficacy for personality trait estimation (as described in section 4.1) was conducted with the approval of the University of Maryland Institutional Review Board (IRB). During the consent process, potential respondents were informed of the research purposes, and that the researchers would remove, anonymize, or pseudonymize names of entities in the collected social media data deemed to risk personally identifying the participant prior to any sharing of the data with those outside the IRB protocol. Any additional potential risks to confidentiality have been minimized by keeping all data on a secure Amazon Web Service (AWS) server, to which only authorized researchers with the requisite IRB training have access. Non-anonymized data will be destroyed upon the close of the IRB protocol; only data which has undergone our de-identification process would be retained.

Although we set collection targets by gender and age bracket to obtain representative samples to encourage greater equity of representation by gender and age, the use case evaluation was naturally biased towards individuals who write and post lots of text on social media (for which women and younger writers were over-represented in our sample). An evaluation which used equal amounts of text for each individual would avoid this bias, at the cost of leaving unused large portions of the corpus.

Since RFET is a toolkit to assist researchers in improving their own NLP applications, the primary beneficiaries are NLP researchers and developers, particularly those working with social media. Likewise, the main source of potential harm lies with what researchers and developers decide to do with the RFET tool. (Personality trait inference is just one example of potential downstream applications and its own ethics of use depend on where and for what purpose it is applied.) Biases may exist in the older texts used (e.g., some of those in the RNC) but since the features used here are largely based on grammatical categories and lists of keywords, the toolkit is arguably more transparent than tools based on semantic embeddings and such bias easier to identify and address.

Acknowledgments

The authors thank Nadiya Klymenko and Ali Bhatti for work on early versions of RFET, Ewa Golonka for Russian language expertise, Jarrett Lee for technical support, and Mike Bunting, Laurel Miller-Sims, Tom Conners, Michelle Morrison, Aric Bills, and several others for assistance in the data collection. We also thank anonymous reviewers whose reviews improved the presentation of the work.

Abstract

In this study, we proposed a novel Lexicon-based pseudo-labeling method utilizing explainable AI (XAI) approach. Existing approach have a fundamental limitation in their robustness because poor classifier leads to inaccurate soft-labeling, and it lead to poor classifier repetitively. Meanwhile, we generate the lexicon consists of sentiment word based on the explainability score. Then we calculate the confidence of unlabeled data with lexicon and add them into labeled dataset for the robust pseudo-labeling approach. Our proposed method has three contributions. First, the proposed methodology automatically generates a lexicon based on XAI and performs independent pseudo-labeling, thereby guaranteeing higher performance and robustness compared to the existing one. Second, since lexicon-based pseudo-labeling is performed without re-learning in most of models, time efficiency is considerably increased, and third, the generated high-quality lexicon can be available for sentiment analysis of data from similar domains. The effectiveness and efficiency of our proposed method were verified through quantitative comparison with the existing pseudo-labeling method and qualitative review of the generated lexicon.

1 Introduction

Sentiment analysis is employed to identify the sentiment orientation and measure the emotional strength (Khan et al., 2016; Khan & Lee, 2019; Silva et al., 2016). To better understand information generated by online user and to take advantage of it, sentiment analysis is becoming major topic in text mining field in last two decades (Duan et al., 2020; Nagarajan & Gandhi, 2019; Valdivia et al., 2017). Previous studies of sentiment analysis can be roughly categorized into two different groups: 1) lexicon-based approaches and 2) machine learning-based approaches (Khan et al., 2019; Khoo & Johnkhan, 2018).

The lexicon-based approaches efficiently calculate the sentiment score of sentence of document since it does not need to train the classification model in advance. However, The lexicon-based approaches depends on the availability of a sentiment lexicon which is collection of manually pre-created sentiment words lexicon and its sentiment polarity (Huang et al., 2020; Taj et al., 2019; Alqaryouti et al., 2019).

Meanwhile, the machine-learning based approaches require a training set consists of labeled data (e.g. positive, negative or neutral). To address the challenge caused by limited labeled data, which is the usual case in practice, semi-supervised learning have attracted more attention recently (Han et al., 2020; Zhang et al., 2020; Lee et al., 2019). The semi-supervised learning can be divided into several categories such as consistency regularization approaches, entropy minimization approaches and augmentation based approaches and pseudo-labeling approaches.

Among those approaches, the pseudo-labeling approaches are one of the most intuitive and widely used semi-supervised learning in sentiment analysis (Xu & Tan, 2019; Wu et al., 2019; Chen et al., 2020). The pseudo-labeling approaches tried to train the sentiment classification model with small number of labeled data and add unlabeled data with high-confidence of sentiment score, calculated by
trained model, into the labeled dataset in each learning cycle. However, existing approaches have a fundamental limitation in their robustness because soft labeling task and classification task completely depends on each other. That is, poor classifier leads to inaccurate soft-labeling, and it lead to poor classifier repetitively (Van Engelen & Hoos, 2020; Devgan et al., 2020). The left illustration in Figure 1 illustrate the limitation of existing approaches of pseudo-labeling. Thus, this study proposes the robust pseudo-labeling approaches by combining heterogeneous frameworks of sentiment analysis. And the performance of the proposed method will be justified by comparing the two changes in accuracy with graphs.

2 Literature Review

2.1 Studies on semi-supervised learning in sentiment analysis

As a fore-mentioned, the semi-supervised learning can be divided into several categories such as consistency regularization approaches, entropy minimization approaches, augmentation based approaches and pseudo-labeling approaches. The principle of consistency regularization underlines that the model predictions should be less sensitive to the extra perturbation imposed on the input samples (Yu et al., 2020). The entropy minimization approaches encourage the model to output confident predictions on unlabeled data, and the augmentation based approaches are methods of generating various augmented data and using it for learning (Tu & Yang, 2019).

Among those approaches, the pseudo-labeling approaches such as self-training (pseudo-labeling) or co-training is one of the most intuitive and widely used semi-supervised learning in sentiment analysis. In self-training, the most confident unlabeled data with their predicted label, are selected to add to the training set. (Baugh, 2013) employ the self-training for increasing the size of the feature space and (Becker et al., 2013) adapt a static polarity lexicon along with self-training to increase the number of labeled dataset. (Haimovitch et al., 2012) makes use of self-training for large-scale reviews of polarity prediction and (Wang et al., 2016) apply the self-training into text sentiment classification to improve the quality of the training text. (Hajmo-hammadi et al., 2016) utilized semi-supervised self-training approaches to incorporate unlabelled sentiment documents from the target language in order to improve the performance of cross-lingual methods.

And co-training assumed that feature space can be divided into two different views. Two different classifiers are trained with the labeled data, and then applied to the unlabeled data to add them into trained set with confidence level of prediction. (Yu et al., 2014) focuses on revisiting co-training in depth and discusses several co-training strategies for sentiment analysis following a loose assumption and (Zhang et al., 2014) applies co-
training to select the most reliable instances according to the two criteria of high confidence and nearest neighbor for boosting the classifier, also exploit the most informative instances with human annotation for improve the classification performance. (Wang et al., 2014) implemented co-training on multiple component learner of different types to allow performance of their respective advantages and (Xia et al., 2015) propose a dual-view co-training algorithm based on dual-view document representation for semi-supervised sentiment classification. (Catal & Nangir, 2017) investigate the potential benefit of multiple classifier systems concept on Turkish sentiment classification problem with co-training approach and (Li et al., 2019) proposed semi-supervised learning approach based on the hybrid mechanism of self-learning for textual sentiment classification.

However, the high confidence is not necessarily correct with aforementioned approaches. Label error will be transferred and accumulated in the training and labeling process, and it lead the unstable semi-supervised learning process without robustness. Thus, we proposed robust semi-supervised learning approach by combining heterogeneous framework based on auto-generated lexicon.

2.2 Studies on explainable model

In order to generate the lexicon utilized for soft-labeling automatically. We utilized numerous explainable models such a Local Interpretable Model-Agnostic explanations (LIME), SHapley Additive exPlanations (SHAP), Layer-wise Relevance Propagation (LRP) and Gradient-weighted Class Activation Mapping (Grad-CAM) respectively or in and ensemble. And, we also utilize linear model-agnostic XAI methods such as Logistic regression (LR) and support vector machine (SVM) in our experiments.

