As one can see in Table 1, the corpus has a little more non-toxic than toxic tweets. In this paper, we adopted the binary version of the corpus, i.e., our objective is to identify if a comment is toxic or non-toxic.

In what follows, we detail our strategy to handle toxic texts.

## 4 Semi-supervised approach

We organized the strategy into four steps, as illustrated in Figure 2. Subsections 4.1, 4.2, 4.3, and 4.4 describe the stages.

### 4.1 Pre-processing

In the pre-processing, we normalized and cleaned the tweets. In the first one, we applied the Enelvo tool (Costa Bertaglia and Volpe Nunes, 2016) to normalise abbreviated and repeated words. In the second one, we simply clean URLs, emojis, and tweet mentions.

### 4.2 Graph-Based Method

We modeled toxic comments detection as a heterogeneous network since this network type contains abundant information with structural relations (edges) among multi-typed nodes as well as unstructured content associated with each node (Zhang et al., 2019). Graph structures have been used for several tasks, such as: topic model, name disambiguation, scientific impact measurement, and others, obtaining good results (King et al., 2014).

We defined a undirected and weighted graph as $G = (V, E, W)$, where $V$ is a set of vertices $V = \{v_1, ..., v_n\}$, $E$ indicates a set of edges $E = \{e_1, ..., e_n\}$, and $W$ is a weighted adjacency matrix, in which $W_{i,j}$ denotes the weight of an edge between nodes $i$ and $j$. We defined two node types: token and sentence and two constraints not allowing link among tokens nodes or among sentences nodes.

The strategy of weighting links between a token and a sentence node is straightforward. The weight is the average of embedding vectors of the token node. To get embedding values for each token, we used 100-dimensional GloVe embeddings for the Portuguese language (Hartmann et al., 2017). Figure 3 shows the scheme of the network designed for this task.

![Figure 3: The network scheme for weighted edges.](image)

One can see that the edges are undirected and weighted, and a sentence node may share several token nodes whenever the token is in the sentence, i.e., the edges between token nodes and sentence nodes are based on word occurrence in sentence.

### 4.3 Regularization

To extract the features regarding the network object classes, we applied a regularization method to the graph. Regularization is a kind of semi-supervised (or transductive) classification method that aims to find a set of labels, minimizing a cost function and satisfying two conditions: (i) the method needs to be consistent with the set of labels manually annotated and (ii) the method needs to be consistent with the network topology, considering that nearest neighbors tend to have the same labels (Ji et al., 2010).

We used the learning with Local and Global Consistence (LGC) (Zhou et al., 2004) as a regularization method. The algorithm designs a classi-
fying function that is sufficiently smooth concerning the intrinsic structure collectively revealed by known labeled and unlabeled points. Thus, the LGC lets every point iteratively spread its label information to its neighbors until a global stable state is achieved (Gui et al., 2014). Also, it allows the class information of the labeled objects to be changed during the classification as objects may be erroneously labeled and, consequently, decrease the performance of the classification. More than that, the algorithm diminished the influence of objects with a high degree (many neighboring objects), therefore, these objects do not have excessive influence in the classification.

To execute the algorithm, a set of nodes need to be pre-labeled. The regularizer randomly pre-labeled, i.e., supposing that the percentage of pre-labeled nodes is equals 5%, it means that 0.25% of each class is randomly pre-labeled. As a result, the regularizer produces values related to coordinates for each object in the network, as shown in Table 2.

Table 2: Example of regularizer output.

From Table 2, **Id** is the object identifier, **Values** refer to coordinates of each object in the network, and **Label 1** shows toxic, while **Label 0** is a non-toxic tweet.

4.4 Classification

With the regularization values, we fed several machine learning algorithms to identify and predict toxic comments. We experimented Multi Layer Perceptron, Naïve Bayes, Decision Tree, Support Vector Machine, and Gradient Boosting from the Scikit-Learn library (Pedregosa et al., 2011).

In the following section, we detailed our carried out experiments, then, the achieved results are presented.

5 Experiments and Results

In order to produce coordinate values for each object from the regularizer, we ranged the number of pre-labeled nodes from 5% to 30%. Then, we applied the machine learning algorithms to train and classifier toxic comments.

We achieved the best result with the Gradient Boosting classifier using only 10% of the pre-labeled nodes i.e., the classification does not improve after this percentage. Table 3 shows the achieved results. It is important to say that only the training set is pre-labeled.

Table 3: Achieved results with the gradient boosting classifier.

Besides our approach, we evaluated other graph models of different structures. First, we used the network graph developed by Anchiêta et al. (2020). That graph does not use weight between the nodes. Second, we used the Term Frequency-Inverse Document Frequency (TF-IDF) as weight instead of the average of embeddings. Third, we used bigrams and trigrams as nodes rather than token nodes. Finally, we used the Pointwise Mutual Information (PMI) measure (Church and Hanks, 1990) as the weight between the bi and trigrams nodes. For these approaches, we adopted the same regularization algorithm, ranging the pre-labeled nodes from 5% to 30%. In Table 4, we present the best-achieved results.

</tbody>
</table>

Table 4: Comparison among graph-based approaches.

From this table, our graph modeling and the gradient boosting classifier achieved better results than these other graphs, as well as classifier variations. This, we think, is because of the embedding value among the graph nodes since it is able to capture morphological, syntactic, and semantic knowledge of a word. As we used the average word embedding value, it includes information from all of the
individual vector values, working as an overall summary of all vector values.

We further compared our strategy with other graph-based approaches: Text Graph Convolutional Network (TextGCN) (Yao et al., 2019) and Heterogeneous Graph Attention Network (HGAT) (Yang et al., 2021). The former models the whole text corpus as a document-word graph with word co-occurrence relations and applies GCN for classification. The latter models the texts using a heterogeneous information network framework and adopts heterogeneous graph attention to embed that framework for text classification based on a dual-level attention mechanism. Finally, we compared our approach with a transformer-based method as it has achieved remarkable results in several areas of Natural Language Processing (NLP). We compared our strategy with BR-BERT (Leite et al., 2020), which is a monolingual BERT, and M-BERT (Leite et al., 2020), which is a multilingual BERT. Table 5 shows the comparison between these methods.

Table 5: Comparison between graph-based and transformer-based methods with our strategy.

As we can see from Table 5, our approach outperformed the graph-based methods and reached a competitive result compared to transformer models. Although our strategy did not outperform transformers, we believe the results are very promising, since it requires much less computational power than transformers. Moreover, our method requires less annotated data (only 10%) than transformers to achieve interesting results.

Our approach is available at https://github.com/rafaelanchieta/toxic.

6 Conclusion and Future Work

In this paper, we explored a semi-supervised strategy to deal with toxic comments from Twitter. We modeled the texts as a heterogeneous network graph with two node types and weighted edges among nodes. Then, we applied a regularization algorithm to extract features related to the toxic texts. Finally, we used these features to feed a classifier to identify and predict toxic comments. Our approach outperformed several graph-based methods and achieved a competitive result compared to the BERT model, using only 10% of the corpus. We hope that this graph model brings insights to hate speech detection research, helping to improve the results. Furthermore, our strategy may be employed in other languages, as it only requires an embedding representation.

As future work, we intend to explore the graph structure, analyzing some network measures, such as degree, centrality, community identification, and others. Also, we aim to examine contextual embeddings rather than traditional embeddings.

Abstract

The paper presents a novel discourse-based approach to argument quality assessment defined as a graph classification task, where the depth of reasoning (argumentation) is evident from the number and type of detected discourse units and relations between them. We successfully applied state-of-the-art discourse parsers and machine learning models to reconstruct argument graphs with the identified and classified discourse units as nodes and relations between them as edges. Then Graph Neural Networks were trained to predict the argument quality assessing its acceptability, relevance, sufficiency and overall cogency. The obtained accuracy ranges from 74.5% to 85.0% and indicates that discourse-based argument structures reflect qualitative properties of natural language arguments. The results open many interesting prospects for future research in the field of argumentation mining.

1 Introduction

Argumentation modelling and mining are steadily gaining attention of the broad natural language processing and engineering community. In many studies and applications, assessment of the argument quality plays an important role. The ability to construct good arguments and engage in argumentative discussions is assessed by argumentation systems focusing on training hypothetical reasoning, creating and structuring arguments (Ashley et al., 2007), preventing opinion manipulation, detecting inconsistent arguments in online discussions and addressing different standpoints, attacking or supporting claims with evidence (DebateGraph1 and TruthMapping2) as well as on the use of multimodal rhetorical devices (Petukhova et al., 2017a). Assessment of argument quality, its organization, clarity, adherence and strength, are approached by several authors as sub-tasks in the evaluation of written essays (Stab and Gurevych, 2014; Persing and Ng, 2015; Wachsmuth et al., 2016; Stab and Gurevych, 2017). Online content is searched to filter or weight the validity of statements and factoids (Rowe and Butters, 2009), to identify fake news and false claims (Popat et al., 2018) and to detect opinion manipulation (Cambria et al., 2010). While the acceptability of an argument in the presence of other supporting or attacking arguments has been addressed (Dung, 1995; Cayrol and Lagasquie-Schiex, 2005), ‘local’ argument quality still deserves our attention – an argument built on a certain set of conditions, is logically strong, rhetorically convincing, socially undistorted by virtue of its intrinsic properties.

In this paper, we present a novel approach to assessing the structural strength and inferential weakness of arguments as merits of argument cogency. The approach relies on the discourse-based reconstruction of argumentation schemes. For this, we apply state-of-the-art discourse parsers and machine learning models to reconstruct argument graphs where the identified discourse units are represented as nodes and the classified discourse relations between them as edges. A Graph Neural Network (GNN) model is built to predict the quality (low vs high) of the reconstructed argument graphs in terms of argument acceptability, relevance, sufficiency and overall cogency.

The paper is structured as follows. Section 2 defines the conceptual framework within which the study is performed. We provide the definition of an argument and elaborate on its internal structure. In Section 3, we survey related work on argument quality assessment. Section 4 presents the argument graph reconstruction approach. The performed GNN-based quality assessment experiments are discussed and results are reported in...
Section 5. Section 6 summarises our findings and outlines directions for future research.

2 Argument and Its Structure

An argument may be considered as an atomic entity without an internal structure. For instance, an argument is defined as an overall position held by a person towards an idea or attitude, e.g. a stance in ‘favour’ or ‘against’ a certain motion (Somassundaran and Wiebe, 2009). A structured argumentation model is an essential element for the tasks aiming at understanding and emulating of human inference, investigating patterns of reasoning, focusing at extraction and validity assessment of arguments. A simple argument structure is then defined as consisting of a claim that is supported by evidence(s) (Mochales and Moens, 2011; Aharoni et al., 2014). A claim is an assertion that an argument aims to prove, i.e. a claim is a conclusion whose merit must be established. Evidence comprises propositions which give reasons or grounds for drawing the conclusion.

This general argument definition has been translated into several discourse-based schemes for analysing and evaluating natural language arguments (Teufel, 1999; Palau and Moens, 2009). An argument is modelled as a group of Argumentative Discourse Units (ADUs) – text segments corresponding to propositions that are argumentatively relevant and have their own argumentative function (Peldszus and Stede, 2013). An EDU can function as a claim, as an evidence or as a conclusion. An ADU can be identified as a collection of several Elementary Discourse Units (EDUs) which correspond to clauses in written discourse and to dialogue acts in spoken discourse (Petukhova et al., 2016). Discourse relations such as Justification, Motivation, Cause, and Exemplification can be used to identify how propositions are related to each other, inferring the type of support that is expressed. A claim may be summarized or re-stated in a conclusion. Figure 1 depicts a general discourse-based argument structure.

ADUs reflect different ways to provide support for a claim, i.e. links between them express the level of support that evidence provides to the claim and the level of their sufficiency to draw a valid conclusion. Figure 2 provides an example of an argument. EDUs (solid-line rectangles) are combined by means of discourse relations into ADUs (dotted-line rectangles) which are connected to each other by support links. Evidence may either together (linked support, e.g. Evidence 2.1 and 2.2) or independently (multiple support, e.g. Evidence 1, 2 and 4) support a conclusion. A premise may provide support for another premise and indirectly support a conclusion (serial support, e.g. Evidence 3 and 2). A special form of lending support to a claim is that of providing examples (example support, e.g. Evidences 4.1 and 4.2).²

3 Related Work

Clear properties of a good argument and successful argumentation are not easy to define. Wachsmuth et al. (2017) proposed a unified taxonomy of argumentation quality assessment that resulted from an extensive analysis of numerous existing approaches. The assessment comprises three quality dimensions: cogency, effectiveness and reasonableness. Argument quality assessment aims at answering the question how logical, persuasive or convincing the given argument is, and how rhetorically appealing it is for the targeted audience.

Evaluation of argument cogency is based on the truthfulness and logical coherence of arguments. An argument is cogent if it has acceptable premises that are relevant and sufficient to support the conclusion (Johnson and Blair, 2006; Govier, 2013). A premise is acceptable if it is rationally worthy of being believed to be true (Wachsmuth et al., 2017). According to Govier (2013), a premise is locally acceptable if it is supported by a cogent sub-argument or another cogent argument; it is a matter of common knowledge, testimony or expert view (appeal to authority). A statement A is positively relevant to another statement B if and only if the truth of A counts in favour of the truth of B. This means that

²For a discussion on other types of support links we refer to Palau and Moens (2009) and Peldszus and Stede (2013).

Elaboration

Figure 2: Argument example from Dagstuhl-15512 ArgQuality Corpus (Wachsmuth et al., 2017) annotated with core ISO 24617-8 core discourse relations (Bunt and Prasad, 2016) and support links observed.

A provides some evidence for B, or some reason to believe that B is true. An argument is locally sufficient if all premises together provide sufficient reasons to accept the conclusion. The preconditions of the argument sufficiency are rooted in its local acceptability and its local relevance (Govier, 2013). The local sufficiency of an argument is often called inferential sufficiency and it holds if one of the following logical patterns is applicable: deductive entailment, conductive support, inductive support and analogy.

Argument quality is found to correlate with the argument’s actual persuasive success. Persuasion is defined as a process of encouraging people to do or believe something through argument. Here, many factors are relevant, including psychological effects of argument memorisation, replication and reviewing (Kumkale and Albarracín, 2004). Certain argumentation patterns are acknowledged as more persuasive than others, however they may differ in different domains. Hornikx (2008) experimentally investigated lay people’s expectations about the persuasiveness of anecdotal, statistical, causal, and expert evidence, and compared these expectations with the actual persuasiveness of these evidence types. Van Eemeren and Grootendorst (2004) defined symptomatic (sign), comparison (resemblance) and causal (consequence) argumentation, and specified what argumentative patterns are more suitable/persuasive for what communicative types in various domains. For persuasive essays, different quality dimensions of argumentation were studied such as essay’s organization (Persing et al., 2010), thesis clarity (Persing and Ng, 2013), prompt adherence (Persing and Ng, 2014) and argument strength (Persing and Ng, 2015). These studies exploit a complex feature-rich approach to predict a score for each essay based on its content or style along with all of these categories. The study of Persing and Ng (2017) looks at the argument persuasiveness from a different point of view: it does not try to estimate how persuasive an argument is but attempts to explain why an argument is experienced as unpersuasive. Research has also targeted various interactive aspects, e.g. capturing the interactions between participants on argument level (Ji et al., 2018) and providing feedback regarding the argument persuasiveness (Ke et al., 2018).

Many studies explore the aspect of argument convincingness4. In contrast to cogency, which is based on the truthfulness and logical coherence of arguments, convincingness is related to subjective perception by the audience (Wei et al., 2016). Experiments were performed to detect more convincing arguments (Habernal and Gurevych, 2016; Simpson and Gurevych, 2018) and evidence (Gleize et al., 2019).

The rhetorical force of an argument should not be underestimated. Due to the use of powerful rhetorical devices, even a not very cogent argument may be perceived as convincing (Petukhova et al., 2017b; Hirschberg, 2002). People generally associate certain speech, personality and interaction features with what they think is a persuasive argument.

4It should be noted here that persuasiveness and convincingness of an argument are terms that are often used interchangeably.
More broadly, the persuasion literature of the last decades has shown that an argument that has higher perceived competence (e.g., evidence-based expert knowledge) and/or higher warmth (e.g., more likeable and trustworthy) is more convincing (Petty and Cacioppo, 1986; Albarracin et al., 2019).

The study of Wachsmuth et al. (2016) suggests an argument quality assessment approach that focuses solely on the argument structure, and defines statistical patterns in the structure of essays and define novel features that are evaluated in argumentation-related essay scoring tasks. The present study investigates the structural properties of a cogent argument and assesses its inferential strength, i.e. structures of inference (argumentation schemes) predicted from the associated amount, depth and type of evidence provided to the claim.

4 Argument Graph Reconstruction

We define argument graph reconstruction to involve: (1) segmentation of a text into EDUs; (2) discourse relation detection and classification between them; (3) identification and classification of ADUs based on the classified discourse relations; and (4) argument completion, i.e. reconstruction of the implicit units to achieve a complete argument structure, see Figure 3.

We performed joint and two-stage segmentation and classification of EDUs. For the joint segmentation and classification, the full PDTB parser developed by Lin et al. (2010) was applied. We observed that the parser failed to identify many EDU spans. Rather low overall F1 scores of 21.20% for exact segment boundaries match and 5-class discourse relation classification were achieved on the Penn Discourse Tree Bank 1.0 corpus (PDTB 1.0, Prasad et al. (2005)), see the right part of Table 1. However, we observed, that in case of the correct span identification, relations classification was reasonably accurate. Misclassified cases mostly belonged to the implicit discourse relations as they were more difficult to classify then the explicit ones, a well known problem reported in the literature.

The two-stage segmentation and classification was performed applying the BiLSTM-CRF based segmentation model NeuralEDUSeg developed by Wang et al. (2018) and the XLNet-large discourse relations classification model by Yang et al. (2019). A segmentation performance of 68.55% in terms of F1 score was achieved when testing on the PDTB 1.0 and PDTB 2.0 datasets (PDTB 2.0, Prasad et al. (2008)). For discourse relation recognition with the XLNet model designed by Yang et al. (2019), we first carried out a binary classification to establish whether any relation exists between the identified units, i.e. discriminate between the Rel class which includes any type of discourse relations and NoRel types. The former comprises explicitly marked (Explicit), implicitly marked (Implicit) and alternatively lexicalized (AltLex) discourse relations, the later includes EntRel relation which is not a discourse relation between clauses but an entity-based coherence relation. Subsequently, we performed five-class top-level (L1) and ten-class fine-grained (L2) relations classification. Table 4 in Appendix I provides an overview of the PDTB discourse relation and their distribution in the PDTB 1.0 and the newer PDTB 2.0 corpora.

Since class distributions were unbalanced in all classification settings, re-sampling was performed: up-sampling of the under-represented NoRel class in binary classification by adding synthetic samples. For this random EDUs from different textual units were combined. In addition to this, down-sampling of the majority classes in the multi-class settings was performed. For the training and evaluation procedures, we fine-tuned each encoder model following the suggestions of Mosbach et al. (2021) and trained it for 10 epochs using a learning rate of

---

5The same observation was made by Hewett et al. (2019).
Table 1: Performance overview on the joined EDU segmentation and 5-class discourse relation classification task with Lin et al. (2010) parser in terms of F1 scores (in %) on the PDTB 1.0 corpus (left); and on the two-stage segmentation and classification tasks performing EDU segmentation with the NeuralEDUSeg model (Wang et al., 2018) in terms of F1 scores (in %) on the PDTB 2.0 corpus, and 5- and 10-class discourse relation classification with the fine-tuned XLNet-large model (Yang et al., 2019) in terms of accuracy (in %) on the DagStuhl corpus (right).

We observed that some argument components, often claims, are implicit, see also Wachsmuth et al. (2017). Without the claim or conclusion, an argument structure is incomplete. Therefore, we reconstructed a claim for every topic in the corpus, either ‘for’ or ‘against’ stance it may present. The reconstructed claim is a simple sentence corresponding to a single EDU, see Table 5 in Appendix II for selected examples.

The identified Dagstuhl arguments are of different length and have various, often complex discourse-based structures distinguishable through diverse linking patterns and number of evidences provided by an arguer to support a claim. Figure 4 provides an example of the identified discourse-based argumentation scheme. The upper node represents the claim *Books are better than TV* which was supported by seven evidence statements, six of them connected to the claim by means of *Contingency.Cause* relation and one by *Expansion.Instantiation*. Five of the evidence statements correspond to one EDU, whereas the other two are more complex and consist of two EDUs.

Finally, argument structures were represented as graphs where the detected EDUs spans are represented as nodes and the classified discourse relations – as edges visualising number and level of supporting evidence through links to the claim and premises. 2,278 reconstructed arguments have 303 structures (argumentative schemes) specifying 172 unique reasoning patterns. Figure 6 in Appendix III provides the most frequent examples of the reconstructed discourse-based argument structures.

5 Argument Quality Assessment Using Graph Neural Networks

Our main assumption is that arguments constructed to follow certain patterns and containing particular discourse relations are of higher quality, i.e. inferentially stronger, than others. Thus, the amount and type of evidence matter. For example, a widely used structure of debate arguments is known as the ARE. ARE comprises a claim of an Argument supported by a Reason and an Evidence, see also Petukhova et al. (2016). Another commonly used argument structuring technique is called chunking (Johnson, 2009). Here, arguers generalise from a claim (chunking up), provide a specific example (chunking down) or draw analogies (chunking side-
Thus, an argument which contains *Cause* or *Instantiation* relations making a claim to be justified and explained, is expected to be of high quality.

A large variety of identified discourse relations may indicate that an argument is very elaborate. However, very lengthy arguments are often difficult to comprehend and may be rhetorically less persuasive.

Particular structures can be important to compute local sufficiency. For instance, conductive reasoning may be expressed by the number of first-level evidence supporting the main claim independently (multiple support) and together (linked support) connected by means of *Expansion* relations. For inductive support, Exemplification discourse relations can be analysed as evidence providing an example support. Finally, the argumentation depth can be relevant for the argument sufficiency assessment and can be computed by looking at evidence which is linked to other evidence statements providing a serial support. Obviously, not only linking patterns but also evidence content would impact the argument quality.

Arguments in the Dagstuhl15512 ArgQuality corpus were annotated by seven independent annotators across 15 quality dimensions including four for argument cogency: acceptability, relevance, sufficiency and overall cogency. Quality scores from 1 (low) to 3 (high) were assigned. A fair inter-annotator agreement for all cogency dimensions was reached ranging from .44 to .47 in terms of Krippendorff’s α (Wachsmuth et al., 2017). Distribution of the annotated quality classes resulted in a rather unbalanced training set, in particular for the sufficiency dimension, therefore we combined the minority class with the adjacent one defining a binary classification task predicting arguments of a *lower* and of a *higher* quality, see Table 2 for distributions.

To assess the argument cogency, we employed a Graph Neural Network (GNN) model which is able to generalize over manifold structures. Errica et al. (2019) presents an overview of GNNs models for graph classification, e.g. DGCNN, DiffPool, ECC, GIN, GraphSAGE. However, none of these models exploit edge features required for our application so it incorporates discourse relation information.

### 5.1 Architecture Overview

For our experiments, we use the Graph Attention Network (GAT) model by Veličković et al. (2018). Initial inputs to the model include the node feature matrix $X^0$ as presented in Figure 5 (left). The matrix is fed to the GNN layer which is able to handle binary edge features, i.e. in our case the model can only handle the existence or absence of a relation between two EDUs. The single-head and multi-head attention mechanisms used within the GNN layer are illustrated on Figure 5 (center and right). As a result, a new node matrix $X^1$ is
produced. The procedure is repeated for every subsequent layer. Our network consists of three such layers. For graph classification, an average pooling layer is applied to the first dimension of $X^{L}$, i.e. the feature matrix is reduced to a single vector representing the whole graph. Subsequently, the fully connected layer is applied to the vector whose outputs are used as logits for the final classification.

The model described above allows incorporating various features in the node feature matrix $X^{0}$. We experimented with three different settings. In the first design, no node features were available. Hence, that model predicts argument quality based solely on the graph structure. In the second design, we encoded the texts corresponding to each node using GloVe embeddings taking the mean of all word embeddings of an EDU to obtain the EDU representation. In the third setting, we used BERT embeddings of an EDU as node features using the DistilBERT pre-trained model optimized for Semantic Textual Similarity task (Reimers and Gurevych, 2019). The vector dimensionality for each of the settings described above was 300, 300 and 768 dimensions, respectively.

### 5.2 Experimental Results

We trained a model for each quality dimension (cogency, acceptability, relevance, sufficiency) varying the number of epochs from 100 to 1000. Subsequently, we determined the best training setting based on the validation set accuracy. We observed that the performance on quality dimensions applying different either GloVe or BERT node features depends on the number of training epochs. Furthermore, we learned that the models with the GloVe and BERT node features reduced loss much faster than the models with uniform node features which indicates a possible overfitting. Therefore, we experimented with dropout rates from 0.2 to 0.6 applying it to the output of the last hidden layer. Test accuracy of BERT-based models improved for all dimensions except for acceptability. 10 training runs for each quality dimension showed that the test accuracy for certain models did not vary much with different dropout rates, the results were also proven not to be statistically significant according to the paired t-test. Table 3 reports the highest mean test accuracy achieved across five runs.

All trained quality assessment models outperformed their corresponding baselines indicating that the graph structure and node features incorporate useful information. Models generally were proven to be resistant to class imbalance. Resampling or weighted training and testing did not result in better performance, which indicates that more sophisticated methods are required to improve results. Further findings suggest that there is no ‘universal’ training setting for various quality dimensions: to achieve acceptable performance some models require longer training and different sets

of node features. Surprisingly, sophisticated node features do not always lead to a better model performance. For instance, for the cogency dimension the model without node features significantly outperformed the GloVe- and BERT-based models which may suggest that the argument structure alone is sufficient to accurately predict argument cogency. This confirms our initial assumption. However, we are cautious with this conclusion and emphasise that further experiments on larger datasets are needed. Training on such small training (242 instances), validation (30 instances) and test (30 instances) sets is a challenging task causing oscillation in the validation and test accuracies. Model instability was also caused, in our view, by a large variety of graph structures which can possibly be resolved by graph pruning or graph unification.

6 Conclusions and Future Work

We presented an approach to the assessment of argument quality, in particular its cogency, evaluating the structural strength of the argumentation schemes applied by an arguer. Argumentation schemes were represented as graphs reconstructed by applying the NeuralEDUSeg model developed by Wang et al. (2018) to segment a text into elementary discourse units and the fine-tuned XLNet-large model of Yang et al. (2019) to classify discourse relations between the identified units. Both segmentation and classification models showed reasonable performance in processing argumentative texts: F1 scores of 47.94% on the segmentation task were achieved; discourse relation classification accuracy ranges from 50.48% to 60.22% depending on the classification scenario (5- vs 10-class discourse relation classification). Parsed argumentative texts subsequently were used to reconstruct discourse-based argumentation structures as graphs of varying complexity reflecting reasoning patterns that emulate human inferencing. Given a graph structure, the argument acceptability, relevance, sufficiency and overall cogency were predicted. The trained models incorporated not only linking structures but also claim and evidence content as node features computed from GloVe and BERT embeddings. We tentatively concluded that overall argument cogency may be predicted based on the argument structure alone without computing sophisticated node text-based features. To ensure that this observation is not an artefact of our data, it needs to be tested on a larger argument set from various domains.

Limitations of the presented study call for further improvements. The next major step is to incorporate edge features which contain important information about the type of relations between claim and evidence units. Further, we intend to explore new discourse processing tools and experiment with mapping between different discourse analysis frameworks, e.g. Rhetorical Structure Theory (RST, Mann and Thompson (1988) and ISO 24617-8 DR-Core (ISO, 2016). Additional argumentative corpora will be explored as well as the assessment of the other quality dimensions.

A Hybrid Approach of Opinion Mining and Comparative Linguistic Analysis of Restaurant Reviews

Salim Sazzed
Old Dominion University
Norfolk, VA, USA
ssazz001@odu.edu

Abstract

The existing research on sentiment analysis mainly utilized data curated in limited geographical regions and demography (e.g., USA, UK, China) due to commercial interest and availability of review data. Since the user’s attitudes and preferences can be affected by numerous sociocultural factors and demographic characteristics, it is necessary to have annotated review datasets belong to various demography. In this work, we first construct a review dataset BanglaRestaurant that contains over 2300 customer reviews towards a number of Bangladeshi restaurants. Then, we present a hybrid methodology that yields improvement over the best performing lexicon-based and machine learning (ML) based classifier without using any labeled data. Finally, we investigate how the demography (i.e., geography and nativeness in English) of users affect the linguistic characteristics of the reviews by contrasting two datasets, BanglaRestaurant and Yelp. The comparative results demonstrate the efficacy of the proposed hybrid approach. The data analysis reveals that demography plays an influential role in the linguistic aspects of reviews.

1 Introduction

Sentiment analysis or opinion mining refers to the process of identifying opinions or sentiments expressed (e.g., positive, negative) in a text document (Liu, 2012). The lexicon-based method and machine learning (ML) based method are the two dominant approaches for opinion mining; although, their combinations have been also explored by the researchers. To evaluate the polarity of a piece of text, the lexicon-based methods rely on the sentiment lexicon comprised of opinion-conveying positive or negative terms and a set of rules (Turney, 2002; Sazzed, 2020b). For the lexicon-based methods, the laborious steps of data labeling are not required. The supervised machine learning (ML) based approaches derive the relationship between features of the text segments and the opinions expressed in the writing in a supervised fashion (Pang et al., 2002; Sazzed and Jayarathna, 2019). Therefore, supervised ML classifiers require a significant amount of annotated data for training a predictive model for determining the polarity of a text document. Labeling a large amount of text data is not only a challenging but also a tedious and costly process (Sazzed and Jayarathna, 2021; Sazzed, 2020a).

Mining customer opinions towards restaurants has attained popularity in recent years due to its impact on business growth and sustainability. Researchers performed a number of studies using the Yelp restaurant review and several other datasets. However, existing research on opinion mining in review datasets mainly focused on data curated in some specific demography (e.g., developed countries or countries with large consumer markets) due to commercial interest and abundance of user-generated review data. As shown in (Nakayama and Wan, 2019), the trait and preferences of users can vary across demography. Therefore, it is important to generate annotated content for various demography (e.g., geography, user, or language) and analyze them to identify the differences, which can ultimately help better decision-making. Nowadays, with the increasing accessibility of the Internet and the popularity of social media, opinion data are increasingly becoming available in many other geographies (e.g., Bangladesh) and languages.

Therefore, the main objective of this work is to create a restaurant review dataset from less-explored demography and introduce a new methodology to improve the performance of sentiment
classification. Besides, this study aims to explore how the demography affects the linguistic characteristics of reviews.

We create a restaurant review dataset, BanglaRestaurant, which contains more than 2300 customer reviews toward various Bangladeshi restaurants. We employ both the lexicon-based and ML-based methods to classify customer’s sentiments in the BanglaRestaurant dataset. To improve the performance of sentiment classification, a hybrid methodology is introduced that leverages a lexicon-based method and an ML-based classifier. We observe an improvement of the F1 score by employing the proposed hybrid approach.

We investigate the characteristics of reviews belong to the BanglaRestaurant dataset written by non-native English speakers and Yelp reviews written by English native speakers. The comparative analysis reveals that demography (i.e., nativeness of language and geography) has influences on the various linguistic features of reviews.

1.1 Contributions

The contributions of this paper can be summarized as follows:

- We create a Bangladeshi restaurant dataset consists of over 2300 customer reviews\(^1\).
- We propose a hybrid approach that improves the performance of sentiment classification by combining the lexicon-based method and supervised ML classifier.
- We analyze the characteristics of two restaurant review datasets curated in different demography.

2 Sentiment Analysis in Restaurant Review Datasets

Kang et al. (2012) created a sentiment lexicon and proposed an improved Naive Bayes (NB) based method for sentiment analysis in a restaurant dataset. Blair-Goldensohn et al. (2008) introduced a sentiment summarizer system where a summary is built by extracting relevant aspects of a service, aggregating the sentiment per aspect, and selecting aspect-relevant text. An attention-based Long Short-Term Memory (LSTM) network was proposed in (Wang et al., 2016) for aspect-level

\(^1\)https://github.com/sazzadcsedu/BanglaRestaurant.git

sentiment classification. Gan et al. (2017) analyzed how various attributes influence customers sentiments on restaurant star ratings. Zhang et al. (2011) incorporated ML-based techniques such as NB and SVM to automatically classify user reviews as positive or negative from online Cantonese-written restaurant reviews.

Zahoor et al. (2020) created a restaurant dataset by collecting over 4000 customer reviews of various restaurants located in Pakistan. Sasmita et al. (2017) performed aspect-based sentiment analysis (ABSA) in Indonesian restaurant reviews. They performed both the (i) aspect extraction and (ii) aspect sentiment orientation classification.

Xue et al. (2017) identified aspect categories and extracted aspect-terms from the user-generated reviews. The authors proposed a multi-task learning model based on neural networks and observed improved performance over the models trained separately on three public datasets. Ahiladas et al. (2015) utilized named entity recognition (NER) and typed dependency techniques to identify different types of food and the opinions associated with them. Tian et al. (2021) performed a case study on Yelp restaurant review data to find what affects restaurant customer’s sentiments. Besides, they noticed consumers rate restaurant service more often than the food quality. Jia (2018) proposed an integrated approach that leverages text mining and empirical modeling to correlate ratings with reviews. The author examined 49,080 pairs of restaurant ratings and reviews from Dianping.com (a Chinese online review community) to identify high-frequency words, major topics, and subtopics. Xiang et al. (2019) presented an LSTM based architecture LSTM-SAT for sentiment analysis of Cantonese style text by incorporating sentiment knowledge into the attention mechanism in the LSTM.

3 BanglaRestaurant Dataset

3.1 Data Collection

The restaurant reviews are manually collected from the restaurant’s Facebook pages. We find the reviews are written in English, Bengali (i.e., the native language of Bangladesh), and Romanized-Bengali (Bengali text in Latin alphabet). English is the main foreign language in Bangladesh which is taught in schools and colleges. Besides, English is frequently used in government administration, educational institutions, courts, businesses, and media of the country. People often use English for
expressing their opinions and feelings on social media as it is more convenient to write English text than Bengali. For example, Bengali has 50 letters (11 vowels and 39 consonants) compared to 26 letters in English. Since this study focuses on the reviews written in English, the final dataset contains only the English reviews.

### 3.2 Data Annotation

We annotate the reviews based on the reviewer’s recommendations; if the reviewer recommends the restaurant, then the corresponding review belongs to the positive class; Otherwise, it goes to the negative class. The final restaurant dataset contains a total of 2315 reviews, 1702 positive reviews (i.e., recommended by customer), and 613 negative reviews (not recommended).

### 4 Proposed Methodology

To determine the semantic orientations of the reviews, we employ both the lexicon-based and ML-based methods, as each of them has certain advantages over the other.

#### 4.1 Lexicon-Based Approaches

We employ four lexicon-based methods: VADER (Hutto and Gilbert, 2014), TextBlob, LRSentiA (Sazzed and Jayarathna, 2021) and SentiStrength (Thelwall et al., 2010) for classifying sentiment from unlabeled data. A non-negative polarity score by these methods is considered as a positive prediction (except VADER, where the compound score is used).

##### 4.1.1 VADER

VADER (Valence Aware Dictionary for Sentiment Reasoning) is a lexicon and rule-based sentiment analysis tool specifically attuned to determine sentiments expressed in social media. In VADER, a compound score indicates the semantic orientation of a review. For binary classification, a non-negative compound score refers to a positive prediction.

##### 4.1.2 LRSentiA

LRSentiA is a lexicon and rule-based method that can classify opinions expressed in unlabeled data. LRSentiA utilizes a binary-level opinion lexicon (Liu, 2010) and a set of linguistic rules to determine the polarity of a review.

##### 4.1.3 TextBlob

TextBlob is a Python library for processing textual data. The predicted polarity score of a review is within the range of \([-1, +1]\), where -1 indicates strongly negative, and +1 means strongly positive.

##### 4.1.4 SentiStrength

SentiStrength predicts the strength of positive and negative sentiments in short texts. The range of sentiment value of negative sentiment could be between -1 to -5; For the positive sentiment, the score can range between +1 and +5.