The key intuition behind LIME is that it is much easier to approximate a black-box model by a simple model locally (in the neighborhood of the prediction we want to explain), as opposed to trying to approximate a model globally. This is done by weighting the perturbed images by their similarity to the instance we want to explain (Hu et al., 2018; Lee et al., 2020).

SHAP is a method to explain individual predictions. SHAP is based on the game theoretically optimal Shapley Values. SHAP values for each feature represent the change in the expected model prediction when conditioning on that feature. For each feature, SHAP value explains the contribution to explain the difference between the average model prediction and the actual
prediction of the instance (Adadi & Berrada, 2018; Lundberg & Lee, 2017).

Grad-CAM uses the gradients of any target prediction flowing into the certain convolutional layer in CNN model to produce a coarse localization map highlighting the important regions in the image for predicting the class of the image (Lee et al., 2020; Selvaraju et al., 2017). We modified the Grad-GAM algorithm to be applied for textual sentiment classification.

LRP is a method to compute scores for image pixels and image regions denoting the impact of the particular image region on the prediction of the classifier for one particular test image (Binder et al., 2016). We also modified the LRP algorithm to be applied for textual sentiment classification.

3 Method

As aforementioned, instead of existing approaches which calculate the confidence of sentiment score for unlabeled dataset by same classifier, we calculated the confidence of sentiment score for unlabeled dataset by auto-generated lexicon. That is, a lexicon is automatically generated through the explainability score calculated while learning the classifier with labeled data, and pseudo-labels are assigned to the unlabeled dataset based on the generated lexicon. The summary of our proposed method is illustrated in Figure 2.

In detail, the learning process in the work of creating lexicon is as follows. First, a binary classification model is trained using data with positive and negative labels. And the importance score of each word is grasped through the coefficients derived from each model. An initial lexicon is created based on this importance score.

Second, pseudo-labels are additionally assigned to N unlabeled data using the generated lexicon, and the previous process is repeated using N additional data, and the lexicon is updated based on this result.

When creating a lexicon, each word's importance score is assigned as the average of the word's scores each time the dictionary is updated.

By repeating the process, the lexicon is updated and the process of assigning pseudo-labels to unlabeled data is completed. These processes are defined formally in the Algorithm 1.

Algorithm 1 Creating Sentiment Lexicon

1: Obtain a small set of L of labeled examples
2: Obtain a large set of U of unlabeled examples
3: for N iterations do
4:   for each explainable classifier Ci do
5:      Learn classifier Ci from L
6:   end for
7:   Update lexicon D from ensemble of Ci
8:   Choose confidently predicted example E from U based on normalized D
9:   E is removed from U and added (with their given labels) to L
10: end for

3.1 Details for creating lexicon

As mentioned in the previous section, several criteria were used in updating the lexicon in the proposed method. This section describes the details applied to update the lexicon. And the basic parameter settings used in each methodology are defined in the Table 1. The setting of each parameter was selected based on experience in various experiments.

Table 1: Entire parameter setting

3.1.1 Linear model-agnostic approaches

LR and SVM calculate the importance of words using the coefficient values of the classification model. The two models vectorized data and trained the model using Term Frequency – Inverse Document Frequency (TF-IDF).

Calculate the importance score of each word and build a dictionary using only words with a score of λ (= 0.1) or higher. And in the process of updating dictionaries, only words with an importance score of δ (=0.2) or higher are used.

When using a Support Vector Machine, a lexicon was created through a binary classifier through Support Vector Classifier. Similar to Logistic Regression, words were generated by calculating
regression coefficients for each word learned in the model.

3.1.2 XAI-based approaches

Unlike linear model agnostic approaches, in XAI-based approaches, scores are assigned to words per sentence. That is, in the process of constructing a lexicon, a score is calculated and updated one by one.

In this study, the importance of words was calculated for each sentence by applying LIME and SHAP to the model trained by Logistic Regression, and the importance of words was calculated for each sentence through Grad-CAM for the model trained with CNN and LRP for the model trained with LSTM. We proceeded to calculate the importance. LIME and SHAP used TF-IDF matrix to vectorize sentences, and CNN and LSTM training data used Word2Vec to embed sentences.

To construct a meaningful lexicon, not all sentences are used for lexicon construction, but only sentences with a predicted value of 0.8 or higher are used, and only the top 20 words of importance score are used in each sentence. In the process of updating a dictionary, the dictionary is updated using only the top 10 words in the sentence.

The process of building a lexicon through Grad-CAM and LRP, use only sentences with sigmoid values greater than 0.75, or less than 0.25, close to zero and one.

Lastly, considering the characteristics of Grad-CAM, which does not show directionality, the frequency of each word in the positive lexicon and the negative lexicon is compared and set as a positive word or negative word.

Table 2 : Summary for dataset

4.2 Experiment setup

In the experiment, we basically verify that the proposed method shows higher performance and robustness than the existing pseudo-labeling method in each dataset. For the performance comparison in the same experimental setting, the same baseline architecture was used, and accordingly, a one-to-one comparison was performed as follows: 1) LR based existing pseudo-labeling approach vs. LR based proposed method, 2) SVM based existing pseudo-labeling approach vs. SVM based proposed method, 3) LR based existing pseudo-labeling approach vs. LIME based proposed method, 4) LR based existing pseudo-labeling approach vs. SHAP based proposed method, 5) CNN based existing pseudo-labeling approach vs. Grad-CAM based proposed method, and 6) LSTM based existing pseudo-labeling approach vs. LRP based proposed method.

The experimental setup of the proposed method is as follows. First, the initial emotion lexicon is constructed using 1000 positive and 1000 negative sentences. Then, based on the lexicon, pseudo-labeling is repeatedly performed by 1000 pieces, and the emotional lexicon update is performed again using the data. In addition, 1000 pieces that were not used for learning were set as test data, and the change in accuracy of pseudo-labeling based on the lexicon was measured.

The experiment of the existing pseudo-labeling methodology was carried out as follows. As in the experiment of the proposed methodology, a classifier is created using 2000 data (1000 positive sentences and 1000 negative sentences), and prediction is performed with an additional 1000 data units. Among them, pseudo-labeling was performed on 100 data, which are the top 10% of
the predicted values, and the change in accuracy of this data was measured.

4.3 Experiment result

Throughout the model, the figures of accuracy for the data were shown similarly. Initially, the accuracy of the automatic generation lexicon was lower compared to the general semi-supervised learning method, but over time, the accuracy of the semi-supervised learning decreased and the accuracy of the proposed method was maintained or increased.

In this study, we conducted an experiment comparing the accuracy of the automatic generation-based method using six methods and the existing method using seven data. In this section, we present Figure 3, only graphs comparing the accuracy of methods that conducted Pseudo-labeling based on CNNs and the accuracy of proposed methods that utilize automatic generative lexicons based on Grad-CAM. In the case of Grad-CAM, it can be seen that the proposed method shows better performance than the existing method at all times. In particular, in the case of the existing methodology, it can be confirmed that the classification performance rapidly decreases after the initial classification performance is poor.

5 Conclusion

In this study, a novel Lexicon-based pseudo-labeling method utilizing XAI approach was proposed that improved the limitations of the existing pseudo-labeling method. The existing approaches have a fundamental limitation in their robustness because soft labeling task and classification task completely depends on each other.

However, the proposed methodology automatically generates a lexicon based on XAI and performs independent pseudo-labeling, thereby guaranteeing higher performance and robustness compared to the existing one. In addition to robustness, since dictionary-based pseudo-labeling is performed without re-learning, time efficiency is considerably increased, the generated high-quality lexicon can be available for sentiment analysis of data from similar domains.

The quantitative excellence of the proposed method was verified through a one-to-one performance comparison with the existing method, and the effectiveness and efficiency of the proposed method were qualitatively verified by reviewing the generated lexicon.

Future research may extend the scope of XAI based lexicon construction in a more general point of view. As shown in the experimental results, there are differences in lexicons for each domain, and a study to construct a general-domain lexicon by integrating them is presented as a future work. Moreover, such studies can be expected to aid in the widespread application of the proposed semi-supervised learning in various tasks arising within the natural language processing domain.

Abstract

The language models nowadays are in the center of natural language processing progress. These models are mostly of significant size. There are successful attempts to reduce them, but at least some of these attempts rely on randomness. We propose a novel distillation procedure leveraging on multiple teachers usage which alleviates random seed dependency and makes the models more robust. We show that this procedure applied to TinyBERT and DistilBERT models improves their worst case results up to 2% while keeping almost the same best-case ones. The latter fact keeps true with a constraint on computational time, which is important to lessen the carbon footprint. In addition, we present the results of an application of the proposed procedure to a computer vision model ResNet, which shows that the statement keeps true in a totally different domain.

1 Introduction

Nowadays the language models became a cornerstone in many natural language processing tasks. Their results in the benchmarks show new high scores. But with great power sometimes comes huge size, the current models could have dozens of billions of weights, e.g. TuringNLG (Rasley et al., 2020), to GPT-3 (Brown et al., 2020) with 175 billion parameters, and counting. In many cases the resources of computational memory are limited and there is a demand for small solutions. One of such solutions is a distillation of language models. There were presented several approaches for the specified task, among others these are TinyBERT (Jiao et al., 2019) and DistilBERT (Sanh et al., 2019).

We analyzed these approaches and found that they share an important flaw - the dependency from the random seed used in the distillation process.

During the distillation a student model needs to be trained multiple times with different random seeds to achieve better performance, although it is not guaranteed that there will be “winning numbers” in your seed choice. So we concentrated on the worst case scenario and proposed a technique to improve it. Considering the computational resources, the improvement could be achieved with the same computational budget, allowing one to diminish the carbon footprint. We propose the novel technique of multi-teacher distillation called to make the mentioned language models more robust to seed selection. We evaluated our method on a computer vision classification model ResNet (He et al., 2016) and make sure that the proposed technique is applicable to a totally different domain.

Our contribution is as follows: we present (i) a new distillation method and an experimental evaluation of this method for three models, namely (ii) TinyBERT and (iii) DistilBERT, where we modified the distillation procedure adding the task-specific distillation, for three natural language understanding tasks and (iv) ResNet for a computer vision task, showing on the one hand that models learned from multiple teachers are consistently better in the worst case and about the same in the best case, and on the other hand, these models are better with a constraint on computational time.

This work is structured as follows: in Section 3 we describe the distillation process and our modification (in Section 3.5); in Section 4 we describe the datasets used in the experiments, which are described in Section 5. The Section 6 concludes the article and discusses the obtained results.

2 Related Work

Common techniques for model compression and acceleration can be roughly grouped into three groups. Pruning parts of large-scale models allows to re-
duce the number of weights and accelerate inference. Sajjad et al. (2020) drop entire layers from pre-trained Transformer models, showing that several top-layers can be dropped, maintaining the performance on downstream tasks. Michel et al. (2019) remove all but one attention head, showing that indeed one head might be sufficient at the test time not only for sentence modeling tasks and but for machine translation also. Quantization keeps the network structure unchanged, but quantizes network weights to smaller data types, such as int8. Quantization can be performed both post training (Bhandare et al., 2019) or during fine-tuning (Zafrir et al., 2019). Knowledge distillation (Hinton et al., 2014) trains the more compact models, students, to reproduce the behavior of a larger model, the teacher. BERT-PKD (Sun et al., 2019), TinyBERT (Jiao et al., 2019) and DistilBERT (Sanh et al., 2019), distilled versions of the BERT model, are commonly used as strong baselines for BERT compression. We describe TinyBERT and DistilBERT models in more detail in the next section. Cho and Hariharan (2019) show that distilling from a better (larger and more accurate) teacher does not always lead to a better student model. We see this result as a motivation for using multiple teachers instead of trying to pick the best one to get a better score.

There are several prior studies considering distillation from multiple teachers for Computer Vision (CV) or Natural Language Processing (NLP) tasks. It can be applied to a multi-task or multi-domain setting. For example, Zhang and Peng (2018) combine the knowledge of teachers trained on different tasks, Wu et al. (2019) train teachers on different features extracted from video frames, Ruder et al. (2017) use domain-specific teachers for domain adaptation, and Tan et al. (2019) obtain multilingual machine translation model using teachers pre-trained for each language pair.

Some authors apply multiple teachers without significantly modifying the distillation pipeline, which is closer to our work. Fukuda et al. (2017) propose two ways to utilize multiple teachers in the distillation process: to augment the training data with soft labels provided by different models or to switch the teacher models dynamically at the mini-batch level. Ze et al. (2020) show that averaging the prediction of three teachers trained with different learning rates can improve the score on Question Answering (QA) and Natural Language Inference tasks. Yang et al. (2020) adopted two-stage distillation procedure and showed improvement in several QA tasks. Liu et al. (2019) show the improvement on several tasks from the GLUE benchmark. Additionally, Sau and Balasubramanian (2016) propose to add normally distributed random noise to the logits of the teacher model during distillation, claiming that such procedure is a simulation of learning from multiple teachers.

Besides prediction averaging, multiple teachers can also be utilized to transfer knowledge contained in hidden states or structural relations between examples. You et al. (2017) average soft-labels of multiple teachers and propose to transfer relative dissimilarity among intermediate representations using teacher voting to select the best ordering relationships. Liu et al. (2020) combine soft-labels of multiple teachers with learnable weights, distill structural knowledge between data examples, and transfer intermediate layer representations making each teacher responsible for a specific group of layers in the student network. Both papers relate to the Computer Vision field, both use models with different architectures as teachers, and both show that 5 teachers are better than 3 for their methods (in terms of classification accuracy), but not better for the original knowledge distillation.

To the best of our knowledge, there is no study dedicated to the isolated investigation of the effect that multiple teachers distillation has on the model quality and robustness and of how this effect change with the number of teachers. Importantly, we use models with exactly the same architecture but fine-tuned with different random seeds as teachers.

3 Model Distillation

We briefly describe the formulation of Original Knowledge Distillation procedure (Hinton et al., 2014), two approaches to distill BERT-like models, and one approach to distill the ResNet CV model. Then we describe how multiple teachers get involved in the process.

3.1 Knowledge Distillation

The Original Knowledge Distillation (OKD), proposed by Hinton and co-authors in (Hinton et al., 2014), became an integral part of transferring knowledge from large neural networks to smaller ones. The idea is to train a network called “student” using the task-specific outputs of the so-
Attention distillation involves a "teacher" model as targets. This method combines two losses, namely $L_{CE}$ and $L_{KD}$. With $\lambda$ being a hyper-parameter to control the relative influence of the teacher knowledge transfer.

$$L_{OKD} = L_{CE} + \lambda L_{KD}. \quad (1)$$

$L_{KD}$, Knowledge Distillation loss component, is a metric of proximity between logits of the teacher and student models ($z_T$ and $z_S$ respectively). In this paper, we use the Cross-Entropy variation as this loss:

$$L_{KD} = -\text{softmax}(z_T / t) \cdot \log \text{softmax}(z_S / t), \quad (2)$$

where $t$ is the softmax temperature applied at training time. At the student model inference its softmax temperature is set to 1. $L_{CE}$ is a classic Cross-Entropy loss for label prediction. The following models are modifying this process each in its own way.

### 3.2 TinyBERT

The TinyBERT (Jiao et al., 2019) model has the same general architecture as BERT (Devlin et al., 2018), but has fewer layers and smaller hidden and feed-forward sizes. We experiment with the smallest 4-layer model. The number of attention heads on each Transformer (Vaswani et al., 2017) layer is the same as in BERT (12 heads).