#### 4.2 Machine Learning Approaches

##### 4.2.1 ML Classifiers

In this work, we employ five popular supervised ML classifiers: Logistic Regression (LR), Ridge Regression (RR), Support Vector Machine (SVM), Random Forest (RF), and Extra Tree Classifier (ET) for identifying the polarity of the customer review.

##### 4.2.2 Experimental Settings

The review texts are segmented into words and converted to a matrix of term frequency-inverse document frequency (TF-IDF) features. We calculate the TF-IDF score for all words in the review using the scikit-learn library (Pedregosa et al., 2011), and the resultant matrix is feed to supervised ML classifiers. To evaluate the performance of various ML classifiers, we use 10-fold cross-validation. For all the ML classifiers, the default parameter settings of the scikit-learn library (Pedregosa et al., 2011) with class-balanced weights are used.

#### 4.3 Hybrid Approach

We present a hybrid methodology for sentiment classification by leveraging both the lexicon-based and ML-based approaches. Based on the predicted polarity scores of the reviews determined by the lexicon-based method LRSentiA (Sazzed and Jayarathna, 2021), we categorize them into three groups.

1. **Minimal opinion group (MOG)**: When LRSentiA assigns a polarity score of 0 to a review, it falls into the MOG category. A review with a 0 polarity score is considered as a positive prediction assuming that a negative review has a higher chance of having negative polarity scores than a positive review with a positive polarity score. Thus, predictions with non-negative polarity scores are considered positive predictions.
2. *Fair opinion group* (FOG): When the predicted polarity score of a review is between $<-2,+2>$, it belongs to the FOG group.

3. *Strong opinion group* (SOG): The reviews with polarity scores above +2 or less than -2 fall into SOG.

We assume if a lexicon-based method predicts the class of a review with a high polarity score (i.e., highly positive (> 2) or highly negative score (< -2)), it is highly probable that prediction is correct. As the lexicon-based method relies on the polarity of individual opinion words, if the overall polarity score is strongly positive or negative, then the review consists of mostly positive aspects (high positive score) or negative aspects (high negative score); thus, the prediction is probably correct.

After excluding the reviews belong to *strong opinion group* (SOG), the remaining two groups contain reviews which the lexicon-based method cannot distinguish confidently based on the opinion words present in the review. This scenario could happen due to various reasons, such as lexicon coverage problems or the complexity of natural languages. These groups are more prone to misclassification by the lexicon-based methods.

ML classifiers have been successfully applied in numerous problems in varying domains when data is noisy or explicit rules can not separate the classes well. Since supervised ML classifiers are capable of characterizing the best mapping from input to output, we employ an ML classifier for the reviews that require learning the implicit pattern from the labeled data rather than just using the polarity of the individual opinion words to find overall sentiment.

The overall predictions by the hybrid method consist of predictions by LRSentiA for the highly polar reviews and an ML classifier for the remaining reviews.

5 Impact of Demography in Linguistic Attributes of Review

We analyze whether the demography of the reviews has any impact on the linguistic characteristics of the reviews. We consider two datasets, which differ in the following demographic aspects, geography (i.e., the location where reviews were written) and language nativeness of speakers (i.e., whether native or non-native speakers of English wrote reviews). Our developed *BanglaRestaurant* corpus is curated in Bangladesh, where people are non-native speakers of English (sample reviews shown in Figure 2). We contrast this dataset with the *Yelp* restaurant reviews, which were written by USA-based (mostly) English native speakers (sample reviews shown in Figure 3).

The *Yelp* dataset contains 6860 positive comments and 1676 negative comments in contrast to 1702 positive samples and 613 negative samples in *BanglaRestaurant* dataset. To avoid any kind of influence of class distribution and dataset size, we use the same number of reviews from both the *BanglaRestaurant* and *Yelp* datasets. For the *Yelp* dataset, we randomly shuffle and then select 1702 positive samples and 613 negative reviews out of 6860 positive and 1676 negative reviews present.
We analyze the following characteristics of the reviews in two datasets. For the Yelp dataset, the numbers represent the average results of five random selections of 1702 positive comments and 613 negative comments.

1. Word count of the corpus: The numbers of words present in both corpora are provided.
2. Sentence count in the corpus: We report the number of sentences present in both datasets.
3. Average review length (word-level): The average review length in word-level indicates the average number of words present in a review of a corpus.
4. Average review length (sentence-level): The average review length in sentence-level refers to the average number of words present in a review of a corpus.
5. Average sentence length: This metric provides the average number of words each sentence contains in reviews that belong to a corpus.
6. Coverage of a lexicon: Furthermore, we compute the lexicon coverage of two English lexicons (Liu, 2010) and (Hutto and Gilbert, 2014) in both datasets. The lexicon coverage can assess the presence of diverse opinion words in the reviews, which indicates the vocabulary range of users.
7. Usage of the complex sentence in reviews: Besides, we study the complexity of the reviews at the sentence level. A complex sentence usually contains one or more dependent (subordinate) clauses and one or more independent clauses. A subordinating conjunction is a word or phrase that connects a dependent clause to an independent clause. Some examples of subordinating conjunctions are, although, as, because, before, how, if, once, since, etc.. We examine the presence of 50 common subordinating conjunctions in both corpora to analyze the complexity of the reviews.

Table 2: Performance of The Best Lexicon-based Method LRSentiA in BanglaRestaurant Dataset

Table 1 reveals that TextBlob, VADER, and LRSentiA perform similarly, where the SentiStrength yields comparatively lower F1 score and accuracy. SVM, LR, and RR provide a similar F1 score of around 0.89 and an accuracy of 91%, which is a bit higher than the top lexicon-based method, LRSentiA. Decision tree-based ML classifiers such as DT and ET provide comparatively low accuracy and F1 score compared to other ML classifiers.

Table 2 exhibits that lexicon-based method LRSentiA fails to classify the reviews correctly in many cases when the predicted polarity score is low (i.e., between -2 and +2, inclusive). In the MOG and FOG groups, only 779 out of 990 reviews are classified correctly. We notice when the lexicon-based method predicts with high polarity score, it is accurate in most cases. Among 1325 reviews, the predictions of LRSentiA are true for 1293 cases with an accuracy of 97.5%.

Table 4 presents the performance of ML classifiers in the complex subsets (MOG and FOG) of BanglaRestaurant reviews (i.e., 990 reviews out of 2315), which the lexicon-based method fails to not discern correctly. We find that most of the ML classifiers yield better performance compared to the lexicon-based classifier. The best performing classifier SVM increases F1 score 12% over the lexicon-based method in the MOG and FOG confidence groups.

Table 5 shows that the proposed hybrid method enhances the F1 score and accuracy of classification by integrating an ML classifier such as LR or SVM with the lexicon-based method. While the best lexicon-based and ML-based methods show F1 scores of 0.86 and 0.893, respectively, the hybrid approach incorporating the SVM classifier attains an F1 score of 0.91.

From Table 3, we observe that Yelp review lengths are much higher in both word and sentence levels. The sentiment lexicon shows higher coverage in BanglaRestaurant; The presence of the subordinate clause, which refers to the complex sentence, is more obvious in the Yelp dataset.

7 Discussion

We observe in the BanglaRestaurant dataset performance of the lexicon-based approach is close to the ML-based classifiers. The best macro F1 score is obtained from the SVM classifier, which is around 89%; The most accurate lexicon-based method LRSentiA achieves an accuracy of 86%. This result is expected as supervised ML classifiers usually perform better than lexicon-based methods.

From Table 2, it is evident that the lexicon-based method is very effective when the review polarity is easily distinguishable either as positive or negative. If a user review is comprised of mixed opinions towards various entities or sentiment is not obvious, it is often difficult to assign the overall polarity using the lexicon-based method. In contrast, the ML classifiers learn implicit patterns from training data, thus, are capable of determining the overall sentiment of a review even though the opinion is
not apparent. Thus combining both the lexicon and ML-based classifiers in the sentiment classification framework improves the performance.

We notice the hybrid approach yields an overall F1 score of 0.915 in the BanglaRestaurant corpus, an improvement of 6% (0.860) over the best lexicon-based method and 3% (0.892) over the best ML-based classifier. Although the increase of the F1 score is not much compared to the best ML classifier, the main advantage of the proposed hybrid approach is that it does not require any annotated data. Review data is usually readily available on the web; the primary challenge is to label the data. Thus, the proposed hybrid approach can be very effective for addressing the data annotation difficulties. We find the features characteristics of the reviews are distinct in BanglaRestaurant and Yelp datasets, which represent data from different demography.

8 Summary and Conclusions

In this work, we introduce a hybrid approach for sentiment classification in a newly created BanglaRestaurant dataset. The proposed hybrid approach combines the lexicon-based method LRSentiA with the SVM classifier to improve the performance of sentiment classification. The results suggest that lexicon-based methods are mainly effective at classifying reviews that contain strong opinions. However, they struggle to determine sentiment when the polarity is not obvious. Hence, it is necessary to incorporate an ML classifier that is robust for complex cases.

In addition, we provide a comparative analysis of review data curated in different demography. We investigate various linguistic features of reviews that belong to these two datasets. The first dataset contains (i.e., BanglaRestaurant) reviews written by non-native English speakers of Bangladesh; while, reviews of the other dataset (i.e., Yelp) were written by (mostly) English native speakers located in the USA. We observe differences in the various linguistic characteristics of reviews in these two datasets.

A Lexicon for Profane and Obscene Text Identification in Bengali

Salim Sazzed
Old Dominion University
Norfolk, VA, USA
ssazz001@odu.edu

Abstract

Bengali is a low-resource language that lacks tools and resources for profane and obscene textual content detection. Until now, no lexicon exists for detecting obscenity in Bengali social media text. This study introduces a Bengali obscene lexicon consisting of over 200 Bengali terms that can be considered filthy, slang, profane or obscene. A semi-automatic methodology is presented for developing the obscene lexicon that leverages an obscene corpus, word embedding, and part-of-speech (POS) taggers. The developed lexicon achieves coverage of around 0.85 for obscene and profane content detection in an evaluation dataset. The experimental results imply that the developed lexicon is effective at identifying obscenity in Bengali social media content.

1 Introduction

The popularity of e-commerce and social media has surged the availability of user-generated content online. Therefore, text analysis tasks such as sentiment classification (Feldman, 2013; Sazzed and Jayarathna, 2019; Yadollahi et al., 2017; Sazzed, 2021b; Sazzed and Jayarathna, 2021), hate speech detection (Poletto et al., 2021; Corazza et al., 2020), profane or abusive content identification (Caselli et al., 2020; Nobata et al., 2016) have received significant attention in recent years. Profanity indicates the usage of taboo or swearing words and is prevalent in social media data across languages (Wang et al., 2014). The presence of swearing, obscene or vulgar words could be linked with hate speech, sexism, and racism. Hence, identifying their presence is important to understanding and monitoring online content. Although the terms profanity, obscenity, swearing, and vulgarity have subtle differences in their meaning, they are closely connected with some overlapping definitions. Thus, in this paper, they have been used interchangeably to refer to filthy content.

A lexicon consisting of a list of words with specific annotations can play an important role in various natural language processing tasks, such as sentiment analysis or inappropriate content identification. A profane or obscene lexicon contains words that convey foul, filthy, and profane meanings (e.g., ass, bitch). An obscene lexicon is instrumental for determining profanity, vulgarity, or obscenity in a text. The presence of swearing in English social media has been investigated by various researchers (Wang et al., 2014; Pamungkas et al., 2020). Wang et al. (2014) found that the rate of swear word use in English Twitter is 1.15%, almost double compared to its use in daily conversation (0.5% - 0.7%) as observed in previous work (Jay, 1992). Wang et al. (2014) also reported that in a random sampling, they observed around 7.73% tweets containing swear words. Furthermore, vulgar word identification can help to improve sentiment classification as shown by various researchers (Volkova et al., 2013; Yang and Eisenstein, 2017).

In Bengali, although few works performed abusive content analysis, none of them focused on determining obscenity or generating resources for identifying obscenity. Until now, no lexicon exists in Bengali that can help to identify profanity in text data. Thus, in this work, the goal is to generate resources for obscenity identification.

To construct the Bengali obscene lexicon, we propose a corpus-based semi-automatic approach. From an existing Bengali obscene corpus, utilizing word embedding and POS tagging, the lexicon is created. To demonstrate the efficacy of this lexicon, we categorize a drama review corpus into profane and non-profane categories based on the presence of swear and obscene terms. We observe that the developed lexicon successfully identifies 85.5% of the obscene or profane reviews in the corpus.
1.1 Motivation and Contributions

With the rapid growth of user-generated Bengali content on social media and the web, the presence of inappropriate content has become an issue. The content which is not in line with the social norms and expectations of a community needs to be censored. In Bengali, no such resources exist; thus, we focus on building a lexicon consisting of swear or obscene words that can help to identify profane content.

The main contributions of this paper can be summarized as follows:

- We introduce a Bengali obscene lexicon comprised of about 200 swear words. We have made the developed lexicon publicly available for researchers.

- We present a semi-automatic methodology for developing a swear lexicon utilizing an obscene corpus and various natural language processing tools.

- We demonstrate that the developed lexicon is effective at profanity detection in Bengali social media content.

2 Related Work

The existence and socio-linguistics characteristics of swearing or cursing in social media have been studied in several studies. Wang et al. (2014) investigated the ubiquity, utility, and contextual dependency of swearing on Twitter. Gauthier et al. (2015) analyzed several sociolinguistic aspects of swearing on Twitter text data. Several studies investigated the relationship between social factors, such as gender with the profanity, and discovered males employ profanity much more often than females (Wang et al., 2014; Selnow, 1985). Other social factors such as age, religiosity, or social status were found to be related to the rate of using vulgar words (McEnery, 2004). Jay and Janschewitz (2008) noticed that the offensiveness of taboo words depends on their context, and found that usages of taboo words in conversational context is less offensive than hostile context. Pinker (2007) classified the use of swear words into five categories: dysphemistic; abusive, using taboo words to abuse or insult someone; idiomatic, using taboo words to arouse the interest of listeners without really referring to the matter; emphatic, to emphasize another word; cathartic, the use of swear words as a response to stress or pain.

Obscenity and profanity filtering has been studied for content filtering, such as parental controls (Weir and Duta, 2012), cyberbullying detectors (Dadvar et al., 2013). A more complex application of obscenity filtering is identifying implicitly abusive content, where both the intention of the author and the usage of obscene language need to be considered (Weir and Duta, 2012).

Research related to the identification of swearing or offensive words has been conducted mainly in English; Therefore, lexicons comprised of offensive words are available in the English language. Pamungkas et al. (2020) created SWAD (Swear Words Abusiveness Dataset), a Twitter English corpus, where abusive swearing is manually annotated at the word level. Their collection consists of 1,511 unique swear words from 1,320 tweets. Razavi et al. (2010) manually collected approximately 2,700 dictionary entries, including phrases and multi-word expressions, which is one of the earliest work offensive lexicon creations. The recent work of lexicon creation for hate speech detection was reported in (Gitari et al., 2015). Another English lexicon of abusive words was provided by (Wiegand et al., 2018).

Eder et al. (2019) explored the vulgar and obscene text in German. They conceived vulgar language is predominantly signaled by an overly lowered language, disgusting and obscene lexicalizations, which is generally banned from any type of civilized discourse. Primarily, it refers to sexual organs and activities, as well as body parts and scatological expressions.

In Bengali, several works investigated the presence of abusive language in social media data by employing supervised ML classifiers and labeled data (Ishmam and Sharmin, 2019; Banik and Rahman, 2019). Emon et al. (2019) utilized linear support vector classifier (LinearSVC), logistic regression (LR), multinomial naive Bayes (MNB), random forest (RF), artificial neural network (ANN), recurrent neural network (RNN) with long short term memory (LSTM) to detect multi-type abusive Bengali text. They found RNN outperformed other classifiers by obtaining the highest accuracy of 82.20%.

Chakraborty and Seddiqui (2019) employed ma-
chine learning and natural language processing techniques to build an automatic system for detecting abusive comments in Bengali. As input, they used Unicode emoticons and Unicode Bengali characters. They applied MNB, SVM, Convolutional Neural Network (CNN) with LSTM and found SVM performed best with 78% accuracy. Sazzed (2020b) created a sentiment lexicon that consists of over 500 Bengali negative opinion words. However, no annotations regarding obscenity or vulgarity were provided for these negative words.

Karim et al. (2020) proposed BengFastText, a word embedding model for Bengali, and incorporated it into a Multichannel Convolutional-LSTM (MConv-LSTM) network for predicting different types of hate speech. They compared BengFastText against the Word2Vec and GloVe embedding by integrating them into several ML classifiers and showed the efficacy of BengFastText for hate speech detection.

Sazzed (2021a) introduced an annotated Bengali corpus of 3000 transliterated Bengali comments categorized into two classes, abusive and non-abusive, 1500 comments for each. For the baseline evaluations, the author employed several supervised machine learning (ML) and deep learning-based classifiers. They observed support vector machine (SVM) shows the highest efficacy for identifying abusive content.

To the best of the author’s knowledge, none of these existing works concentrated on recognizing obscene words in Bengali social media content. Besides, no lexicon exists so that profanity or obscenity can be determined without using any annotated data. This work is the first effort to identify profanity in the context of Bengali social media data by introducing a obscene lexicon.

3 Corpora

Two Bengali obscene datasets are used in this study, one for constructing the lexicon (development corpus), and the other one is for evaluating the performance of the created lexicon (evaluation corpus).

3.1 Development Corpus

The development corpus is a subset of a Bengali corpus deposited by (Abu, 2020). This Bengali corpus consists of 10221 user comments which belong to different categories, such as toxic, racism, obscene, insult, etc.

For developing the lexicon, only the obscene comments are used. After discarding the noisy reviews (e.g., empty comments, punctuation only comments, etc.) and reviews that belong to other classes, the development corpus consists of 3902 obscene comments (each contains 1-100 words).

Figure 1 represents some examples of the obscene comments from the development corpus.

3.2 Evaluation Corpus

The evaluation corpus is a subset of the dataset deposited by Sazzed (2020a). This corpus consists of viewer’s comments towards a number of Bengali dramas collected from Youtube. Originally, this dataset contains 8500 positive and 3307 negative reviews. These 3307 negative reviews are further categorized into two classes, obscene and non-obscene. After annotation, this corpus consists of 2643 non-obscene reviews and 664 obscene reviews.