The TinyBERT distillation process involves several loss functions. Assume that the student model has $M + 2$ layers, with 0 and $M + 1$ being the indices of the Embedding layer and Prediction Layer respectively. The Transformer (Vaswani et al., 2017) layers are numbered from 1 to $M$. Every Transformer layer of the student model receives knowledge from the teacher network. Illustrations to this process are presented in Fig. 1. The mapping $g(k)$ between the teacher and student layers is established by a uniform function, in our case the $k$-th layer of the student model learns from $g(k) = 3k$-th layer of the teacher network (BERT BASE). The objective is defined as MSE between the Attention score matrices plus MSE between the outputs of the Transformer layer (after its FFN part). In order for the dimensions of the student and the teacher hidden states to match, a learnable linear transformation is applied to the student states. The resulting loss function looks as follows:

$$L_{\text{Transformer}}(k) = \text{MSE}(H^S_k W_H H^T_{g(k)}) +$$

$$\frac{1}{h} \sum_{i=1}^h \text{MSE}(A^S_{k,i} A^T_{g(k),i}), \quad (3)$$

where $H_k$ is the output of the $k$-th Transformer Layer, $W_H$ is the linear transformation matrix, $h$ is the number of attention heads, and $A^S_{k,i}$ is the Attention matrix of layer $k$ and head $i$. Whether the states are associated with the student or the teacher is indicated by the upper indices S and T, respectively. Similarly, MSE is used to distill the embeddings $E^{S,T}$:

$$L_{\text{emb}} = \text{MSE}(E^S W_e, E^T). \quad (4)$$

For the prediction layer, the Knowledge Distillation loss (2) described above with temperature $t = 1$ is used to adjust the weights of the student.

There are two stages of the TinyBERT distillation process. The first stage is called General Distillation (GD), the large unlabeled corpus (English Wikipedia) is used and the general linguistic knowledge contained in model weights is transferred from teacher to student (the prediction layer is untapped). The following objective is minimized during the distillation process:

$$L_{\text{tiny}} = \sum_{k=0}^M L_{\text{layer}}(S_k, T_{g(k)}). \quad (5)$$

For each layer the loss function is defined by

$$L_{\text{layer}}(k) = \begin{cases} L_{\text{emb}}, & k = 0, \\ L_{\text{Transformer}}(k), & 0 < k \leq M. \end{cases} \quad (6)$$

The second stage is called Task-Specific Distillation (TD) and aims to transfer the task-specific knowledge. It is in fact split into two phases. First, Intermediate Layers Distillation (ILD) is performed...
with the same loss $L_{\text{tiny}}$ (5) as in the General Distillation. Then, Prediction Layer Distillation (PLD) is performed with $L_{KD}$.

The authors apply an augmentation procedure to extend the task-specific training dataset. For every example in the training dataset, $N$ new examples are generated by replacing random words in a sentence with candidates provided by BERT (Devlin et al., 2018) as a language model or by nearest neighbors search in GloVe (Pennington et al., 2014) embedding space. The number $N$ is called the augmentation factor. A detailed description of the algorithm can be found in the original paper (Jiao et al., 2019).

### 3.3 DistilBERT

The DistilBERT (Sanh et al., 2019) model also shares the general architecture with BERT, slightly modifying it by removing the token-type embeddings and the pooling layer. Following the original work, we use 6-layer DistilBERT. The student layers are initialized directly from the teacher network (BERT_{BASE}) weights using the uniform strategy for layer mapping.

In the original work, DistilBERT only obtains knowledge from the teacher BERT through General Distillation, although the authors mention experiments with Task-Specific Distillation on SQuAD dataset (Rajpurkar et al., 2016). For General Distillation, a concatenation of English Wikipedia and Toronto Book Corpus (Zhu et al., 2015) is used as training data. The student model uses both supervised training loss (Masked Language Modeling loss, $L_{\text{MLM}}$) and Knowledge Distillation loss, with logits for the teacher and the student being obtained on Masked Language Modeling (Devlin et al., 2018) task. In addition, the cosine embedding loss $L_{\text{cos}}$ is used, where the cosine distance is calculated between the outputs of the FFN on the last Transformer layers of the teacher and student. Thus, the general DistilBERT model is trained using the following loss:

$$L_{\text{distil}} = L_{\text{MLM}} + L_{\text{KD}} + L_{\text{cos}}.$$  

In the original work, the model is then directly fine-tuned on downstream tasks without the help of a teacher network. In the present work, we experiment with the Task-Specific Distillation applied to DistilBERT. We adopt the two-stage procedure similar to TinyBERT. After obtaining the general model, we perform distillation on task-specific datasets. We experimented with different loss function combinations and found out that the best task-specific performance is achieved when three loss functions are used:

$$L_{\text{TS}}^\text{distil} = L_{CE} + L_{KD} + L_{\text{cos}},$$  

where $L_{CE}$ is the standard Cross-Entropy loss (calculated with ground truth data labels) and $L_{\text{cos}}$ is the same cosine embedding loss as used during the General Distillation. Unlike TinyBERT, we do not split the Task-Specific Distillation stage into two phases (since there is no need to transfer knowledge between deep layers of the networks) and do not use data augmentation.

### 3.4 ResNet

We also tested our method in application to a computer vision task. We use the classic ResNet model described in (He et al., 2016). The key idea behind the ResNet architecture is a residual block which consists of convolutions layers with skip connections, that helps to reduce the gradient vanishing problem which makes possible to build a deeper neural network.

The key difference between knowledge distillation in NLP (both TinyBERT and DistilBERT variations) and CV is the stage of distillation. A CV distillation does not contain the General Distillation phase, hence teacher and student models are not pre-trained on a general task. In our experiments teacher and student models were ResNet variants, namely ResNet-110 and ResNet-20 respectively.

### 3.5 Multiple Teachers (Our Method)

A possible way to provide a student model with more knowledge is to make use of multiple teacher models. This can be achieved by combining predictions, outputs, or hidden states of several models. In the present work, we focus on averaging the logits of all teachers before the final softmax layer. That means that multiple teachers are used exclusively during Prediction Layer Distillation to TinyBERT and during Task-Specific Distillation to DistilBERT. All other stages are conducted with one (primary) teacher. We also use outputs from only one primary teacher model for $L_{\text{cos}}$ loss function during Task-Specific Distillation to DistilBERT to ensure more fair comparison with TinyBERT. Thus, the use of $k$ teachers $\{S_1, \ldots, S_k\}$ is introduced by
slightly changing the $L_{KD}$ formula (2):

$$L_{KD}^k = -\text{softmax}(z^T / t) \times \log \text{softmax}(\sum_{i=1}^k z S_i / (k \cdot t)).$$  \hspace{1cm} (9)

In this paper we obtain different teacher networks for each downstream task simply by fine-tuning BERT\textsubscript{BASE} with different random seeds. We leave the study of other ways of selecting teacher networks to combine as future work.

As for ResNet distillation, since there are no other phases, except the phase of target task distillation, we use multiple teacher distillation technique on it. We again simply fine-tune ResNet-110 with different random seeds to build a set of teachers.

4 Datasets

For evaluation we use a subset of tasks from the GLUE benchmark (Wang et al., 2019) for NLP models. We chose the CoLA task, since the performance drop is the biggest on this dataset for both considered models. The MRPC and SST tasks were chosen in addition to CoLA task due to the average performance drop. Also, the size of MRPC is comparable to CoLA, while SST-2 is a much bigger corpus. Another important feature is that MRPC and SST-2 corpora have test labels publicly available, while the CoLA dataset has not, so below all the results are provided on the development set from this dataset. A brief description of the datasets is provided in this section. We summarize information about the datasets in Table 1. The original results of considered NLP models are presented in Table 2. There are additional datasets in GLUE benchmark, namely: MNLI-m, MNLI-mm, QQP, QNLI, RTE, and STS-B. We provide results on these datasets for reference.

For a computer vision model we chose the classic CIFAR-10 dataset. For the chosen implementation the results, on this dataset are 93.68% and 91.73% for teacher and student respectively\(^1\).

### MRPC

The Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005) contains sentence pairs in the online news domain. The task is to classify whether the sentences in the pair are semantically equivalent (i.e. have the same meaning). We use classification accuracy as the evaluation metric. The test labels are publicly available for this dataset.

### CoLA

The Corpus of Linguistic Acceptability (Warstadt et al., 2019) consists of sentences from linguistic literature. Each example is annotated with a binary label of whether it is a grammatically acceptable English sentence. We evaluate the Matthews correlation coefficient (Matthews, 1975) on the development set only, due to the test labels are not publicly available.

### SST-2

The Stanford Sentiment Treebank (Socher et al., 2013) contains sentences from the movie reviews. We evaluate the classification accuracy on binary sentiment annotation (positive/negative), which can be obtained from publicly available fine-grained five-way sentiment labels for both development and test sets.

### CIFAR-10

CIFAR-10 dataset was presented in (Krizhevsky et al., 2009). It consists of the 50000 training images and 10000 test images scraped from the Internet. They are labeled with 10 categories for classification: plane, car, cat, dog, bird, deer, frog, horse, ship, truck. In this paper, we evaluate the classification accuracy metric in this task. The test labels are publicly available for this dataset.

5 Experiments

In this section we describe the experimental setup and then provide the results and their analysis. All the experiments were performed on a single GeForce RTX 2080 Ti.

---

\(^1\)These results are better than reported in the original paper (He et al., 2016) due to mistakes in the original implementation.
Table 2: Results are evaluated on the test set of GLUE official benchmark datasets. All models are learned in a single-task manner. In the parentheses we provide performance drop (or gain with ‘-’) in comparison to the teacher model marked with *.

5.1 Distillation Setup

For each dataset we fine-tuned 6 teacher models with different random seeds. Each teacher NLP model is initialized with BERT_BASE uncased version from Huggingface’s Transformers open-source library² (Wolf et al., 2020). We used 30552 as the vocabulary size. Each teacher CV model is initialized as a ResNet-110 model trained on CIFAR-10.

To study the dependence between the number of teachers and the student model scores, we vary the number of teachers from 1 (single teacher distillation) to 6. For each number $k$, we perform experiments with every $k$-combination (unordered) from a 6-teacher set. For instance, for $k = 2$ we have $C_6^2 = 15$ possible combinations. Since distillation procedures for NLP models contain parts where a single teacher is used (ILD for TinyBERT and $L_{cos}$ for DistilBERT), we actually conduct $k$ experiments for each $k$-combination with every teacher from that combination being selected as primary.

For both TinyBERT and DistilBERT, we experiment only with Task-Specific Distillation. As initialization, general models published by the authors are used³. For ResNet models we use an existing

---

²We used Transformers version 2.9.0

³General 4layer-312dim TinyBERT from https://github.com/huawei-noah/Pretrained-Language-Model/tree/master/
implementation\(^4\) to train the models on the CIFAR-10 dataset, since there is no pre-training stage in this model distillation process.

For TinyBERT, we perform Task-Specific Distillation from a single teacher using the original pipeline presented in (Jiao et al., 2019). The only difference is that for the MRPC dataset where a pair of sentences is passed as model input we apply augmentation procedure to both input sentences simultaneously, while (Jiao et al., 2019) leave one of the sentences unchanged. For distillation from multiple teachers, the Intermediate Layers Distillation part remains the same and Prediction Layer Distillation is modified as described above. For each teacher combination, we perform distillation 3 times on MRPC and CoLA with training data files generated by different runs of the augmentation procedure. Since SST-2 has significantly more training data, the results are less dependent on randomness in the augmentation procedure, so we use only one generated file for it.

For DistilBERT, we use our Task-Specific Distillation procedure described above. As we already mentioned, we do not use data augmentation, so we perform distillation 3 times with different random seeds on all datasets to reduce the impact of randomness on the results of our experiments and to have the same number of experiments as with TinyBERT.

5.2 Results
We conducted a series of experiments in order to prove a hypothesis that a distilled model learned from multiple teachers is more robust to a seed choice. We call a model more robust if it has higher worst possible scores, while keeping the best possible scores about the same level.

At first we would like to compare single-teacher models with multiple teacher ones. To do that, we calculate the minimum and the maximum score achieved with each teacher \(k\)-combination. In single teacher mode we simply reuse scores obtained with each teacher included in the combination, while in multiple teacher mode we use all teachers in the combination for the \(L_{\text{KD}}\). Then we average these minimum and maximum scores over all TinyBERT\(\text{distilbert-base-uncased}\) model from Transformers library (https://github.com/huggingface/transformers/tree/master/examples/distillation)\(^4\) https://github.com/akamaster/pytorch_resnet_cifar10

Figure 4: Results for TinyBERT considering time spent on distillation. Shaded: ± one standard deviation.

Figure 5: Results for DistilBERT considering time spent on distillation. Shaded: ± one standard deviation.
combinations for each $k$, obtaining the aggregated measure of models performance.

The scoring results for TinyBERT are provided at Fig. 2, the scoring results for DistilBERT are provided at Fig. 3, while ResNet results are presented at Fig. 6. As one could see the initial hypothesis could be considered true for all the datasets and more than that, the best achievable results are more probable with multiple teacher models for the most models and datasets, with exception of SST-2 for DistilBERT and CoLA for TinyBERT.

One could point out concern regarding the multiple teacher models: these models require significantly larger computational resources to be trained. In order to reduce the potential carbon footprint, we collected additional data for training duration. Since all the training procedures were performed on the same hardware, these measurements could be used for the computational budget comparison. The metrics for TinyBERT are presented at Fig. 4, the metrics for DistilBERT are presented at Fig. 5, while the time consumption for ResNet is presented at Fig. 7. It is readable from the figures that with additional restriction on comparable computational time the hypothesis keeps true, the distilled models are better in the worst case and keep about the same results in the best case, which allows us to call them more robust than the single ones.

6 Conclusion

We showed that the existing distillation process could be improved with the usage of multiple teachers which differ only with random seed initialization. For the NLP models we applied our method to the task-specific distillation, thus improving TinyBERT results. For DistilBERT we modified the original procedure, which led to the improvement in most cases. We also applied the proposed method to ResNet model distillation on the CIFAR-10 task, which led to the quality improvement in all evaluated cases. More than that, the models with roughly the same time consumed by the learning (and distillation) process are better in the worst case, keeping the best results about same level. This keeps true for all the evaluated models and datasets.

As future work, we see an application of the developed technique to the wider variety of models, including the computer vision ones. We hope that our approach can improve the robustness of other modern distillation methods. The additional experiments could be done with more specific tasks, like dialog generation and information retrieval. We hope that our work will foster the research on this topic in the future.

BERT Embeddings for Automatic Readability Assessment

Joseph Marvin Imperial
National University
Manila, Philippines
jrimperial@national-u.edu.ph

Abstract

Automatic readability assessment (ARA) is the task of evaluating the level of ease or difficulty of text documents for a target audience. For researchers, one of the many open problems in the field is to make such models trained for the task show efficacy even for low-resource languages. In this study, we propose an alternative way of utilizing the information-rich embeddings of BERT models with handcrafted linguistic features through a combined method for readability assessment. Results show that the proposed method outperforms classical approaches in readability assessment using English and Filipino datasets—obtaining as high as 12.4% increase in F1 performance. We also show that the general information encoded in BERT embeddings can be used as a substitute feature set for low-resource languages like Filipino with limited semantic and syntactic NLP tools to explicitly extract feature values for the task.

1 Introduction

Automatic readability assessment is the task of evaluating the level of ease or difficulty of text documents such as web articles, story and picture books, test materials, and medical prescriptions. Often readability levels can be expressed in many forms: discrete values with grade and age levels such as in the Common European Framework of Reference for Languages (CEFR)\(^1\), or with continuous values from a given range such as in the famous Lexile Reading Framework\(^2\). In machine learning setting, this task is most often viewed as a classification task where an annotated set of corpora is trained with its corresponding gold-standard labels evaluated by an expert as mostly done in previous works (Vajjala, 2021; Chatzipanagiotidis et al., 2021; Weiβ and Meurers, 2018; Xia et al., 2016; Reynolds, 2016; Hancke et al., 2012; Vajjala and Meurers, 2012). Recent works have tried testing unexplored resources by utilizing large pre-trained language models such as Bidirectional Encoder Representations or BERT (Devlin et al., 2019) which is based on the attention-driven Transformer architecture by Vaswani et al. (2017) by (a) directly processing the data to the network (Martinc et al., 2021; Tseng et al., 2019) or by (b) using the discrete output of the network via transfer learning (Deutsch et al., 2020) as an additional feature. For these methods, however, evidence of efficacy are only seen in high-resources readability datasets in English. Thus, we propose an alternative way of incorporating the knowledge of large language models such as BERT by combining its information-rich sentence embeddings as a separate feature set for traditional machine learning algorithms with handcrafted linguistic features. We argue that this method is not only low-resource friendly but also preserves the semantic and syntactic information encoded by the attention heads of BERT since the embeddings itself will be used. We show that such information can act as a substitute for languages with limited tools for explicitly extracting semantic and syntactic features where results describe non-significance in difference of performances between models using semantic and syntactic features versus models using BERT embeddings.