4 Creation of Obscene Lexicon

4.1 Text Processing Tools

4.1.1 POS Tagger

Part-Of-Speech (POS) tagger is a text analysis tool that assigns a POS tag (e.g., noun, verb, adjective, etc.) to each word of a piece of text data. As adjectives, nouns, and verbs usually convey opinions, the POS tagger can help to identify words that convey obscenity. Some of the popular POS taggers in English are NLTK POS tagger (Loper and Bird, 2002), spaCy POS tagger (Honnibal and Montani, 2017), etc.

We utilize a Bengali POS tagger to identify opinion conveying word (i.e., adjective and verb). However, the existing Bengali POS taggers are not as accurate as of its English counterpart. Hence, manual validation is needed to check the correctness of the POS tags assigned to words.

4.1.2 Word Embedding

The word embedding is a learned representation for textual content. A word embedding creates similar representations of words that are related in some ways. The word-embedding provides an efficient way to use the dense representation of words of varying lengths.
There exist two main approaches for learning word embedding, count-based and context-based. The count-based vector space models heavily rely on the word frequency and co-occurrence matrix with the assumption that words in the same contexts share similar or related semantic meanings. The other learning approach, context-based methods, build predictive models that predict the target word given its neighbors. The best vector representation of each word is learned during the model training process.

The continuous Bag-of-Words (CBOW) model is a popular context-based method for learning word vectors. It predicts the center word from surrounding context words.

4.2 Lexicon Creation Framework

Leveraging lexical resources can assist in identifying the presence of profanity in Bengali social media. This study presents a semi-automatic approach for creating a swear lexicon utilizing an annotated corpus, word-embedding, and POS tagger. The lexicon development framework consisting of three phases, as shown in Figure 2,

1. Selection of seed words
2. Expansion of lexicon
3. Manual validation

4.2.1 Selection of Seed Words

The proposed methodology adopts a labeled obscene corpus to generate a list of seed words. The occurrences of individual words in the corpus are counted. Based on the word-occurrence count, the top 100 words are selected. We observe the presence of some non-vulgar words among the top 100 words, which are excluded.

4.2.2 Expansion of Lexicon

The lexicon expansion step involves utilizing word embedding to identify similar words of the seed list. The Gensim (Řehůřek and Sojka, 2010) continuous Bag-of-Words (CBOW) implementation is used to find similar words in the development corpus.

The entire procedure consists of the following steps.

- In the first step, we identify words that are the most similar to the seed words.
- The second step iteratively finds words similar to obscene words recognized in the first step. The duplicate words are removed automatically. In addition, we exclude words that are not a noun, adjective, or verb. This iteration stops when we notice no significant expansion of the obscene word list.

4.2.3 Manual Validation

In the final step, we manually exclude non-obscene words that exist in the lexicon. As lexical resources
Figure 3: Examples of obscene/swear words from the created lexicon, such as POS tagger in Bengali are not sophisticated enough, a manual validation step is necessary to eliminate non-obscene words. Moreover, we find that vulgar comments often do not follow the usual sentence structure; therefore, the POS tagger often fails to tag them correctly.

4.3 Developed Lexicon

Figure 3 shows some examples of Bengali obscene words and corresponding English translations. The English translation is provided to give an idea of the type/characteristics of the lexicon. Due to language-specific differences, the exact English translation may not be available for some of the words present in the developed obscene lexicon.

5 Obscenity Detection in Textual Content

As no lexicon exists in Bengali for obscene content detection, we compare the performance of the developed lexicon with several supervised classifiers in the evaluation corpus.

5.1 ML Classifiers

Two supervised ML classifiers, Logistic Regression (LR) and Support Vector Machine (SVM), and an optimizer, Stochastic Gradient Descendent (SGD), are employed in the evaluation corpus to identify profane reviews.

Logistic regression (LR) is a predictive analysis model that assigns observations into a discrete set of classes. LR assumes there are one or more independent variables that determine the outcome of the target.

Support Vector Machine (SVM) is a discriminative classifier defined by a separating hyperplane. Given the labeled training data, SVM generates an optimal hyperplane that categorizes unseen observations. For example, in two-dimensional space, this hyperplane is a line dividing a plane into two parts where each class lays on either side.

SGD is an optimization technique and does not correspond to a specific family of machine learning models. It is only a way to train a model. For SGD, we use hinge loss and l2 penalty.

As a feature vector, we use the unigram and bigram-based tf-idf score. 10-fold cross-validation is performed to assess the performance of various ML classifiers. We use the scikit-learn (Pedregosa et al., 2011) library implementation of the above-mentioned classifiers. For all the classifiers, default parameter settings are used.

To evaluate the performance of various ML classifiers and the SGD optimizer, we employ them in both original class-imbalanced and modified class-balanced settings. For class-balancing, initially, we employ the sampling method, SMOTE (Synthetic Minority Oversampling Technique) (Chawla et al., 2002). SMOTE is an oversampling technique where the synthetic samples are generated for the minority class with the help of interpolation. We notice it can not eliminate the inequality of class distribution in the original dataset. Thus, we use the subsampling method to make the dataset class-balanced.

In the original class-imbalanced setting, all the 664 obscene comments and 2643 non-obscene negative comments are utilized. In the modified class-balanced setting, all the 664 obscene comments are used; however, for the non-obscene class, we randomly select 664 non-obscene comments from a set of 2643 non-obscene comments.

5.2 Evaluation Metric

To show the effectiveness of the created lexicon, we utilize document-level coverage, $DCov$. $DCov$ of a lexicon corresponding to a review corpus is calculated as follows:

First, the number of reviews containing at least one word from the created lexicon is counted; afterward, it is divided by the total number of reviews present in the corpus. The following equation is used to calculate $DCov$ of a lexicon corresponding to a corpus:
Table 1: Comparative Performance of Various Methods for Obscene Text Identification

<table>
<thead>
<tr>
<th>Type</th>
<th>Method</th>
<th>Correctly Identified (Out of 664)</th>
<th>DCov/Recall</th>
</tr>
</thead>
<tbody>
<tr>
<td>Lexicon-based</td>
<td>Developed Lexicon</td>
<td>564</td>
<td>0.8493</td>
</tr>
<tr>
<td>ML Classifier (Unbalanced)</td>
<td>LR</td>
<td>400</td>
<td>0.6024</td>
</tr>
<tr>
<td></td>
<td>SVM</td>
<td>399</td>
<td>0.6009</td>
</tr>
<tr>
<td></td>
<td>SGD</td>
<td>384</td>
<td>0.5783</td>

<td>594</td>
<td>0.8945</td>
</tr>
<tr>
<td></td>
<td>SGD</td>
<td>589</td>
<td>0.8870</td>
</tr>
</tbody>
</table>

The main motivation behind creating the obscene lexicon is to identify comments and reviews that contain swearing, profane, or obscene words; thus, DCov is shown only for recognizing the usage of dirty language. Besides, the developed lexicon is manually validated at the final step; thus, it primarily contains obscene or profane words; hence, there is a very low chance that it identifies a non-obscene comment as obscene (false positive). However, this scenario could occur for few words present in the lexicon when they are used in different contexts. For example, one of the Bengali words in the lexicon may refer to either tits or milk, depending on the context.

For the ML classifiers, DCov depicts the recall score for obscene class detection.

5.3 Comparison Results

Table 1 shows that among the 664 obscene reviews present in the evaluation corpus, the developed lexicon registers 564 reviews as obscene by recognizing the presence of at least one obscene/swear/profane term in the review, which is a document-level coverage of around 0.85.

Table 1 provides the coverage of various ML classifiers in the evaluation corpus. We present their performances in two different settings: original class-imbalanced setting and modified class-balanced setting.

From the Table 1, we observe that when the original class-imbalanced data is used, all the three ML classifiers achieve coverage of only 0.60. However, when a class-balanced dataset is utilized, the coverages of classifiers dramatically increase; they achieve around 0.90 coverage.

6 Discussion

The results reveal that the developed lexicon is capable of identifying obscene content in Bengali social media. It shows higher document-level coverage than in-domain labeled data in original class-imbalanced settings (i.e., when the dataset contains mostly non-obscene comments). However, in a class-balanced dataset, we find ML classifiers and the SGD optimizer perform better than the developed lexicon.

Labeled data are scarcely available in low-resource languages such as Bengali; therefore, the developed lexicon can be a practical resource for obscenity identification when labeled data are unavailable. Besides, as shown in Table 1, the performances of ML classifiers can be affected by the class distribution of the training dataset. The obscene or vulgar comments usually occupy only a small portion of a dataset. The ML classifiers can be less effective with the presence of a small sample size of obscene comments. The developed lexicon can be very effective in this scenario.

7 Summary and Conclusion

This study presents a semi-automatic methodology for creating a lexical resource (i.e., an obscene lexicon) to detect obscene content in Bengali. An obscene corpus and various text processing tools and resources are leveraged to develop the obscene lexicon. The developed lexicon is made publicly available. The proposed methodologies can be adapted to other resource-limited languages to create lexical resources.

The efficacy of the obscene lexicon suggests that it can be utilized to distinguish obscenity in Bengali social media content when annotated data are

\[ DCov = \frac{\#\text{reviews with } (>0) \text{ obscene word identified}}{\text{total number of reviews in corpus}} \]

https://github.com/sazzadcsedu/Bangla-Vulgar-Lexicon.git
unavailable. However, it should be noted that labeling textual content as obscene or vulgar entirely based on obscene or swear words may not be sufficient due to the complexity of the natural languages. Still, a well-annotated lexicon of moderate size can assist in identifying profane content; especially, in resource-scarce language. Our future work will involve expanding the size of the lexicon by utilizing larger and multi-domain development corpora.

A Case Study of Deep Learning-Based Multi-Modal Methods for Labeling the Presence of Questionable Content in Movie Trailers

Mahsa Shafaei*, Christos Smailis*, Ioannis A. Kakadiaris, Thamar Solorio
Department of Computer Science, University of Houston, Houston, TX, USA
mshafaei@uh.edu, csmailis@central.uh.edu, ikakadia@central.uh.edu, tsolorio@uh.edu

Abstract

In this work, we explore different approaches to combine modalities for the problem of automated age-suitability rating of movie trailers. First, we introduce a new dataset containing videos of movie trailers in English downloaded from IMDB and YouTube, along with their corresponding age-suitability rating labels. Secondly, we propose a multi-modal deep learning pipeline addressing the movie trailer age suitability rating problem. This is the first attempt to combine video, audio, and speech information for this problem, and our experimental results show that multi-modal approaches significantly outperform the best mono and bimodal models in this task.

1 Introduction

Movie trailers can be found in abundance throughout the web using services such as video streaming platforms. However, not all types of content in trailers are suitable for every audience. Specifically, movie trailers may contain explicit, aggressive, or violent content that may be harmful to the psyche of young viewers. Previous research has documented that some of the negative effects of mass media in young viewers include aggression and anxiety (Wilson, 2008; Chang and Bushman, 2019), as well as increasing the risk of sexual onset and alcohol and drug consumption, unwanted pregnancies, and sexually transmitted diseases (Strasburger, 1989).

The Advertising Administration of the Motion Picture Association of America (“MPAA”) established guidelines for manually rating the age-suitability of movie trailers (Motion Picture Association). The rating of movie trailers is independent of the rating of the movie itself, as a trailer includes only a short overview of the entire movie. Due to the time consuming nature, as well as the challenges to scale the MPAA rating process, automating the task poses interesting challenges to multi-modal classification systems, as the source of the objectionable content can come from any, or the combination of, these sources: language (use of bad words or discussion of adult themes), images (graphic violent scenes, nudity, drug or alcohol use), and audio (loud noises and music score denoting suspenseful content). A successful rating approach should integrate evidence provided by the multiple modalities when making the predictions.

In this paper, we study the performance of different multi-modal deep learning methods, to automatically predict the MPAA age-suitability rating of movie trailers using cues from the video, audio, and text modalities. Our goal is to show the feasibility of automating the rating task, and in particular, the relevance of multimodal solutions. We explore the use of late fusion, feature concatenation fusion and Gated Multi-modal Unit (GMU) Fusion (Arevalo et al., 2017). Since the proposed pipeline does not use any type of metadata for trailers or movies, it can be easily extended to be applied to any type of online video content. The main contributions of this work are: (i) we introduce a new task in multi-modal classification; rating videos based on the MPAA rating metric for movie trailers; (ii) we introduce the Multi-modal Movie Trailer Rating (MM-Trailer) dataset that contains movie trailers and their corresponding MPAA tags, audio files, subtitles of the trailers, and the metadata of the target movie; and (iii) we demonstrate empirically that combining the different modalities yields significant improvements over the strongest monomodal model. Our results show that both, the GMU and late fusion approaches yield promising results.

2 Related Work

This work is related to four different areas, namely: (i) text classification, (ii) video classification, (iii)
audio classification, and (iv) movie classification datasets.

**Text Classification:** In (Martinez et al., 2019), the authors proposed an RNN-based architecture for detecting violence in movies on a segment level as well as the full movie level, by using the movie’s script. In Shafaei et al. (2019), the authors proposed an RNN-based architecture with an attention mechanism that jointly models the genre and the emotions in movie script to predict the MPAA rating of a full movie. The main difference between our work and aforementioned papers is that they only use scripts to predict the movie ratings (violence rating and MPAA ratings), while we employ various modalities (audio, video, and text) to predict if a trailer (not the entire movie) is appropriate or not for children. It should be noted that the rating schema is different for trailers compared to movies (details in Section 3), and movies are not freely available on the internet.

**Video Classification:** Early approaches, such as (Karpathy et al., 2014) on video classification using Deep Learning, explored the use of several temporal fusion methods for combining information from multiple consecutive video frames using features extracted from CNN architectures. The authors in (Donahue et al., 2015) introduced an end-to-end architecture based on a combination of CNNs used for feature extraction from RGB frames. The CNN features are then forwarded to an LSTM layer that models the temporal variation of frames. A different approach is followed in (Tran et al., 2015), namely 3D-CNN, where authors propose the use of a CNN variant that takes into account convolutions performed into both the spatial and temporal domains of a video. An expansion of the 3D-CNN approach was proposed by (Carreira and Zisserman, 2017), where the authors propose a two-stream 3D-CNN architecture for video classification. Again the two streams used as input RGB frame data and Optical flow images.

**Audio Classification:** In past research, several types of handcrafted feature extraction techniques have been proposed for the audio modality (Davis and Mermelstein, 1980; Geiger et al., 2013; Papakostas et al., 2017) with the ones being the most prominently used in the literature being Mel-frequency cepstral coefficients (MFCCs). However, recently several approaches have been proposed for combining audio features such as spectrogram information with deep learning architectures to perform audio classification (Papakostas et al., 2017; Hershey et al., 2017; Koutini et al., 2019). Audio has been explored as a modality for classifying movie content in several works such as (Rasheed and Shah, 2002; Hebbar et al., 2018). However, none of these methods has focused on the problem of movie trailer age-suitability rating.

**Movie Classification Datasets:** Several movie classification datasets have been proposed in the past. In (Demarty et al., 2014), the authors introduced MediaEval 2013 Violent Scene Detection, which provided annotations for detecting violent scenes in movies. In Constantin et al. (2020), the authors proposed an evaluation framework, for Violent Scenes Detection in Hollywood and YouTube videos along with a dataset (VSD96). Although these datasets are relevant to our work, they only cover the violence aspect and cannot address the problem of age-suitability rating (violence is only one of many aspects of age rating). In (Shafaei et al., 2019), the authors proposed a movie dataset focusing on the task of predicting the MPAA rating of the movie. However, the aforementioned dataset only includes movie scripts and corresponding metadata but does not include movie trailers or related age-suitability tags (As we mentioned earlier, the MPAA rating scheme is different for movies and trailer). In (Cascante-Bonilla et al., 2019), authors introduced Moviescope, a dataset for movie genre classification. Similarly, it does not include MPAA age-suitability rating labels for movie trailers.

### 3 Dataset

To the best of our knowledge, there is no previous trailer dataset with age-suitability rating. Thus, we assembled the multi-modal Movie Trailer dataset (MM-Trailer) \(^1\) by collecting the rated trailers from the IMDB website and YouTube. Typically trailers are advertising movies soon to be released and shown in theaters before a movie starts. Rating in trailers is shown by a colored band (red, yellow, green) and a message that appears at the beginning of the trailer. The rating of the trailers adheres to the rating of the movie being shown in the theater. For instance, if the movie playing at the theater is rated as NC-17 (no one under 17 is recommended to watch this movie), the green band trailer that is advertised before this movie may not be appropriate for children even if the color is green. The

---

\(^1\)https://ritual.uh.edu/RANLP2021/
yellow band is designed for trailers advertised on the internet, and it indicates that the corresponding trailer is suitable for “age-appropriate internet users” as visitors to sites are mainly adults. The last group of trailers are red band trailers; red color indicates the content is only appropriate for a “mature audience” or “restricted audience”.

Since our goal is to design an automated system that is able to predict which movie trailers are not recommended for children, we define only two classes of trailers for the dataset:

1. **Green-band trailers**: this category includes (i) trailers with the message “all audiences”, and (ii) green band trailers with “appropriate audience” whose associated movie is rated as G and PG.

2. **Red-band trailers**: all red-band trailers, these include restricted and mature audiences (not appropriate for children).

We also extracted separate audio files and trailer subtitles. Subtitles include narrator and actor speech. Some of the YouTube trailers include the video subtitle. For these cases, we pre-process the subtitles by removing timestamps to keep only words. For trailers that do not include a subtitle file, we use a python speech recognition tool (Zhang) to automatically generate the subtitle from the audio. Our dataset includes 11G of audio streams. For each trailer the audio file is a combination of background music and vocals together, so the duration of audio is the same as the duration of the trailer. The number of total words in all trailer scripts is equal to 1,478,139 (on average, there are 576 words per trailer). Note that 20,783 words of the vocabulary set are unique words. Table 1 shows the statistics of our dataset.

### Methodology

Our goal is to predict the age-suitability rating for movie trailers following the guidelines of the Advertising Administration of MPAA for trailer rating. The problem is formulated as a binary classification task where trailers are labeled as either appropriate for all audiences (green-band trailers) or restricted audiences (red-band trailers). To achieve this goal, the Multi-modal Movie Trailer Rating (MMTR) system is proposed. Within this system, the trailers are modeled as a fusion of three modalities: subtitles, audio, and video of the trailers. We train Recurrent Neural Networks (RNNs) for subtitles and audio, and a combination of Convolutional Neural Networks (CNNs) with LSTM for video, as separate streams in order to extract a representation for each respective modality. Then, we combine all stream representations using a fusion module to take advantage of the cues coming from different modalities. Figure 1 shows the overall design for the system architecture.