2 Previous Work

The first generation of readability formulas and indices date as early as 1920-1940s with the works of Thorndike (1921), Dale and Chall (1948), and Flesch (1948) primarily using surface-based variables such as raw frequencies and average values of sentences and words per document. The process for using such indices requires manual computa-

---

\(^1\)https://www.cambridgeenglish.org/exams-and-tests/cefr/
\(^2\)https://lexile.com/
tion and plugging of values to formulas which can be tedious as the length of a document increases. Likewise, experts argue that considering narrow, surface-based features do not entirely capture the linguistic complexity of a given text (Macahilig, 2015; Collins-Thompson and Callan, 2004; Si and Callan, 2001). Thus, incorporation of deeper, linguistic variables such as a language’s semantics, syntax, morphology, and discourse properties are imperative and worth exploring for the task. To answer this call, the use of handcrafted linguistic features remained the most popular type of input for training readability assessment models through the years. Handcrafted linguistic features are often represented as real-valued numbers serving as potential predictors of the difficulty of reading materials. These features span on a wide range of linguistically motivated factors that base on syntax, semantics, morphology, cohesion, and cognition to name a few. These features also serve as the input in the form of vectors for conventional readability assessment setups using traditional classification-based algorithms. To note, not all linguistic features can be applied or extracted for all languages as some have limited NLP tools suitable for use especially for low-resource languages. Notable works in various languages such as Greek (Chatzipanagiotidis et al., 2021), German (Weiß and Meurers, 2019; Weiß and Meurers, 2018; Hancke et al., 2012), Bangla (Sinha et al., 2012), and Filipino (Imperial and Ong, 2021a, 2020) have used this approach in combination with traditional machine learning algorithms such as Logistic Regression and Support Vector Machines. Likewise, another reason why studies have resorted to the classical approach of model building is that deep neural models are not practical for the task without a large amount of training data.

The advent of large and complex pre-trained language models such as BERT and its variations spawned a handful of studies on how these models fare with the readability assessment tasks. The work of Martinc et al. (2021) on the supervised experiment setup explored directly using English benchmark corpus such as Weebit and OneStopEnglish as input for BERT via transfer learning while Deutsch et al. (2020) explored using the final discrete output of BERT as a feature for the same datasets. Results from both studies show effectiveness of BERT for English data as direct input while no significant improvement is seen when the discrete output itself is used as a feature. While these results are remarkable, BERT’s effectiveness remain a gray area for low-resource languages.

3 Task Definition
We define our task at hand as a supervised learning setup. Given a text document \(d\) where a feature vector \(x = [x_1, x_2, \ldots, x_n]\) is extracted, a model \(M\) is trained using said collection of features \(X\) along with the gold label \(Y\) or expert-identified readability level. The label is relative in form (discrete or continuous) based on how readability levels are categorized for each corpus.

Table 1: Data distribution for English and Filipino corpus.

4 Corpus
We describe each corpus used in the study below as well as the statistics and breakdown in Table 1

OneStopEnglish. The OSE corpus is a collection of 567 texts in three different reading levels (beginner, intermediate, and advanced) for adult ESL learners from the MacMillan Education website\(^3\). This corpus was first used in the work of Vajjala and Lučić (2018) and has become one of the most-used benchmark datasets for readability assessment and text simplification in English.

Common Core Exemplars. The CCE dataset contains 168 prose texts from the Appendix B of the Common Core State Standards Initiative (CCSS)\(^4\) for English Language studies and first used by Flor et al. (2013) for readability assessment. The initiative was a project of the National Governors Association and the Council of Chief State School Officers in USA\(^5\). The dataset is divided into three age-range categories: 2-5, 6-7, and 9-12.

Adarna House. The Adarna House corpus is a collection of 265 story books for grades 1-3 from Adarna House Inc.,\(^6\) the largest children’s litera-
ture publisher in the Philippines. This corpus has been used by Imperial et al. (2019); Imperial and Ong (2020, 2021a) for readability assessment in Filipino.

5 BERT Embeddings + Handcrafted Linguistic Features

BERT’s efficacy on a wide range of NLP tasks stems from its implicit capability to encode linguistic knowledge such as hierarchical parse trees (Hewitt and Manning, 2019), parts of speech and syntactic chunks (Liu et al., 2019; Tenney et al., 2019), semantic roles (Ettinger, 2019) as well as entity types and relations (Tenney et al., 2019) to name a few. In view with this, we find such amount of knowledge an extremely valuable resource which can potentially improve performances of readability assessment models especially for low-resource languages if used correctly. Thus, to maximize the potential of BERT for low-resource readability assessment, we propose a combined training of its raw embeddings with handcrafted linguistic feature sets through a concatenation process and feeding them to traditional machine learning algorithms. The embeddings of BERT generated by the multi-head attention layers are information-rich, specifically on semantic and syntactic knowledge (Rogers et al., 2020), due to the nature of its training. We describe our proposed architecture in Figure 1 with a sample Filipino sentence for context.

6 Experiment Setup

For the OSE and CCE corpus in English, we extracted over 155 linguistic features covering lexical diversity and density features, syntactic features based on parse trees, morphosyntactic properties of lemmas, and word-level psycholinguistic features. For the Adarna House corpus in Filipino, we extracted over 54 linguistic features covering traditional surface-based features, lexical features based on POS tags, language model features, morphology based on verb inflection, and orthographic features based on syllable pattern. For the complete and detailed list of features for English and Filipino, please refer to the resources at Vajjala and Lučić (2018) and Imperial and Ong (2020) respectively. The size of the BERT embeddings for all datasets remain equal with a fixed dimension of $H = 768$ since the base version of BERT for English (Devlin et al., 2019) and Filipino (Cruz et al., 2020c; Cruz and Cheng, 2020, 2019) were used. The embeddings and extracted linguistic feature sets were concatenated, for a total of 923 dimensions for combined features for both English datasets and 823 for the Filipino dataset. Recipes for feature extraction were obtained from the studies of Vajjala and Meurers (2016, 2014) for English and Imperial and Ong (2020, 2021a,b) for Filipino. We used the sentence-transformers library by Reimers and Gurevych (2019) with mean pooling option to extract BERT embedding representations for the readability corpora.

For the traditional machine learning algorithms, we used three of the commonly utilized in previous works: Logistic Regression, Support Vector Machines, and Random Forest. Models for each dataset were trained on a 5-fold cross validation procedure. We used weighted F1 as the overall metric for performance evaluation.

7 Results

7.1 Ablation

We compared performances of models on three different setups, (a) linguistic features only, (b) BERT sentence embeddings only, and (c) combined training of the two feature embeddings to gauge the efficacy of the proposed framework.

As described in Table 2, generally speaking, models trained using the proposed combined training of handcrafted linguistic feature sets with contextual BERT embeddings outperform both performances of only using each exclusively on English and Filipino datasets. On average, we note an increase of performance of 2.63% for OSE, 6.23% for CCE, and 12.4% in weighted F1 score for Adarna House across all algorithms. From this, we infer that extracting and incorporating the information-rich embeddings of any readability dataset using BERT to commonly-used linguistic feature sets can substantially improve model performance.

Interestingly, there are a few notable cases reported in Table 2 where BERT embeddings alone outperformed the traditional method of using handcrafted linguistic feature sets as primary input. These cases are evident in the all models utilizing the Adarna House dataset in Filipino with an

(c) Random Forest

Table 2: F1 performance via training with (a) Logistic Regression, (b) Support Vector Machines, and (c) Random Forest using handcrafted linguistic features, BERT sentence embeddings, and combined training of both.
average increase of 9.5% weighted F1 scores. From this, we infer that the general semantic and syntactic knowledge implicitly encoded in BERT embeddings as detailed in probing tasks from previous works (Rogers et al., 2020; Hewitt and Manning, 2019; Liu et al., 2019; Tenney et al., 2019) may be significantly more informative than the traditional handcrafted linguistic features for discriminating reading difficulty. Consequently, this poses as a probable and alternative solution for low-resource languages with little to no NLP tools such as a good part-of-speech tagger, stemmer, syntactic parse tree extractor, and morphological analyzer to name a few for manually extracting linguistic information from documents. Since BERT models are trained in an self-supervised manner, the overhead of developing these tools from scratch can be disregarded, at least for readability assessment. We discuss further experiments on this inference in the next section.

7.2 Substituting Semantic and Syntactic Features for BERT Embeddings

To empirically test if BERT embeddings can act as substitute for semantic and syntactic linguistic features for readability assessment, we removed features from the three datasets that assume semantic and syntactic knowledge. For OSE and CCE, we removed 56 features covering part-of-speech densities, lexical richness, type-token densities, and general parse-tree based features. For Adarna, we removed 22 features covering part-of-speech densities, type-token densities, and verb inflection densities. There are no parse-tree based features for Adarna House as there are currently no NLP tools for extracting such feature set for Filipino. The rest of the linguistic features from the datasets denoting other aspects of reading difficulty measurement such as frequency-based features and syllable patterns remain unchanged. Models were retrained using the three selected machine learning algorithms for comparison.

Results of substitution experiments can be found in Table 3. Generally speaking, it is evident that models trained using the combined method still outperforms models using the reduced feature set on the account of CCE and Adarna data. However, we note the 1.2% increase in F1 score on the OSE data. Stemming from this observation, we also note small differences in performances of using the combined features against decreased features. In the CCE corpus, the highest performing model using decreased features obtained 86.9% F1 score which is less 2.4% than using the model with combined features. For the Adarna data, the difference is 6.4%.

To identify if such difference is significant, we used a two-tailed test of difference via Mann-Whitney U using the performance scores of models with combined features and models with decreased features for all datasets. We arrived at a p-value of 0.522 (p >0.5), meaning that the difference of the scores between two groups is not significant. Thus, we conclude that BERT embeddings can be fully used as a substitute for semantic and syntactic features if such information cannot be explicitly extracted from readability data due to the lack of NLP tools and low-resourceness of other languages. To add, since BERT models are trained in an self-supervised manner and there are over 3,000 pretrained models from online repositories, these resources and the proposed combined training method as a viable option.

7.3 Feature Decomposition for Performance Boost

In extending the effort to improve the performance of BERT-enriched readability assessment models and reduce feature size or dimensionality, we resort to the use of feature decomposition to the large feature vector sizes (BERT + linguistic features) via Principal Components Analysis (PCA). PCA works by projecting the overall feature set (often large) to a lower dimensional property while preserving quality and information of features (Hotelling, 1933). We experimented on differing values of variance percentages: 25, 50, 75, 95, and 100 (full, no feature removed). Results of feature decomposition via PCA for each machine learning model are described in Figure 2.

For SVM and Random Forest, all datasets have the highest performances if all features are retained (100 variance percentage). While for Logistic Regression, 75 variance percentage obtained the highest performance with 82.7 F1 score for OSE, 95 variance percentage obtained the highest performance with 83.8% F1 score for CCE, and 100% or full features for Adarna. Thus, we infer that there is no need to perform feature decomposition to find the principal components as the highest-performing

models for OSE, CCE, and Adarna use 100% of the combined feature set (BERT + linguistic features).

8 Conclusion

In this study, we proposed an alternative way of combining information-rich BERT embeddings with handcrafted linguistic features for the readability assessment task. Results from our experiments showed that the method outperforms classical, vanilla approaches in readability assessment using English (OSE and CCE) and Filipino (Adarna) datasets in various machine learning algorithms such as Logistic Regression, Support Vector Machines, and Random Forest. We also demonstrated that the knowledge implicitly encoded in BERT embeddings (semantic and syntactic information) can be used as a full substitute feature set for low-resource languages like Filipino with limited NLP tools to explicitly extract feature values for the task. We are looking forward to the application of our proposed method to other languages struggling with the extraction deep linguistic features to trained readability assessment models. Future directions of the study include deeper exploration of BERT such as isolating extracted embeddings for each of the twelve attention layers.

9 Acknowledgments

We would like to thank Dr. Ani Almario from Adarna House, Dr. Sowmya Vajjala from the National Research Council of Canada, and Dr. Michael Flor from ETS for providing the Adarna, OSE, and CCE datasets respectively.

10 Ethical Considerations

We report that there are no major ethical concerns in the study as it involves no human subjects nor discriminate any identifiable group of people. As for the dataset, for Adarna House, permission was obtained from the publishing house while for the OSE and CCE datasets, it remains open-sourced. As for energy consumption, the study only uses pre-trained BERT models and the authors did not actually perform the pre-training phase itself.

Abstract
The amount of information available online can be overwhelming for users to digest, specially when dealing with other users’ comments when making a decision about buying a product or service. In this context, opinion summarization systems are of great value, extracting important information from the texts and presenting them to the user in a more understandable manner. It is also known that the usage of semantic representations can benefit the quality of the generated summaries. This paper aims at developing opinion summarization methods based on Abstract Meaning Representation of texts in the Brazilian Portuguese language. Four different methods have been investigated, alongside some literature approaches. The results show that a Machine Learning-based method produced summaries of higher quality, outperforming other literature techniques on manually constructed semantic graphs. We also show that using parsed graphs over manually annotated ones harmed the output. Finally, an analysis of how important different types of information are for the summarization process suggests that using Sentiment Analysis features did not improve summary quality.

1 Introduction
With the advance of web technologies during the last decades, a numerous amount of textual data is produced constantly, especially User Generated Content within social media and e-commerce domains, which include opinions towards many entities, such as products, organizations, and others. Such quantity of information is virtually impossible for other users to assimilate by their own, which creates a need for automated content selection and summarization methods, originating the Opinion Summarization research area, which integrates both the Text Summarization and Sentiment Analysis areas. (Kim et al., 2011; Liu, 2012).

There are two main types of summaries: extracts, which are composed by copying excerpts from the original texts literally, and abstracts, consisting of new text constructions derived out of the information obtained from the input data. Some authors in the literature call attention to the need of incorporating semantic knowledge into the summarization process (Mani, 2001; Li, 2015; Huang et al., 2020), particularly for producing abstracts, since humans usually create summaries by rewriting, paraphrasing and, mainly, interpreting texts (See et al., 2017; Dohare et al., 2018). This kind of information can be explicitly formalized as semantic representations, such as Predicate Argument Structure (PAS) (Khan et al., 2016, 2018), Abstract Meaning Representation (AMR) (Liu et al., 2015; Liao et al., 2018; Dohare et al., 2018) and others.

There are also arguments promoting the usage of explicit semantic representations to deal with texts from the opinions genre – in which the sentiment expressed by the author is an important information – as this type of linguistic knowledge is able to associate correlated information scattered throughout the texts and also to deal with many different semantic phenomena (such as negations and multi-word expressions) that can alter the interpretation that would be obtained in a word-by-word basis (Cambria, 2013). However, there are, to the best of our knowledge, no works that focus on integrating these representations for opinion summarization.

In this context, this paper focuses on exploring techniques of Text Summarization based on explicit semantic representations upon opinions. As a base to instantiate the semantic knowledge, we used the Abstract Meaning Representation (AMR) (Banarescu et al., 2013), which has already been used in previous research in Text Summarization (Liu et al., 2015; Liao et al., 2018; Dohare et al., 2018) and has also been adapted for the Portuguese language in other former works (Anchiêta and Pardo,
As a result, we present one of the first applications of methods based on explicit semantic representations for Opinion Summarization, showing that the Random Forest machine learning algorithm produced the best summary graphs, according to the metrics applied, outperforming other AMR-based approaches from the literature for manually annotated graphs. The results also indicate, in the same manner as previous works (Liu et al., 2015), that the quality of the AMR graphs used have an impact on the output. The experiments also suggest that using Sentiment Analysis features do not improve summary quality.

In short, the main contributions of this paper are the following:

- Development of four new summarization methods based on the AMR representation with results compatible to the current state of the art on using Semantic Representations for Text Summarization;
- Investigation of how other methods of the literature, not developed initially with opinions in mind, behave in a sentiment analysis context;
- Implementation of a semantic-based opinion summarization tool, which is publicly available\(^1\);
- Analysis of the importance of proposed features for text summarization.