Our approach is based on independently identifying the best individual modality model and then combining information from all three monomodal models (subtitle, audio, and video) through one of the following three fusion methods: (i) Gated Multi-modal Unit (GMU) (Arevalo et al., 2017), (ii) Feature Concatenation Fusion, or (iii) Late Fusion. All modules of the system are described in the following sections.

#### 4.1 Text Stream

The subtitles of the trailers are a rich source of information. They can help in identifying the topic of the video content. Moreover, the presence of specific words in the dialogue can be a strong indicator for some types of sensitive content, while more subtle cues can be inferred from analyzing the entire transcript. To model the information originating from the subtitles, we feed them to the following modules:

**BERT + Long Short-Term Memory (LSTM) with Attention**: We use BERT (Devlin et al., 2018) to leverage the well-known power of transformer-based word representations. The word vectors are then passed to an LSTM layer to model the sequence of the words in order to extract the semantic information of the text. Afterwards, the resulting hidden representation of the LSTM is passed to an attention mechanism (Bahdanau et al., 2014) to find the importance of each word in the dialogue. Even though BERT has seen a series of improvements (RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2019)), our goal in this paper is to present empirical evidence that a multi-modal approach can solve this task with acceptable performance, the specific contextualized embeddings used being of less relevance.

**Emotion Vector**: We expect to observe that
strong negative emotions (fear, anger, sadness) correlate more with red band trailers. Similarly, positive emotions, such as joy, are more correlated with green band trailers. We made this assumption following research by (Shafaei et al., 2019) where they found promising results for using emotions in a movie rating task.

We model emotions with the use of the DeepMoji model (Felbo et al., 2017). This model was trained using 1.2 billion tweets with emojis to understand how language is used to express emotions. Recent work in abusive language detection shows promising results from using DeepMoji (Safi Samghabadi et al., 2019), thus it seems reasonable to expect good results in this task as well. To incorporate this model into our system, the last hidden layer representation of the pretrained model was used to transfer the text to emotional feature vectors. Finally, the emotion vector was concatenated with the output of the attention and the entire vector was passed to a fully connected layer to further fine-tune the joint representation.

4.2 Video Stream

The video modality is a rich source of visual and temporal cues that are useful for analyzing multimedia content. Specifically, in this task, video can help for modeling the objectionable content such as a depiction of nudity or bloody scenes and suggestive elements. To this end, in order to learn spatiotemporal video features, a CNN-LSTM model based on the works by (Donahue et al., 2015) and (Yue-Hei Ng et al., 2015) is adopted. Each video is sub-sampled to a fixed number of frames, evenly distributed across its duration to form a visual temporal sequence. The raw RGB frames are used as input to a CNN model. This CNN model produces a feature representation for spatial information within each frame. The output of the final pooling layer of the CNN is passed to an LSTM that models temporal dependencies between frames.

4.3 Audio Stream

The audio of the trailer can help the model to learn the genre and theme of the movie, and as a result, it is a powerful tool to distinguish red-band trailers from green-band ones. For example, horror and thriller movies (that usually include suspenseful music) are less likely to be suited for children. In addition to the music score, the emotion conveyed by the speakers’ tone and pitch can provide relevant cues for rating the trailer. It should be noted that the entire audio is used in our model (the music and dialogue combined). To model the audio, the Mel Frequency Cepstral Coefficients (MFCC) are extracted from the audio stream. MFCCs are one of...
the most common feature representations for audio classification (Andén and Mallat, 2011) and speech recognition tasks (Tiwari, 2010). The entire audio is divided to n chunks, $n \in \{10, 20, 50, 100\}$, then the MFCC feature vector is extracted for each chunk. Moreover, by performing averaging over the MFCC vector in each chunk, a fixed-length representation for the entire audio, regardless of its duration is obtained. The vector is then passed to an LSTM module to model the MFCC variations during the entire video. Lastly, by adding an attention mechanism, the model learns the importance of each audio chunk and feeds the weighted average of LSTM hidden representation to a fully connected layer that helps the model to be fine-tuned for the task.

4.4 Fusion

The goal of the fusion module is to learn to predict the rating of the trailer by integrating evidence from the video, audio and text modalities. We evaluate three established fusion methods in order to form a unified representation for each trailer.

Gated Multi-modal Unit (GMU): The GMU allows the model to learn an intermediate representation by combining the different modalities, where the gate neurons learn to decide the contribution of each modality to the intermediate representation. A great advantage of the GMU model is its ability to adjust the activation from each modality depending on the specific instance. This method is inspired by control flow in recurrent architectures. In RNN models, the recurrent units decide how much the current and previous evidence engage in building the current state. In GMUs, the activation function for building the output using different modalities is measured, in order to form a unified intermediate representation for all modalities.

The original GMU was successfully applied to a movie dataset of plot synopsis and movie posters to predict genre. In the original paper, the authors implemented a bimodal system (the equation is provided in the Appendix). We follow their formulation to extend the model to include three modalities using the straightforward approach discussed in their paper. The exact formulation is shown in Equation 1; where $W_i$, $Y_i$ are learnable parameters, $x_i$ is the feature vector for modality $i$ and $[.,.]$ stands for concatenation.

$$h_1 = \tanh(W_1x_1)$$
$$h_2 = \tanh(W_2x_2)$$
$$h_3 = \tanh(W_3x_3)$$
$$z_1 = \sigma(Y_1,[x_1,x_2,x_3]) \quad (1)$$
$$z_2 = \sigma(Y_2,[x_1,x_2,x_3])$$
$$z_3 = \sigma(Y_3,[x_1,x_2,x_3])$$
$$h = z_1 * h_1 + z_2 * h_2 + z_3 * h_3$$

Feature Concatenation Fusion: One popular fusion method is generating a joint multi-modal representation through feature concatenation (Baltrušaitis et al., 2018) where the representation vectors of each modality are concatenated, and the unified representation is passed through multiple hidden layers or used directly for the prediction.

Late Fusion: Another vastly used fusion method is late fusion (Fu et al., 2015). In late fusion, different modalities are merged in the decision level using various rules (e.g., majority voting, averaging) (Baltrušaitis et al., 2018). Here, the average of all modality outputs is calculated and used as the final output.

Before performing either feature concatenation or GMU based fusion, information from each modality is represented with a feature vector extracted from pretrained models, acting as modality streams. Then, we transform the vectors from all modalities into a single vector using the GMU or concatenation module. Finally, we pass the fused representation to a fully connected layer, creating a vector of size two (we have two classes). The sigmoid function is then applied to the two-dimensional vector to assign a label to each trailer. For late fusion, we capture the output of each single modality model before the sigmoid function (vectors of size two) and compute the average. Lastly, we pass the single representation to a sigmoid function for the classification.

5 Experiments

The goal of this section is to demonstrate that a multi-modal approach is an effective way to solve the task. We, therefore, compare the prediction performance of single modality models against all multimodal variations of the system.

As mentioned in the dataset section, the MM-Trailer dataset is imbalanced. Thus, to obtain reliable results, 5 fold cross-validation was selected as an evaluation method. In each fold, we select 10%
of the train sent as the validation set to obtain the best model. It should be noted that the dataset was split using the stratified approach, so as to ensure that each set has the same proportion of examples from each class. The metric used to evaluate the performance is the weighted F1 score, averaged over all 5 folds for each experiment.

5.1 Baseline Methods

Most Frequent Baseline: The first baseline is a naive approach to show that the problem is not easy to solve. In this model, we assign the most frequent class to all the instances in the validation and test sets, and we measure the F1 score by considering the ground truth label.

Text Baseline - Traditional Machine Learning: For the text baseline model, we provide a traditional machine learning method with hand-crafted features. We extract unigram and bigram features from subtitles and apply term frequency-inverse document frequency (TF-IDF) as the weighting scheme. Then, the feature vectors are passed to an SVM model for classification. We chose an SVM model as it performed well on the similar task of violence detection (Martinez et al., 2019).

Text Baseline - BERT + Attention + NRC: A popular resource to extract the emotion in the text is the NRC emotion lexicon (Mohammad, 2011). This dictionary maps words to eight different emotions (anger, anticipation, joy, trust, disgust, sadness, surprise, and fear) and two sentiments (positive and negative). Using this dictionary, we compute the normalized count of words per emotion over the entire subtitle and create a vector of size 10 for each trailer. We use this vector as an alternative to DeepMoji vector in the model.

Text Baseline - DeepMoji + fully connected layer: To show how much emotion by itself can contribute to the prediction of rating, we only use the DeepMoji vector as the input and pass it to a fully connected layer and sigmoid classifier for the prediction.

Video Baseline: Our video baseline is based on the deep 3-dimensional convolutional network (3D CNN) architecture proposed by (Tran et al., 2015). The 3D-CNN architecture applies 3D convolution and 3D pooling operations on video volumes instead of images. Each video is sub-sampled to an 18 evenly distributed frames that are used as input to the model. The training was performed for 50 epochs, using a 0.5 dropout rate, with a learning rate of $10^{-5}$ and a batch size of eight samples.

Audio Baseline: CNNs have shown promising results for audio classification (Hershey et al., 2017). To this end, for each full video, the log-Mel spectrogram is extracted from the audio using the LibROSA python library (McFee et al., 2015) and then used as input to a CNN architecture. For the log-Mel spectrograms 128 Mel-spaced frequency bins were used, while for the CNN model for this baseline, Inception V3 was adopted. The CNN model was trained for 100 epochs using a batch size of 64 samples and a learning rate of $10^{-5}$. An early stopping policy was used during training to avoid over-fitting.

6 Results

Table 2 summarizes the results of our experiments. To examine the contribution of each modality for the rating task, we report the results for all single modality models; Audio only Model (A-MFCC), Text only Model with DeepMoji (T-BAD), and Video only Model (V-CNN/LSTM). As expected, our experimental results confirm that by leveraging all modalities we achieve a better result. As noted in Table 2 the highest weighted F1 score, 86.06%, is achieved by the GMU Fusion variant of the MMTR model with all modalities. This result improves the weighted F1-score of the best single modality model (T-BAD) over 3 percentage points ($P < 0.05$ based on t-test).

We also report the result for different combinations of two modalities using all fusion methods to show the effect of engaging all modalities (T-BAD + A-MFCC, T-BAD + V-CNN/LSTM, A-MFCC +V-CNN/LSTM, T-BAD + A-MFCC + V-CNN/LSTM). Based on the results, the combination of two modalities works better than every single modality, yet not as good as the combination of all modalities.

When comparing the different fusion approaches, we can see that GMU fusion outperforms the concatenation fusion systems. We speculate that the gains from GMU come from the ability of the gated unit to dynamically adapt the contribution of each modality to the intermediate representation. Statistical significance testing using t-test, demonstrated a significant difference between GMU and feature concatenation fusion ($p−value < 0.05$). However, the test does not confirm a significant difference.
Table 2: Evaluation of the different variants of the MMTR system and other baselines using the MM-Trailer dataset. WF stands for weighted F1 score and results are averaged over 5 folds. A '*' indicates that the difference between the two classifiers’ performance is shown to be statistically significant.

between late fusion and GMU. Thus, we can claim that for the trailer age-suitability problem, late fusion can generalize as good as GMU fusion.

The results for T-BAD and T-BA indicate that DeepMoji is a relevant feature for the rating task, and it helps the model to better discriminate red-band trailers from green-band ones. However, the result of DeepMoji+FC shows that the DeepMoji model is not sufficient to solve the task.

To obtain a better understanding of fusion results, we also provide other evaluation metrics using the MMTR system variant with GMU Fusion in Table 3 (as GMU version is the winner approach based on the result table). Based on the detailed result, most of the incorrectly predicted instances are red-band trailers. The first potential explanation behind this observation is that there are fewer instances of red-band trailers in our training set compared to green-band. As a result, it is more difficult for the model to capture all patterns in this class. The second reason may be the diversity of video content in red-band trailers. Recall that this class covers any content that is not appropriate for children.

It is thus reasonable to assume that this class is more heterogeneous than the green band class. We plan to explore the possibility of a fine-grained classification of objectionable content as the next steps in this work.

7 Discussion

To analyze the weaknesses and strengths of the MMTR system, we first investigate the incorrectly predicted cases using the most effective version of the system (GMU Fusion) on each fold of the data. By averaging results over all folds, about 35% of incorrectly predicted cases with the MMTR system are also incorrectly predicted by each and every modality independently, fusion is thus unlikely to help in this case. We found that in about 50% of the instances where two modalities predict the wrong rating, the MMTR system justifiably trusts the single modality that is correct. In about 93% of the cases where only one modality is wrong, the MMTR GMU Fusion variant predicts the correct label, relying on the other two modalities.

After averaging results among all folds, we no-
that the MMTR GMU Fusion variant system is not able to predict about 38 out of 294 instances per fold. We watched 40 incorrectly classified trailers (selected across all folds) to analyze why the model is not able to successfully predict the label. We introduce the following hypothesis for each of the individual modalities:

1) **Text Modality:** One main source of errors in text modality comes from the output of the speech recognition tool. First, the free version of the tool only works on short audio files. As a result, we split the whole audio to 10-second chunks. Thus, it is possible that we miss some words if the audio is cut off in the middle of the word. Also, low-quality audio impacts the word recognition rate of the automatic speech recognition system, which in turn cause the model not to recognize the specific bad words present in the video or the other way around, generate bad words by mistake (detect “please” as “pussy”). However, in some cases, the trailer either has very little speech (less than 10 words) or there is really no sensitive content in the language used. Not surprisingly, the text modality cannot work properly. Finally, in some green band videos, we observed that the trailer subtitles have the words “gun” and “shot”, thus they are predicted incorrectly by the text modality. It seems that the text model is biased against the occurrence of these words that are presumably strongly correlated with violent content.

2) **Video Modality:** One main reason that the video modality model misses the sensitive content may relate to the video sampling rate. The inappropriate/violent scenes in these trailers disappear fast, or they may appear with a low frequency. As a result, we may miss them during sampling the frames in our model. The second potential reason is the quality of the trailers. We recognized that some of the trailers are old or are available in small files, so the frames are blurry, and even in some cases, not very clear to the human viewer. Lastly, we found out, there are some green-band trailers that still include brief sensitive content like the depiction of guns and blood, and our video modality model predicts them as red-band. These instances are mostly the R-rated movies that are sanitized for the trailer. However, the theme of the movie reflects itself in some frames. We can conclude that sometimes a single rating is not sufficient for expressing the type of the content, and as future work, we can predict a list of sensitive material in the video instead of a single label.

3) **Audio Modality:** In some cases, the music of the trailer is not compatible with the content. For example, we encountered musical movies with a high level of violence, but with smooth jazz music. Thus, it is difficult for the audio modality to distinguish between appropriate and inappropriate content. Moreover, in audio modality (similarly to the video modality), we capture samples from the continuous stream. Hence, if the intense audio (such as a scream or a gunshot) happens in a short period, our model may miss that.

We also investigated the genre of incorrectly predicted trailers in one of the data folds. The interesting point is that, for incorrectly classified red-band trailers, 55% are categorized as “Thriller” or “Horror” movies and 30% as “Comedy” (based on IMDB metadata). We do not incorporate metadata into our model to make the model suitable for any kind of online content. This observation shows that the genre of the movie can be a potential feature for the model if we have metadata available.

**8 Conclusion**

In this paper, we present a deep learning system named MMTR for automating the task of movie trailer age-suitability rating. MMTR fuses information from the video, audio, and text modalities. We also introduce a new data set to support research in this area. This dataset contains movie trailer videos along with their rating and metadata. The results of comparing our model with strong baselines demonstrated that the task is not easy, and a complicated multi-modal systems (GMU and late fusion) can achieve performance gains compared to other baselines. Beyond the practical use of a binary classification system, we are interested to move to the more challenging task of detecting the type of objectionable content and introducing explainability elements within the MMTR System.

A Appendices

A.1 Implementation Details

This section discusses how the different streams of the MMTR system were implemented. For all experiments, we used the ADAM optimizer and the Cross-Entropy Loss function. Hyperparameter values were selected using manual tuning of the model using the best value of the weighted F1 Score for the validation partition, as the criterion.

Text Stream: For the BERT model we used the implementation provided by (Wolf et al., 2019). The LSTM layer consisted of 256 RNN units. Training was performed for 50 epochs, using a 0.3 dropout rate, with a learning rate of $10^{-5}$ and a batch size of eight samples.

Video Stream: For each movie trailer, frames were extracted with a rate of one frame per second, from which 18 evenly distributed frames were used to represent each video within the model. For the CNN feature extractor, we used the Inception V3 architecture pre-trained with ImageNet (Russakovsky et al., 2015). The model was trained using a learning rate of $10^{-5}$ and a batch size of 64 samples and by using an early stopping policy to avoid overfitting.

Audio Stream: For each trailer, the audio was split in 20 chunks. For the LSTM layer 256 RNN units were used. Training was performed for 50 epochs, using a 0.1 dropout rate, with a learning rate of $10^{-5}$ and a batch size of eight samples.

System Specifications: All models were developed using the Tensorflow (Abadi et al., 2015), Keras (Chollet et al., 2015) and PyTorch (Paszke et al., 2019) libraries on a machine with Ubuntu 14.04 LTS as the operating system. The system had an Intel Core™ i7 CPU running at 2.67GHz with four cores and 8 GB RAM memory. The video card used was a GeForce GTX 1080 Ti.

A.2 The GMU model:

The original equation of the GMU is represented in Equation 2; where $W_v$, $W_t$, and $W_z$ are learnable parameters, $x_v$ and $x_t$ are modality feature vectors and $[., .]$ stands for concatenation.

$$
h_v = \tanh(W_v x_v), h_t = \tanh(W_t x_t) 
$$

$$
z = \sigma(W_z [x_v, x_t]) 
$$

$$
h = z \ast h_v + (1 - z) \ast h_t
$$

Note that in the extension to more than two modalities, the model ends up having more parameters as the the gates are no longer tied. But as shown empirically, this does not seem to be a problem for the model.
A Domain-Independent Holistic Approach to Deception Detection

Abstract

The deception in the text can be of different forms in different domains, including fake news, rumor tweets, and spam emails. Irrespective of the domain, the main intent of the deceptive text is to deceive the reader. Although domain-specific deception detection exists, domain-independent deception detection can provide a holistic picture, which can be crucial to understand how deception occurs in the text. In this paper, we detect deception in a domain-independent setting using deep learning architectures. Our method outperforms the State-of-the-Art (SOTA) performance of most benchmark datasets with an overall accuracy of 93.42% and F1-Score of 93.22%. The domain-independent training allows us to capture subtler nuances of deceptive writing style. Furthermore, we analyze how much in-domain data may be helpful to accurately detect deception, especially for the cases where data may not be readily available to train. Our results and analysis indicate that there may be a universal pattern of deception lying in-between the text independent of the domain, which can create a novel area of research and open up new avenues in the field of deception detection.

1 Introduction

In the current era of the flood of information, deception has become an undeniable event, causing a financial or political catastrophe and even the loss of human lives. Often, we do not have the necessary resources to validate a tweet or a catchy social media forwarded news link. Our idea is to capture the writing style hidden “between-the-lines”, intended to deceive the reader. The deception can be in the form of any textual stream and on any topic. So, our objective is to find a holistic model that can leverage thousands of textual resources and find a learning architecture to decode the deception.

Adopting the definition of Deception from Burgoon and Buller, we define Deceptive Text as any textual content that aims to misconstrue an affair in a deliberate way causing the reader at a disadvantage either directly or indirectly (Burgoon and Buller, 1994). Deceptive text can be of various forms. For example, in the news and public media domain, the deceptive text is known as Fake News. In social media, a deceptive text can happen in the form of a rumor. Spam or a phishing email is treated as deceptive content in the personal mail or messaging domain. Each domain’s deceptive text has distinct ways to deceive the reader. While fake news can spread falsified propaganda, spam or phishing email can be used for merely monetary gain. Therefore, the ways of formulating a deceptive text can have significant variations. Notwithstanding, all deceptive texts share a common goal of tricking the reader and thus, a general deception pattern should exist in these texts. Unraveling the pattern can play a pivotal role to provide a holistic view of deception, which in-turn can bolster the deception-detection. However, Gröndahl and Asokan indicated that existing works fail to generalize the deception across different domains (Gröndahl and Asokan, 2019). In this work, we hypothesize that— (H1) A deep learning architecture trained on a generalized deceptive-writing setting (both in-domain and out-of-domain data) can better understand the underlying general pattern of deception than using the in-domain data only.

On the rise of a fairly new event, we may not have data available to detect deceptive text floating around social and mass media, especially the labeled data for supervised training. Such occasions pose a unique challenge to stop the spread of misinformation. A holistic deception detection system can come in handy in such situations. For example, although the pandemic was as ancient as human civilization, in the age of massive data availability,
COVID-19 becomes a new event, and misinformation caused by this event can be hard to battle. Therefore, we hypothesize that (H2) A generalized dataset can be helpful to detect deception in a new event, even when little or no in-domain data is available. To test our two hypotheses, we train and fine-tune a BERT model, SBERT model, and character-level-CNN model (Devlin et al., 2019; Reimers and Gurevych, 2020). We further investigate the intermediate-layer learning mechanism using t-SNE visualization and attention-weight analysis.

Researchers worked meticulously to model deception on different domains, but a unified approach has not been successful. Hernández-Castañeda et al. suggested a cross-domain approach for a generalized deception-detection model (Hernández-Castañeda et al., 2017). Although they claimed to build a domain-independent system, their choice of the datasets, namely DeRev, OpSpam, and Opinion (a dataset where the participants were told to lie about their opinion about selected topics), are of the type opinion-only. Moreover, the Opinion dataset can hardly be treated as deceptive. That is because when people are told to lie about an opinion, the lie may not have the potential of deceiving someone which contradicts our definition of Deception. On the contrary, our choice of datasets have at least three variations of categories – fake news, Twitter rumor, and spam.

Thus, we summarize the main contributions of this paper as–

• Our work is the first to propose a domain-independent holistic approach to detecting deception leveraging available public datasets.
• We quantitatively show that for an unseen event, only a fraction of the total available data can be helpful in successfully detecting the deception.

2 Literature Review

In this research, we aim to detect deceptive content intended to mislead people rather than entertain them. Therefore, the deceptive contents can be viewed as deceptive news, disinformation, cherry-picking, and click-bait (Zhou and Zafarani, 2020). There have been several approaches for manual fact-checking, both in the form of expert-based (Pol, accessed February 2, 2021; gos, accessed February 2, 2021; fac, accessed February 2, 2021) and crowd-sourced (CRE, accessed February 2, 2021). However, given the enormous influx of information, such manual approaches are time-consuming and often biased. Therefore, automated fact-checking came in handy. Based on how users spread the falsified information, researchers adopted following approaches to detect deceptive content: news-cascade, which is a tree-like structure to analyse the propagation in social-media (Ma et al., 2018), and Propagation Graph(Zhou et al., 2019b). However, such approaches are also constrained by the availability of propagation detection resources. Moreover, false information cannot be detected before it spreads out. Additionally, some research tries to detect false news based on the source credibility (Viviani and Pasi, 2017). Nevertheless, the stream of new sources now and then makes the task challenging.

Therefore an AI-based method aiming to detect deception based on the textual content can be handy. Because of the fewer dependencies and availability of content, many researchers worked in that direction. Zhou et al. divided the task into two steps: (i) how well the deceptive news content is captured, and (ii) how well the classification model performs to detect deception (Zhou and Zafarani, 2020). Approaches, such as the Bag of Words (BOW) model, POS tagging, rhetorical relationships, were used as features to detect deceptive news (Bhatt et al., 2018; Zhou et al., 2019a; Zhou and Zafarani, 2020). Nevertheless, we are more interested in the semantics, as the task of deception may lie in between the text. Word level context embeddings, including Continuous Bag of Words (CBOW) and skip-gram models were used to represent text for detecting fake news (Potthast et al., 2017). Along with such representations, several machine learning algorithms are used for classification purposes. Additionally, with the rise of deep learning, Convolutional Neural Network (CNN) and many variants of Recurrent Neural Network (RNN) are used as well (Li et al., 2019; Ajao et al., 2018).

Recently the Bidirectional Encoder Representations from Transformers (BERT) model and its variants have gained enormous popularity due to its pretraining capability (Devlin et al., 2018). Müller et al. proposed COVID-Twitter-BERT (CT-BERT), which is pretrained on COVID-19 related Twitter messages (Müller et al., 2020). Such task-specific BERT model outperforms the generic BERT models in the significant margin in many COVID-
related classification tasks, including AAAI2021 COVID-19 shared challenge of COVID-19 Fake News Detection (Glazkova et al., 2021). A similar fine-tuning approach is used by Liu et al., where they proposed a two-stage approach for short fake news detection. Unlike the original BERT model, they utilized all hidden states to apply the attention mechanism to calculate weights for text representation. Their approach produced a 34% accuracy in the LIAR dataset (Liu et al., 2019). Kaliyar et al. proposed FakeBERT, which uses a CNN model after the BERT embedding layer (Kaliyar et al., 2021).

Although the current deception detection methods work well, the methods are highly dependent on the training of the specific domain. On the contrary, we intend to eliminate dataset-specific training and train our model for the generic deception detection task.

3 Dataset

We curate ten datasets for our analysis. We broadly categorize them as—i) Spam, ii) Fake News, and iii) Rumour. The details of the datasets are described below.

3.1 Email and Text Spam

For the spam datasets, we select two personal-messaging datasets. First, we select SMS Spam collection Dataset from UCI Machine Learning Repository (Almeida et al., 2011). This dataset collection has messages collected from different sources totaling 5,574 messages, of which 4,827 are Hams, and 747 are Spams. We also curated the Enron-Spam datasets, which is a benchmark dataset for email spam collection from six different users (Metsis et al., 2006). There were 15,421 Spam emails and 14,923 Ham emails, totaling 30,344 emails.

3.2 Fake News

For the Fake News datasets, we start by collecting the COVID-19 related fake news. The first one is Constraint@AAAI2021 - COVID19 Fake News Detection in English (Patwa et al., 2021). The data are collected from various social media platforms. The training data has 6,420 texts, validation data has 2,410 texts, and the test data has 2,140 texts. The dataset has overall 52% real and 48% fake news. Another COVID-19 related dataset we use is Zenodo– COVID Fake News Dataset (Banik, 2020). The Zenodo COVID dataset has 10,201 texts, out of which there are 9,733 fake news and only 468 real news.

Next, we collect a dataset of varying unreliability, developed by Rashkin et al., where each text was considered as either a Satire, a Hoax or a Propaganda (Rashkin et al., 2017). Unlike our definition of Deceptive-text, Satire cues the reader of the news being a joke only, and thus, we treat Satire as a non-deceptive text. The Hoax and the Propaganda are meant to misguide people, and therefore, we treat them as Deceptive-text. There are 38,859 texts, of which 24,839 were deceptive texts and 14,020 non-deceptive texts. Additionally, they collected 4,362 data from PolitiFact, which are rated in a 6 pt. scale, namely, True, Mostly-True, Half-True, Mostly-False, False, Pants-on-Fire False. We consider the first three as non-deceptive text, and the last three are deceptive text. The dataset comes with a separate train, test, and a dev set.

Additionally, we use the FakeNewsNet dataset which comes with real and fake news content from PolitiFact and GossipCop (Shu et al., 2018, 2017a,b). In total, there were 23,196 data. The last dataset we use in the Fake News Category is the Liar benchmark dataset (Wang, 2017). Along with the text and the labels, the dataset comes with 12 other metadata. The dataset comes with a separate train, test, and a dev set. In total, the dataset contains 12,791 texts.

3.3 Rumour

We collect the PHEME dataset of rumors and non-rumors, which contains the Twitter rumor and non-rumors during breaking news, namely in the events of Charlie Hebdo, Ferguson, Germanwings, Ottawa Shooting, Sydney Siege (Zubiaga et al., 2016). We treat rumors as deceptive text and non-rumors as non-deceptive text. In total, we have 6,425 texts.

4 Methodology

4.1 Deep Learning Frameworks

4.1.1 Bidirectional Encoder Representations from Transformers (BERT) model

BERT is a pre-trained language representation model proposed by Devlin et al. (Devlin et al., 2019). BERT is trained on a bidirectional setting of context and with the objective of Masked Language Modelling and Next Sentence Prediction. The transfer learning capability of BERT makes it a popular candidate for many NLP tasks, such as sentiment classification, fake news detection, question-
answering. The BERT model consists of several transformer blocks, which are made of attention and feed-forward layers (Vaswani et al., 2017). In this work, we fine-tune the bert-base-uncased version of the BERT model, which consists of twelve transformer blocks. The 768-dimension output vector from the BERT model (position of \([CLS]\) token) is fed to a one-layer fully-connected network for classification. We use the recommended batch size of 16, and other hyperparameters (epoch, hidden-unit, learning-decay-rate) are chosen by cross-validation.

4.1.2 Sentence-BERT
The Sentence-BERT (SBERT) is a modified version of BERT capable of representing semantically meaningful sentence embedding (Reimers and Gurevych, 2019). SBERT is based on siamese and triplet networks for fine-tuning over BERT. It performs a pooling operation (min, max, or mean pooling) on the output of BERT. SBERT has a much faster running time compared to BERT. In our work, we use the pre-trained SBERT model and fine-tune it with two fully-connected hidden layers on top of that. We use cross-validation to choose hyperparameters (hidden units, batch size, and epochs).

4.1.3 Character-level-CNN model
Convolutional Neural Net (CNN) is a popular network of computer vision tasks, and it extends to NLP tasks (Kim, 2014). The Character-Level CNN (Char-CNN) was first proposed by Zhang et al., which is capable of dealing with Out-Of-Vocabulary (OOV) words by focusing on the character-level rather than the word or sentence level (Zhang et al., 2015). The Char-CNN consists of six convolutional layers and three fully-connected layers, followed by a max-pooling layer. We empirically choose the convolution filters to be 256. The fully-connected layer units, batch size, and the dropout rate is chosen by cross-validation.

4.1.4 Ensemble model
There can be two ways to ensemble the DL models—1. Hard Decision and 2. Soft Decision. In Hard Decision, we make the prediction based on the majority voting on a test sample. However, the majority voting can eliminate the effect of a strong probability confidence model by predicting a class even when two of the three models predict a class with weak probability confidence. Therefore, in the Soft Decision ensemble, we take the average softmax probability score of the DL models before the prediction phase. For illustration, let’s assume in a two-class classification setting, the softmax layer output of BERT, SBERT, and Char-CNN is \([b_0, b_1], [s_0, s_1], [c_0, c_1]\) respectively. The ensemble model will have the softmax probability output of, \([b_0 + s_0 + c_0, b_1 + s_1 + c_1]\). In this work, we use the Soft Decision ensemble model.

4.2 Experimental Set-up
We use the dataset-provided test set for Liar, Rashkin-Politifact, and COVID-AAAI datasets for the general holistic deception detection task. For the rest seven datasets, we randomly sample the data into training, validation, and test set as 60%-20%-20% and repeat the experiments for three different splits. We report the average performances of the three splits.

For the new-event holistic deception detection task, we select COVID-19 as a new event and combine the test set of COVID-AAAI and COVID-Zenodo. First, we train only on the out-of-domain eight datasets. Then, we add 20%, 40%, 60%, 80%, and 100% in-domain COVID data along with the out-of-domain datasets for training. We also use 20% of the training data as the validation set. This setup enables us to examine the strength of a holistic model in an unknown or little-known event.

5 Results and Discussion
To test the hypotheses, we divide our experiments in two parts: i) General Holistic Deception Detection and ii) New-Event Deception Detection.

5.1 General Holistic Deception Detection
The idea behind a general holistic deception detection task is to build a generalized system that will be able to detect deception in the text irrespective of the topic or target domain. Being a domain-independent system, the holistic model may have more robustness than the domain-specific model.

From the standalone model performances on Table 1, we can see the varying degree of performance across different datasets. However, in almost every case, BERT outperforms the Char-CNN and SBERT model. With the self-attention mechanism, BERT may better capture the nuances within the text than the Char-CNN model, which can give potential cues to detect deception. Despite being a variant of BERT, the SBERT model may lose some
The superior performance of the BERT model
outperforms the other models. However, current
SOTA accuracy on the COVID-AAAI dataset is
achieved using a COVID-twitter-BERT model,
which was trained on a large corpus of COVID-
related tweets, and outperforms our best model by
3.30% (Glazkova et al., 2020). As explained later,
with the cost of adding more in-domain data, the
performance tends to improve. Thus, we may have
achieved a better score if we would have trained on
more in-domain data.

For the ENRON email spam dataset, our ensemble
model performs the best amongst all the models.
It outperforms the SOTA hybrid network for spam
email detection by 3.70% in F1-Score (Douzi et al.,
2020). Our ensemble model achieves the best accuracy in the
SMS Spam dataset, which outperforms our best model by
0.78% (Almeida et al., 2011).

The soft decision ensemble model does not perform
better on five of the ten datasets than the standalone
datasets. As the ensemble model takes an
average of the softmax decision of the models, a
weak classifier gets an equal weight to a strong
classifier, which in turn may hurt the final decision.
Further investigation may be undertaken to develop
a weighted average ensemble of the models for a
more robust classifier.

The superior performance of the BERT model
information by the fine-tuning and the pooling pro-
cess, which creates further research direction to-
towards fine-tuning the SBERT model for deception
detection. We find the best overall performance for
the ensemble model, with an accuracy of 93.42%,
and an F1-Score of 93.22%. The best performing
standalone model – BERT lags slightly behind that
with an accuracy of 92.72%, and an F1-Score of
92.50%.

For the PHEME dataset, we find the best performing F1-Score in the ensemble model as
82.74%, which is better than the current top scorer
staA-HitPLAN based model (77.4%) (Khoo et al.,
2020). Similarly, for the Liar dataset, the ensemble
model achieves the best performance with an accuracy of 70.72%, and F1-Score of 62.60%, which
performs the other models. However, current
SOTA accuracy on the COVID-AAAI dataset is
achieved using a COVID-twitter-BERT model,
which was trained on a large corpus of COVID-
related tweets, and outperforms our best model by
3.30% (Glazkova et al., 2020). As explained later,
with the cost of adding more in-domain data, the
performance tends to improve. Thus, we may have
achieved a better score if we would have trained on
more in-domain data.

For the ENRON email spam dataset, our ensemble
model performs the best amongst all the models.
It outperforms the SOTA hybrid network for spam
email detection by 3.70% in F1-Score (Douzi et al.,
2020). Our ensemble model achieves the best accuracy in the
SMS Spam dataset, which outperforms our best model by
0.78% (Almeida et al., 2011).

The soft decision ensemble model does not per-
form better on five of the ten datasets than the stand-
alone models. As the ensemble model takes an
average of the softmax decision of the models, a
weak classifier gets an equal weight to a strong
classifier, which in turn may hurt the final decision.
Further investigation may be undertaken to develop
a weighted average ensemble of the models for a
more robust classifier.

The superior performance of the BERT model
information by the fine-tuning and the pooling pro-
cess, which creates further research direction to-
towards fine-tuning the SBERT model for deception
detection. We find the best overall performance for
the ensemble model, with an accuracy of 93.42%,
and an F1-Score of 93.22%. The best performing
standalone model – BERT lags slightly behind that
with an accuracy of 92.72%, and an F1-Score of
92.50%.

For the PHEME dataset, we find the best performing F1-Score in the ensemble model as
82.74%, which is better than the current top scorer
staA-HitPLAN based model (77.4%) (Khoo et al.,
2020). Similarly, for the Liar dataset, the ensemble
model achieves the best performance with an accuracy of 70.72%, and F1-Score of 62.60%, which
outperforms a text-based BERT-CNN architecture
by 5.18% and 1.80% respectively (Upadhayay and
Behzadan, 2020).