The remaining of the text is organized as follows: in section 2, we present a general notion of the AMR. Later, in section 3, previous works in Text Summarization are outlined with main focus on the ones based on the chosen semantic representation (AMR). Our methods are shown in section 4 followed in section 5 by some important notes about the experiments executed, whose results are then introduced in section 6. Finally, some conclusions and further discussing are made in section 7.

2 Abstract Meaning Representation

Sentences in AMR are represented as rooted directed graphs in which nodes correspond to concepts and edges to relations between them. An example can be seen in Figure 1. Concepts can be of different kinds, e.g framesets (possible-01, recommend-01, ler-01) originated from separate repositories containing predicates and their corresponding arguments. For the English language, this repository is called Propbank\(^2\) (Kingsbury and Palmer, 2002), whilst for Brazilian Portuguese, there is VerboBrasil\(^3\) (Duran and Aluísio, 2015).

The concepts can also be words from the base language, extracted directly, as they are, from the sentence (e, eu, coisa) or derived by some annotation procedure provided in the guidelines, such as the transformation of the comparative “melhor” (better) into a degree relation between “mais” (more) and “bom” (good) (bom, mais). There are also concepts that are specific of the representation formalism (e.g., have-degree-91).

All edges are of two types: argument relations defined for each predicate (ARG0, ARG1, ARG2, ARG3) and the ones determined by the AMR project (op1, op2).

As the original representation was developed specifically for the English language, there is need for adaptations of the guidelines\(^4\) towards other languages. For Brazilian Portuguese, this initiative was made by Anchiêta and Pardo (2018b), followed by Cabezudo and Pardo (2019), dealing with some phenomena that are not so common in English,\(^5\)

such as indeterminate and hidden subjects.

3 Related Work

There are two main areas related to our work: Summarization based on Semantic Representations and Opinion Summarization, each with a long history in the literature. Thus, we present the works most related to ours, those using the Abstract Meaning Representation and other Opinion Summarization methods.

3.1 Summarization Based On Abstract Meaning Representation

The usage of semantic representations for Text Summarization can be traced back until the 1980s, with the TOPIC system (Reimer and Hahn, 1988). Since then, numerous techniques upon various representations have been developed, such as UNL (Martins and Rino, 2001; Mangairkarasi and Gunasundari, 2012), LNS (Rusu et al., 2009), RSG (Moawad and Aref, 2012) and many others. With a special focus on the AMR representation, used in this paper, there are some works – exclusively for the English language – that are going to be explained more thoroughly below.

The first incorporation of AMR into the Summarization process was conducted by Liu et al. (2015). Their method uses several numerical features to represent nodes and edges, used to calculate a score for the given graph; each attribute has a weight trained through AdaGrad (Duchi et al., 2011), so that graphs similar to gold standard handmade summary graphs are assigned to higher scores. Afterwards, Integer Linear Optimization (ILP) is used upon the original text AMR graph in order to select the subgraph which maximizes the scoring. The authors report a maximum F-score for nodes prediction of 58.7% and of 39% regarding edges.

Later, this technique was enhanced by Liao et al. (2018), as they included new attributes, and a previous sentence clustering step using Spectral Clustering (von Luxburg, 2007), which leverages similarity metrics between each clause, in order to identify the multiple topics in the input. Then, a small amount of sentences are selected from each cluster to proceed with the ILP summarization. They obtained a prediction F-Score of 30.1% for nodes and 9.8% for edges; it is important to note that they used exclusively parsed graphs, which have already been indicated as a factor that harms the results (Liu et al., 2015).

In parallel to these techniques, an unsupervised approach for Summarization using AMR has been developed by Dohare et al. (2018). This method uses the TF-IDF score of each concept in order to select a subset of relevant nodes to serve as a basis for the summary graph. Then, a few rules are used to determine the most important path between each pair of nodes chosen and to, finally, expand these paths by adding edges and nodes according to OpenIE (Banko et al., 2008) triples. This unsupervised method obtained a node prediction F-score of 60.4%, however there is no report for edges.

3.2 Opinion Summarization Approaches

This paper is also included within the Opinion Summarization area, which, to the extent of our knowledge, has no initiative of using explicit semantic representations during this process. Therefore, we focus here on two main works related to ours.

The Opinosis method (Ganesan et al., 2010) uses a graph representation obtained from the text to perform the summarization of opinions. It is important to note that this graph does not convey the semantics of the input, but rather the order with which the tokens occur. A single graph encloses multiple sentences, so that identical tokens are merged into a single node, capturing redundancy. Then, a set of rules are applied upon this graph to find those relevant valid paths, prioritizing nodes which occur in more input sentences. Finally the summary text is composed from these selected paths of tokens with some other additional rules for combining them through conjunctions.

More recently, the Opizer system (Condori and Pardo, 2017) was developed as one of the few projects of Opinion Summarization with a specific focus on the Portuguese language. It comprises two main methods: an extractive (Opizer-E) and an abstractive one (Opizer-A). In Opizer-E, the sentences are first clustered together with respect to their general sentiment polarity and also to which aspect of the product they describe (e.g. the camera, battery, durability, etc.). Then, they are ranked according to an importance score which leverages the sentence position within the document and how the aspects and their corresponding sentiment words are related. The most important sentences are then selected to compose the summary.

In its turn, Opizer-A focuses on the selection of salient n-grams rather than full sentences, clustering them according to the polarity, aspect and con-
tent. Afterwards, a set of representative n-grams is chosen from each cluster with respect to their TF-IDF scores. Lastly, they are used to fill in a predefined textual pattern, resulting in the final abstract.

From this overview of the literature, some methods can be derived and developed, as we present in the following.

4 Methods

As discussed before, the usage of explicit semantic information represents an interesting path for both Text Summarization and Sentiment Analysis, consequently for Opinion Summarization. Thus, we chose the Abstract Meaning Representation as an instance of semantic knowledge. The starting point of our research is, therefore, all the previous works which exploited this representation in the process of summarizing texts (Liu et al., 2015; Liao et al., 2018; Dohare et al., 2018), even if for other genres rather than opinions.

First, some preprocessing is necessary. As AMR is a sentence-level representation, we need to combine multiple sentences into a multi-document graph. This has been done, in this work, similarly to Liu et al. (2015) by merging every node that contains the same concept. Some semantic units – such as named entities or dates – are represented in multiple nodes, which are collapsed before the merging, only allowing the combination of entities with the same overall information (same name or date). This was applied upon all comments about each product, resulting in a multi-document semantic representation of all opinions about some given book or electronic device.

4.1 Rule-based Method

As discussed by Dohare et al. (2018), all steps of their method can be directly applied to multi-document summarization. In this paper, we argue that the usage of the traditional TF-IDF scoring may not be suitable for a multi-document scenario, since it penalizes concepts that occur in a larger range of texts, potentially penalizing important information that is common to a large number of comments. For example, if a lot of comments state that the camera quality of a given smartphone is poor, this information should not be penalized, but rather rewarded. Therefore, we propose a simple variation of this method, by substituting the ranking score form TF-IDF to TF only, i.e. the number of occurrences of each concept across the texts.

4.2 Score Optimization Method

Following the objective of improving the original Dohare et al. (2018) method, we decided to explore the usage of multiple different information in order to enhance the ranking of important nodes.

Similarly to Liu et al. (2015), various features may be applied to represent each node or edge in the graph and then weights can be used to combine these attributes into a salience score for the given element. This idea has been transposed into our work, however we do not use the same features as Liu et al. (2015), as they turn each one into multiple boolean values without any specification of how the thresholds were defined. Thus, we decided to develop our own feature set based on the work of Leskovec et al. (2005), which used graph-based and linguistic features to perform the classification of relevant graph nodes for summarization. Our feature set is presented in Table 1.

As can be seen, our features are almost exclusively focused on the graph structure, excluding four last ones (TF, TF-IDF, Sentiment polarity and Aspect). We decided to keep both TF and TF-IDF, as they can convey some differences, as discussed before, and a combination of both may be interesting. Both Sentiment polarity and Aspect features are common within the Opinion Summarization area (Condori and Pardo, 2017). It is important to report that Leskovec et al. (2005) also states that they used another 118 linguistic features that did enhance the summaries quality, however there is no indication of which these features were, so we decided to not include any other features, as it would be necessary to do a more focused feature engineering research in order to determine which other linguistic information is important and how they should be represented.