The current SOTA F1-Score in FakeNewsNet–
Gossipcop (FNN-Gossipcop) and Politifact (FNN-
Politifact) is 75.50% and 92.80% in F1-Score using
a news and user-comment encoder, and co-attention
network (Shu et al., 2019). However, their experiments differ from ours in the fact that i) they used
the news with at least three user comments, reduc-
ing their sample size by 73% and 60% compared to
the original data size, and ii) besides the news text,
they took user comments into account as well. The
user comments contain crowd opinion, which pro-
vides vital information to detect deceptive content
(Guo et al., 2018; Shu et al., 2019). Nevertheless,
selecting the source with user comments can sig-
nificantly reduce the data space, and thus, we do
not use them.

Our SBERT model performs the best in the
Rashkin-Politifact dataset, which outperforms the
baseline model provided in the paper by 37.46% (Rashkin et al., 2017). Our model performs the best
in the Rashkin-Newsfiles dataset in discriminating
between Satire and Hoax-Propaganda, achieving
an accuracy of 99.43%, and an F1-Score of 99.71%
in the BERT model.

For the COVID datasets, the BERT model out-
performs the SOTA hybrid network for deception
detection by 3.70% in F1-Score (Douzi et al.,
2020). Our ensemble model achieves the best accuracy in the
SMS Spam dataset, which outperforms the
baseline model provided in the paper by 37.46% (Rashkin et al., 2017). Our model performs the best
in the Rashkin-Newsfiles dataset in discriminating
between Satire and Hoax-Propaganda, achieving
an accuracy of 99.43%, and an F1-Score of 99.71%
in the BERT model.
comes from the self-attention layer in the transformer blocks, which is also confirmed by Vashishth et al. (Vashishth et al., 2019). We take the [CLS] token output as the feature vector, and thus the attention heads in each layer for the [CLS] token may have an important impact. We randomly take the deceptive text “if you have bank account or you can open new one then we need you!” into account and visualize the attention weights of [CLS] token. Figure 2 depicts the average attention weights of all attention heads in the final layer. Due to the averaging effect, apart from the [SEP] token, all the words show a close attention weight. However, different attention head focuses on a different part of the text, e.g., we observe that last two attention heads focus on the words ‘have’, ‘account’, ‘open’, ‘need’, and ‘!’, while the third head focuses on the word ‘you’, and “bank”. With a complex mechanism of self-attention and feed-forward network, the BERT model represents the sentence as a 768-D vector, which is used for the downstream deception-detection task.

We analyze the misclassified samples by the best performing standalone model–BERT. In Figure 1, we plot the BERT embeddings using t-SNE. We observe that BERT does not perform well when deceptive and non-deceptive text has overlapping embedding, which indicates a limitation of the textual feature representation by the BERT model. Future research might be undertaken to develop a variant of the BERT model that can better distinguish between deceptive and non-deceptive text.

To further analyze the type of misclassified texts, we randomly select False Positive examples (Not deceptive but predicted to be deceptive).
the name “Trump” has a false positive rate (FPR) of 23.17%, “Obama” has an FPR of 16.18%. On the contrary, the non-political names like “Gates” have an FPR of 2.01%. These findings suggest that the models may suffer from bias towards political names.

Next, we analyze the True Negatives (deceptive, but all our models predicted it to be non-deceptive). We randomly select the following samples:

1. You have received your mobile content. Enjoy
2. Celebrities slam Trump decision to end DACA as ‘callous,’ ‘disgusting,’ and a ‘grave mistake’
3. I’ve been here almost every day.
4. Forty-five percent of doctors say they’ll quit if health care reform passes
5. Says 57 percent of federal spending goes to the military and just 1 percent goes to food and agriculture, including food stamps

From the True-Negative samples, we observe a wide variety of examples that were misclassified to be non-deceptive. For the first sample, the models probably expect more persuasion to detect the deception. The third sample is a statement by the Missouri governor which was a lie. We infer that it may be hard for any model to detect a text as deceptive without proper context. These findings raise intriguing questions regarding the extent of the deceptive text, and for the model to successfully detect deception, maybe the context should be a part of the text.

Therefore, based on the overall analysis, the results of the holistic deception detection task supports H1.

5.2 New-event Deception Detection

The holistic model with a complete set of out-of-domain data and a fraction of in-domain data can perform well enough to detect the deceptive text on a new event like the COVID-19 pandemic. From Figure 3, we observe that BERT, SBERT, and Char-CNN give F1-Score performance of 67.96%, 62.70%, and 52.39% respectively while having no knowledge on the COVID event, which indicates a cold-start (Adomavicius and Tuzhilin, 2005). However, when added with only 20% in-domain COVID training data, the performance improves sharply to 94.50%, 90.38%, and 87.69%, with an average improvement of 29.84%. From that point, we gradually increase the in-domain training data by 20%, and we find the optimal performance by adding 100% in-domain data. Nevertheless, our holistic model achieves 95.40% of optimal performance by only seeing the 20% in-domain training data. Thus, our results support H2.

6 Conclusion and Future Work

This research presents the holistic deception detection technique where we intend to find a domain-independent system to detect deception. Our general holistic approach outperforms some of the benchmark datasets for deception detection, where we observe the superior performance of the BERT model. Additionally, we analyze the strength of our holistic approach in case of a new event like COVID-19. We show that an out-of-domain general training set with a small fraction of the in-domain training set can help achieve satisfactory performance. Based on our work, there can be several directions for further research –

- The BERT and SBERT model work for 512 tokens only. For deception within the long text, models like Longformer, DocBERT can be used (Beltagy et al., 2020; Adhikari et al., 2019).
- It is not clear which part of the text may contain the cues to be a deceptive one. Thus, researchers can investigate to localize deception.
• The current pre-trained models are not free of bias, which we also observe in this work. Further research can be done to avoid the bias.

• The analysis of how deception occurs within the text is still not a clearly studied area. Thus, deceptive text generation can unravel many unexplored areas. Besides, we can investigate certain psycho-linguistic traits like fear, greed, persuasion within the text and quantify these attributes for a stronger holistic deception detection model.

Towards Domain-Generalizable Paraphrase Identification by Avoiding the Shortcut Learning

Abstract

In this paper, we investigate the Domain Generalization (DG) problem for supervised Paraphrase Identification (PI). We observe that the performance of existing PI models deteriorates dramatically when tested in an out-of-distribution (OOD) domain. We conjecture that it is caused by shortcut learning, i.e., these models tend to utilize the cue words that are unique for a particular dataset or domain. To alleviate this issue and enhance the DG ability, we propose a PI framework based on Optimal Transport (OT). Our method forces the network to learn the necessary features for all the words in the input, which alleviates the shortcut learning problem. Experimental results show that our method improves the DG ability for the PI models.

1 Introduction

Paraphrase Identification (PI) is the task of recognizing whether one text is a restatement of another text, preserving the same meaning while adopting a different expression (Bhagat and Hovy, 2013). Neural network based models have been proposed for the supervised PI task, and achieve decent performance in the single-domain setting (Yin and Schütze, 2015; Wang et al., 2017; Yang et al., 2019). At present, the existing PI corpora are restricted to several particular domains (Dolan et al., 2004; Xu et al., 2014; He et al., 2020), while the practical sentence pair for the paraphrase judgment can be from any unlabeled domain. At the same time, building a PI corpus for a novel domain needs massive human effort and is expensive. Therefore, a natural question is: for the supervised models trained in the domains with annotated PI corpora, to what extent can they generalize to an out-of-distribution (OOD) domain?

In this paper, we investigate the multi-source (Blanchard et al., 2011) Domain Generalization (DG) (Wång et al., 2021; Zhou et al., 2021) problem for supervised PI. More specifically, we try to learn a PI model based on information from several annotated source domains, and it could generalize well to an unlabeled domain. We investigate several competitive PI models in the DG setting, and observe that their performance deteriorates dramatically when tested in an OOD domain. We conjecture that the poor performance is caused by the models’ tendency to the shortcut learning (Geirhos et al., 2020). More specifically, these models are prone to relying on the shortcut features, e.g., some cue words, for classification. These shortcut features are often unique in one particular dataset or domain. When tested on an OOD domain, the models’ performance deteriorates because the shortcuts are missing. Interestingly, this phenomenon is also observed in other NLP tasks or models, such as NLI (Gururangan et al., 2018; Du et al., 2021), reading comprehension (Kaushik and Lipton, 2018; Lai et al., 2021), and BERT (Ni- ven and Kao, 2019).

The PI models usually follow the sentence-pair classification paradigm (Lan and Xu, 2018; Devlin et al., 2019). Some models originally proposed for the other sentence pair classification tasks, e.g., Semantic Textual Similarity (STS) or Natural Language Inference (NLI) can be easily adapted to PI. In what follows, we directly apply the suitable models without further clarification. One general characteristic of these models is: they have a component of information aggregation, i.e., the extracted and encoded features are aggregated into one fixed-length vector before computing the loss function. We point out that this step is one cause of the shortcut learning problem. Because in this step, it is not uncontrollable that which features should be preserved or discarded in the aggregated vector. Inspired by this, we conduct a new design for the final network layer of PI models to improve the DG
ability. The motivation of our method is: if we can force the PI model to learn the necessary features for all the input words instead of just relying on the domain-specific shortcuts, then the effects of shortcut learning can be alleviated. To this end, our proposed network layer outputs the importance scores and contextualized representations for all the input words, and adopt the Optimal Transport (OT) (Villani, 2008) distance to decide whether two sentences are paraphrase or not. The resulting PI models can be trained end-to-end, the feature extraction and encoding layers are not affected. In the experiments, the PI data from four different domains are adopted for simulating the DG setting. To validate the effectiveness of our method, we consider two representative PI models and equip them with our proposed module. The evaluation results show that our method improve the OOD domain generalizability of these PI models.

2 Problem Formulation

The PI corpus is usually organized as a set \{((x_i, \bar{x}_i), y_i)\}_{i=1}^N. For each tuple \((x, \bar{x}), y\), \(x\) and \(\bar{x}\) are two input sentences, the label \(y = 1\) indicates that \(x\) and \(\bar{x}\) are the paraphrase while \(y = 0\) denotes the non-paraphrase. The associated domain of this dataset is defined as a joint distribution \(P_{XY}\) on \(\mathcal{X} \times \mathcal{Y}\), where \(\mathcal{X}\) is the space of input sentence pairs\(^1\), and \(\mathcal{Y}\) is the label space. Then the target of a PI model is to learn a function \(f: \mathcal{X} \rightarrow \mathcal{Y}\), which predicts the label \(y\) based on the sentence pair \((x, \bar{x})\).

We adopt the common setting of multi-source DG as in Blanchard et al. (2011). Specifically, assume that we can access a set of \(K(K > 1)\) distinct source domains \(\mathcal{S} = \{S^k\}_{k=1}^K\). Each \(S^k\) is associated with a distinct joint distribution \(P_{\mathcal{X}Y}^k\), i.e., \(P_{\mathcal{X}Y}^k \neq P_{\mathcal{X}Y}^{k'}, \forall k \neq k'\) and \(k, k' \in \{1, \ldots, K\}\).

For \(S^k\), the associated dataset contains i.i.d. data \(\{(x_i^k, \bar{x}_i^k), y_i^k\}_{i=1}^{N_k}\) sampled from \(P_{\mathcal{X}Y}^k\). The target domain denoted as \(\mathcal{T}\) is associated with a joint distribution \(P_{\mathcal{X}Y}^T\), where \(P_{\mathcal{X}Y}^T \neq P_{\mathcal{X}Y}^k, \forall k \in \{1, \ldots, K\}\). Then DG problem for PI is defined as: given the labeled source domains \(\mathcal{S}\), we try to learn a model based on information from \(\mathcal{S}\) such that the model can generalize well to an unseen domain \(\mathcal{T}\). It should be noted that DG is more challenging than the related settings such as domain adaptation (Patel et al., 2015) or transfer learning (Pan and Yang, 2009). The difference primarily lies in that DG cannot access both the feature distribution and the label distribution of the target domain \(\mathcal{T}\), which makes it more practical for real-world applications.

3 Method Description

3.1 Shortcut Learning Problem

Regardless of the implementation differences, most neural models for the supervised learning of PI follow the sentence pair classification paradigm, i.e., the features from two sentences are extracted and encoded into one vector for the classification (Lan and Xu, 2018). For these approaches, the final output representation fuses features from all the input words together, and we conjecture that it is the reason for the poor OOD generalizability. Concretely, these models are prone to the shortcut learning, i.e., utilizing the features from some cue words that are specific to the training domains. In the fused representations of the final output, the model neglects the features from the words that actually decide whether two sentences are paraphrase or not, because the model already makes the correct decision based on the shortcut features. When these shortcuts are missing in the OOD domain, the model performs poorly.

**Dataset**: PARADE (He et al., 2020).

Table 1: Examples of paraphrase and non-paraphrase text pairs, which come from two different domains. We manually annotate the phrase-to-phrase alignment, and the semantically related phrases are annotated with the same superscript. For the sake of brevity, we do not annotate more detailed word-to-word alignment, and some unimportant words such as stop words are not annotated. We use red italic font to denote the words that cannot be suitably aligned.

### 3.2 OT Distance for Measuring the Text Similarity

As a preliminary to our method, we introduce the OT distance first. It provides an explainable approach to measuring the text similarity. Concretely, given two pieces of texts \(x = [w_1, w_2, \ldots, w_m]\) with \(m\) words and \(\bar{x} = [\bar{w}_1, \bar{w}_2, \ldots, \bar{w}_n]\) with \(n\) words, the OT distance between \(x\) and \(\bar{x}\) is defined as:

\[
D_{OT}(x, \bar{x}) = \min_{P \in \Pi(\mu, \tilde{\mu})} \langle P, C \rangle = \min_{P \in \Pi(\mu, \tilde{\mu})} \sum_{i=1}^{m} \sum_{j=1}^{n} c(w_i, \bar{w}_j) \cdot P_{ij}. \tag{1}
\]

Here, \(C\) stands for the cost matrix, whose element \(C_{ij} = c(w_i, \bar{w}_j)\) determines the cost of transporting the word \(w_i\) to the word \(\bar{w}_j\). \(c(w_i, \bar{w}_j)\) is smaller when \(w_i\) and \(\bar{w}_j\) are more semantically similar. The matrix \(P\) is the transport plan, where \(P_{i,j}\) is larger when \(w_i\) and \(\bar{w}_j\) are more closely aligned. \(\Pi(\mu, \tilde{\mu})\) is the set of all the feasible transport plans. \(\langle \cdot, \cdot \rangle\) stands for the Frobenius dot product between two matrices of the same size. The vectors \(\mu = [\mu_1, \ldots, \mu_m]\) and \(\tilde{\mu} = [\tilde{\mu}_1, \ldots, \tilde{\mu}_n]\) satisfy that \(\sum_{i=1}^{m} \mu_i = \sum_{j=1}^{n} \tilde{\mu}_j = 1\), and the element \(\mu_i\) or \(\tilde{\mu}_j\) reflects the relative importance of the corresponding word in the text.

In Figure 1, we give an example of OT distance between two sentences. From this example, we can observe that: by solving the optimization problem in Formula (1), the solution matrix \(P\) explicitly aligns the semantically related words. And the optimal objective value of Problem (1) is the distance of moving sentence \(x\) to sentence \(\bar{x}\).

For the values of vectors \(\mu\) and \(\tilde{\mu}\), different models behave differently. Word Mover’s Distance (WMD) (Kusner et al., 2015) requires that all the words in one text are equally treated, i.e., \(\mu_i = \frac{1}{m} (\forall i, 1 \leq i \leq m)\), and \(\tilde{\mu}_j = \frac{1}{n} (\forall j, 1 \leq j \leq n)\). Yokoi et al. (2020) point out that WMD is not suitable for unsupervised STS, because the importance of each word should be differentiated. They propose Word Rotator’s Distance (WRD) and adopt the norm of the pretrained embedding as the weight of the corresponding word. For the unsupervised methods WMD and WRD, the values of \(\mu\) and \(\tilde{\mu}\) are fixed, and independent of whether the sentence pair \((x, \bar{x})\) is paraphrase or not. However, we claim that they depend on each other in the supervised setting. Consider some examples in Table 1. Since the nature of paraphrase is semantic equivalence, for the paraphrase sentences (e.g., s1 and s2 in Table 1), the unaligned words (e.g., **US researchers** and **the record time**) are unimportant. Conversely, the key to a non-paraphrase is to find the difference in between. For the non-paraphrase sentences (e.g., s3 and s4 in Table 1), the unaligned words (e.g., **problem data** and **coefficients**) are key to make the difference and are
Algorithm 1 Log-domain Sinkhorn algorithm for computing the entropy-regularized OT distance.

Input: $k = 0$, $u^0 = 0_m$, $v^0 = 0_n$, $K$ is the maximum number of iterations allowed.

1: while $k < K$ do
2: $u^{k+1} = u^k + \varepsilon \log(\mu) - \log (R(u^k, v^k)1_n)$. 
3: $v^{k+1} = v^k + \varepsilon \log(\tilde{\mu}) - \log (R(u^{k+1}, v^k)1_m)$. 
4: $k = k + 1$.
5: end while
Output: $P^* = R(u^k, v^k)$.

thus important. Another important issue is the value of $c(w_i, \tilde{w}_j)$. For the unsupervised methods such as WMD and WRD, the value of $c(w_i, \tilde{w}_j)$ is fixed. It is usually computed based on the pretrained embeddings of the corresponding words. However, this practice lacks flexibility when representing the word relatedness in the supervised setting. The contextualized word representations should be adopted.

3.3 Domain-Generalizable PI via OT layer

The analysis in Section 3.1 indicates that the shortcut learning problem is caused by the aggregated representation in the classifier layer, which is adopted by most existing PI models. To make the PI models more domain-generalizable, we change the output layer of the network to memorize the necessary features of all the words during the in-domain training. The analysis in Section 3.2 suggests that the values of $\mu$, $\tilde{\mu}$, and $C$ should be adaptive in the supervised setting of PI. At the same time, these values are all specific to individual word. Therefore, we parameterize the word importance vectors and the contextualized word embeddings as the learnable outputs of a neural network. The neural network is trained so that the OT distance $D_{OT}(x, \tilde{x})$ is minimized for the paraphrase, while is maximized for the non-paraphrase:

$$
\begin{align*}
\begin{cases}
\min \ D_{OT}(x, \tilde{x}) & \text{if } y = 1; \\
\max \ D_{OT}(x, \tilde{x}) & \text{if } y = 0.
\end{cases}
\end{align*}
$$

(2)

In this way, we force the network to memorize representations for each individual word, instead of learning a fused representation. And we expect the shortcut learning problem can be alleviated. For the practical usage, we adopt the following regression based objective:

$$
\min_{\theta} \frac{1}{N} \sum_{i=1}^{N} \left\{ (\exp(-D_{OT}(x_i, \tilde{x}_i)) - y_i)^2 \right\},
$$

(3)

where $\theta$ denotes the network parameters. The objective in Formula (3) is mathematically equivalent to the objective in Formula (2), but is more numerically stable. Following the practice as in Chen et al. (2019, 2020), we compute the value of cost $c(w_i, \tilde{w}_j)$ as the cosine distance between the corresponding contextualized word representations. We name our method as Domain Generalizable Optimal Transport (DG-OT) layer. Except the final output layer, the preceding layers of PI models can be unchanged. In Figure 2, we present the architecture of decomposable attention model (Parikh et al., 2016) when equipped with our proposed DG-OT layer.

3.4 Computing the OT Distance

To incorporate the OT distance into neural networks, we adopt the practice in (Cuturi, 2013; Frognier et al., 2015) and solve the following entropy-regularized OT problem:

$$
\min_{P \in \mathcal{P}([\mu, \tilde{\mu}])} \langle P, C \rangle - \varepsilon H(P).
$$

(4)

Here, $H(P)$ is the entropy regularization term defined as: $H(P) = -\sum_{i,j} P_{ij} \log(P_{ij}) - 1$. $\varepsilon$ is a positive hyper-parameter for controlling its relative importance. When the value of $\varepsilon$ is small enough, Problem (4) is a good approximation of original OT distance in Formula (1). In this paper, we utilize the Sinkhorn algorithm in the log domain (Chizat et al., 2018; Schmitzer, 2019) to solve Problem (4). The details are presented in Algorithm 1, in which the function $R(u, v)$ is defined as: $R(u, v) = diag(\exp(\frac{u}{\varepsilon})) \exp(\frac{-v}{\varepsilon}) diag(\exp(\frac{u}{\varepsilon}))$. After computing the entropy-regularized OT distance between $x_i$ and $\tilde{x}_i$ with Algorithm 1, we substitute $D_{OT}(x_i, \tilde{x}_i)$ in Formula (3) with the objective value of Problem (4). The resulting OT classifier layer is fully differentiable, and the whole PI model can be trained in an end-to-end way.
Compute OT distance

Table 2: Statistics of the processed PI datasets. The symbol + indicates the paraphrase sentence pairs, while the symbol - indicates the non-paraphrase sentence pairs.

4 Experiment

4.1 Datasets and Settings

We consider four publicly available PI datasets from different domains for the experiment:

- **Microsoft Research Paraphrase Corpus (MRPC)** (Dolan et al., 2004), which contains sentence pairs from news articles.
- **Paraphrase Identification from Twitter (PIT-2015)** (Xu et al., 2014), which contains pairs of Twitter tweets.
- **Quora Question Pairs (QQP)**, which contains Quora question pairs.
- **PARAphrase identification based on Domain knowledge (PARADE)** (He et al., 2020), which contains definitions of terminologies from the domain of computer science.

To simulate the DG setting, we use three datasets for the in-domain training, and use the remaining one dataset for evaluating the OOD generalization ability. During the in-domain training stage, the validation set is merged from three in-domain validation sets. We also conduct the in-domain testing for the purpose of comparison, where the in-domain testing set is merged from three in-domain testing sets. To prevent the PI models from being dominated by one or several particular domains, we process the datasets so that each domain has relatively the same number of sentence pairs. Because the original splittings of these four datasets differ, and it is hard to directly sample training/validation/testing sets and ensure they are of comparative and relatively-large size over different domains. Therefore, for each
dataset, we merged the original splittings of training/validation/testing sets together, and randomly sample the new training/validation/testing sets. We conduct sampling without replacement. The statistics of the processed datasets are described in Table 2. Following the previous works, we adopt accuracy and F1 score as the evaluation metric.

### 4.2 Baselines

We adopt the following models for the experiment:

- **DECATT** (Parikh et al., 2016), a decomposable attention model. We change the original three-way classification to two-way classification.

- **BiMPM** (Wang et al., 2017), a bilateral multi-perspective matching model.

For these models, we adopt and adapt the implementations in AllenNLP-Models\(^3\). To validate the effectiveness of DG-OT layer, we equip these two models with DG-OT layer, and compare them with their vanilla versions. To be fair, the shared network structures have the same size. **DECATT** should be compared with **DECATT+DG-OT**, and **BiMPM** should be compared with **BiMPM+DG-OT**, when the other settings are the same. For all the methods, we adopt GloVe (Global Vectors for Word Representation)\(^4\) to initialize the word embeddings. The hyper-parameters are tuned based on the performance in terms of F1 on the validation set.

### 4.3 Results

The results of in-domain testing and OOD generalization are reported in Table 3, from which we can draw the following conclusions:

- When other conditions are the same, the OOD performance is poorer than the in-domain performance, which agrees with the common expectation. The reason is the underlying data distributions are different.

- In the same setting, the performance of BiMPM is generally better than that of DECATT. It suggests that BiMPM is more suitable for the PI task in the setting of multi-domain training.

- When equipped with DG-OT, both the performance of DECATT and BiMPM are improved obviously in both the in-domain and OOD setting. And the performance dropping brought by OOD domain is less obvious when DG-OT is equipped by the model. These results validate that DG-OT helps to avoid the shortcut learning.

### 5 Conclusions and Future Works

As a preliminary attempt in this direction, we investigate the DG problem for supervised PI task in this paper. We point out that the aggregation operation is one reason for the poor OOD generalization ability of the existing PI models. We incorporate the Optimal Transport (OT) distance and design a novel classifier layer, i.e., DG-OT layer. It tackles the shortcut learning problem by enforce the network to learn the importance weights and contextualized representations for all the words. The experiments validate the effectiveness of DG-OT layer. Avoiding the shortcut learning is only one factor to the DG ability of PI models. Another important aspect is how to handle the domain shift, which is left as our future work. Besides, sentence pair classification include other tasks such as STS and NLI. It is still unclear whether our method is suitable for STS and NLI, and we leave this topic as the future work.

Abstract

This paper describes the training process of the first Czech monolingual language representation models based on BERT and ALBERT architectures. We pre-train our models on more than 340K of sentences, which is 50 times more than multilingual models that include Czech data. We outperform the multilingual models on 9 out of 11 datasets. In addition, we establish the new state-of-the-art results on nine datasets. At the end, we discuss properties of monolingual and multilingual models based upon our results. We publish all the pre-trained and fine-tuned models freely for the research community.

1 Introduction

Transfer learning and pre-trained word embeddings became a crucial component for most Natural Language Processing (NLP) models. Contextualized methods (McCann et al., 2017; Peters et al., 2018; Howard and Ruder, 2018) overcame the initial context insensitive word embeddings approaches (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017). (McCann et al., 2017; Peters et al., 2018). The word representations generated by the named methods are usually used as input features for other task-specific models that are further trained. Starting with the BERT (Devlin et al., 2018), the BERT-like models (Lan et al., 2020; Liu et al.; Sanh et al., 2019; Yang et al., 2019) based on Transformer architecture (Vaswani et al., 2017), achieved a significant performance improvement in many NLP tasks (Raffel et al., 2019). These recent models are trained on a language model task or tasks that are closely related to it. Such pre-training allows them to capture the general representation of language and text. The pre-trained models are then directly fine-tuned with specific data for a selected downstream task. The performance improvement of these models is paid by the vastly increased requirements (i.e., data and computational resources) for their training.

The mentioned models are primarily trained for English. Recently, models for other, mostly larger, languages have been released, e.g., French (Martin et al., 2020; Le et al., 2019), Polish (Kleczyk, 2020), Turkish (Schweter, 2020), Russian, German, Arabic (Safaya et al., 2020), but also for languages that are spoken by a relatively small number of people, i.e., Romanian (Dumitrescu et al., 2020), Dutch (Vries et al., 2019) or Finish (Virtanen et al., 2019). There were also introduced multilingual models (Conneau and Lample, 2019; Conneau et al., 2020), that can be used for multiple languages at once but usually at the cost of lower performance in comparison to solely monolingual models (Martin et al., 2020; Virtanen et al., 2019; Dumitrescu et al., 2020) as we show in this paper.

Our main motivation is to train and provide publicly available models for the Czech language that performs better than available multilingual models.

In this paper, we describe a process of training of two BERT-like models for Czech language and their evaluation on six tasks along with a comparison to two multilingual models, i.e. mBERT (Devlin et al., 2018) and SlavicBERT (Arkhipov et al., 2019). More concretely, the architectures of our models are based on the ALBERT (Lan et al., 2020) model (Czert-A) and the original BERT (Devlin et al., 2018) model (Czert-B). Both of our models are trained on a text corpus of the approximate size of 36 GB of plain text consisting of Czech Wikipedia articles, crawled Czech news and Czech

1http://docs.deeppavlov.ai/en/master/features/models/bert.html
2https://github.com/dbmdz/berts
3The model is available at https://github.com/kiv-air/Czert
National Corpus (Křen et al., 2016). We train the models from scratch (i.e., with random initialization) using Masked Language Model (MLM) and Next Sentence Prediction (NSP) tasks as training objectives with a slight modification of the NSP task, see Section 3. We evaluate our models on six tasks: Semantic Text Similarity (STS), Named Entity Recognition (NER), Morphological Tagging (MoT), Semantic Role Labeling (SRL), Sentiment Classification (SC) and Multi-label Document Classification (MLC).

Our main contributions are the following ones: 1) We release a pre-trained and ready-to-use BERT model (Czert-B) for the Czech language that outperforms the compared models on all evaluated sentence-level tasks and it performs comparably on Semantic Role Labeling task. Along with the pre-trained model, we also release the fine-tuned models for each task. 2) We achieve new state-of-the-art results on seven datasets. Moreover we outperform the multilingual models with our newly trained Czert-B model on 7 out of 10 datasets.

2 Related Work

2.1 English BERT and ALBERT

The BERT (Devlin et al., 2018) model adopts the multi-layer Transformer-encoder architecture (Vaswani et al., 2017) with two pre-training tasks: Masked Language Modeling and Next Sentence Prediction.

The goal of the MLM task is to recover artificially distorted sentences where some of the original tokens are masked out (hidden), and some are randomly replaced with other tokens. These distorted tokens and few other unchanged tokens are selected for prediction (classification). The ratios of predicted tokens can be tuned. For example, in the original BERT model, 15% of input tokens are predicted, 80% of them are masked out, 10% are changed randomly, and 10% are left intact.

The NSP is a binary classification task of sentence pairs. For two sentences A and B taken from the training corpus, the goal is to decide whether the sentence B is the actual next sentence (following the sentence A) or whether it is a randomly selected sentence from the corpus. In the BERT paper (Devlin et al., 2018), the random sentences are sampled uniformly from the whole corpus.

The BERT model represents a big step in massively pre-trained models. The experiments\(^5\) show that a large stack of cross-attention layers with a huge amount of parameters of BERT and BERT-like models can significantly boost the performance of many downstream tasks. A relatively short fine-tuning phase is usually sufficient to set new state-of-the-art results in many tasks using the pre-trained model.

In the original paper (Devlin et al., 2018), the authors publish the BERT\textsubscript{BASE} and BERT\textsubscript{LARGE} models. BERT\textsubscript{BASE} contains 12 layers, 12 attention heads, and the size of the hidden state is set to 768. In total, it requires 110M parameters. The BERT\textsubscript{LARGE} model has 24 layers, 16 attention heads and the size of the hidden state is set to 1024, which results in 340M parameters.

Training such huge models requires vast computational resources. Therefore, researchers developed methods to reduce the training complexity, memory demands or prediction time, while maintaining similar performance on the fine-tuned tasks. ALBERT model (Lan et al., 2020) represents an example of such an approach.

ALBERT slightly modifies BERT to use the parameters more effectively. First, the authors argue that word embedding size equal to the hidden size (768 for base) is unnecessarily large. They propose to use a smaller size (128) and project the embeddings to the hidden size, which significantly reduces the number of parameters (25M less than in the base variant). Another modification is in cross-layer parameter sharing. In ALBERT, all the weights are shared across all the layers. Another modification consists of replacing the NSP task with a harder task of sentence ordering prediction (SOP). That should result in making the model understand semantics better. The authors introduce models ALBERT\textsubscript{BASE}, ALBERT\textsubscript{LARGE}, ALBERT\textsubscript{XLARGE}, ALBERT\textsubscript{XXLARGE} with 12M, 18M, 60M and 235M parameters, see Table 1.

2.2 BERT-like Models for Other Languages

Researchers publish a multilingual variant of standard BERT\textsubscript{BASE} model (mBERT)\(^6\). It is jointly trained on Wikipedia pages of 104 languages. The model settings are almost the same as in

\(^{5}\)Experiments in the BERT paper (Devlin et al., 2018) or in many consequent research papers.

\(^{6}\)See https://github.com/google-research/bert/blob/master/multilingual.md.
BERT\textsubscript{BASE}; it differs only in the vocabulary size\textsuperscript{7}.

However, researchers around the world trained the monolingual variant of the BERT and showed the domination of the monolingual version over the mBERT in many tasks, for example, French (Martin et al., 2020), Finish (Virtanen et al., 2019) or Romanian (Dumitrescu et al., 2020).

Arkhipov et al. (2019) used a combination of four Slavic languages: Bulgarian, Czech, Polish, and Russian. They trained their model using Wikipedia dumps for all four languages and a huge set of Russian news texts. They use the same model architecture and training process as mBERT, and they initialized the model with mBERT weights. Table 1 shows the sizes of each corpus in terms of quantities of raw text data, pre-process them and prepare automatically labeled training data.

Training corpora We use two publicly available corpora and our crawled dataset of Czech news:

- Czech national corpus (CsNat) 28.2GB, (Křen et al., 2016),
- Czech Wikipedia (CsWiki) 0.9GB, dump\textsuperscript{8} from May 2020,
- Crawled of Czech news (CsNews), 7.8GB.

The CsNat corpus composes of randomly-ordered blocks of texts sized maximum size of 100 tokens. Each block contains at least one sentence. This must be considered later for the NSP task, which requires a continuous block of texts. Table 3.1 shows the sizes of each corpus in terms of blocks and sentences counts.

Pre-processing We prepare two versions of the corpus: \textit{cased} and \textit{uncased}. Both versions are tokenized with the WordPiece tokenizer (Wu et al., 2016) which is trained on the entire corpus.

Pre-training Objective We employ MLM and NSP tasks (see section 2.1) for training our model.

The MLM task is used exactly as in the BERT model. The NSP task needs a few considerations. The NSP task requires the availability of continuous blocks of text to form pairs of sentences where one sentence follows the other. At the end of each block, we lose the last sentence that has no sentence to form a pair with. The effect of this issue becomes more apparent with the decreasing length of the continuous text blocks, such as in the case of the CsNat corpus. Here, we observe 5.6 sentences per continuous block on average. That means that we are able to use 4.6 sentences out of 5.6 (i.e. approximately 18% of sentences cannot form a pair). When compared to the two remaining corpora, this number is relatively high. In the CsWiki and CsNews corpora, only 6% and 4%, respectively, of sentences cannot form a pair.

Moreover, we design more difficult negative samples for the NSP task – we select sentences from the same paragraph (that do not directly follow the first sentence) to build non-trivial negative pairs instead of drawing random sentences from the whole corpora as in BERT.

The final dataset consists of 578 158 196 training pairs of sentences. In Table 3.1, we provide some basic statistics of the dataset used in our setup.

3  Pre-training Process
3.1 Dataset Description

Training BERT-like models require to collect large quantities of raw text data, pre-process them and prepare automatically labeled training data.

Training corpora We use two publicly available corpora and our crawled dataset of Czech news:

- Czech national corpus (CsNat) 28.2GB, (Křen et al., 2016),
- Czech Wikipedia (CsWiki) 0.9GB, dump\textsuperscript{8} from May 2020,
- Crawled of Czech news (CsNews), 7.8GB.

The CsNat corpus composes of randomly-ordered blocks of texts sized maximum size of 100 tokens. Each block contains at least one sentence. This must be considered later for the NSP task, which requires a continuous block of texts. Table 3.1 shows the sizes of each corpus in terms of blocks and sentences counts.

Pre-processing We prepare two versions of the corpus: \textit{cased} and \textit{uncased}. Both versions are tokenized with the WordPiece tokenizer (Wu et al., 2016) which is trained on the entire corpus.

\textsuperscript{7}BERT\textsubscript{BASE} uses a vocabulary with 30K sub-word tokens while mBERT increases the size to 120K tokens.

3.2 Models

We train two models: a smaller ALBERT\textsubscript{BASE} model (Czert-A, 12M parameters) and a larger BERT\textsubscript{BASE} model (Czert-B 110M parameters).

Czert-A is very similar to the standard ALBERT\textsubscript{BASE} with a few modifications: we use WordPiece tokenizer, the batch size is set to 2048 (due to cluster limits), and we use our version of NSP introduced in Section 3 instead of SOP.

Czert-B is configured exactly as the BERT\textsubscript{BASE} model with increased batch size to 2048.

Optimization Both models are trained using a learning rate of 1e-4 with the linear decay using...
Adam optimizer (Kingma and Ba, 2014). First, we iterate over the dataset once (single epoch) with the maximum sequence length set to 128. It leads to 300K batches (steps). Similarly to the BERT approach, we then increase the maximum sequence length to 512. We perform about 50K steps with the increased sequence length. In this second shorter iteration, we decrease the batch to 256 samples to fit the cluster memory limits. More details about the computational cluster and its configuration are located in Appendix A.

4 Evaluation

The following section summarizes the performance of Czert on various tasks and compares our model with similar available models. We also add experiments without the pre-training phase to highlight the impact of additional unsupervised data in the Czech language. We also compare Czert with the following baselines:

**Baselines**

- SlavicBERT – a model trained on four Slavic languages (Russian, Bulgarian, Czech and Polish) (Arkhipov et al., 2019),
- mBERT – a multilingual version of BERT (Devlin et al., 2018),
- ALBERT-r – a randomly initialized ALBERT model without any pre-training.

4.1 Evaluation Tasks

We evaluate our models on six tasks that cover three main groups of NLP tasks: Sequence Classification (Sentiment Classification, Multi-label Document Classification); Sequence Pair Classification (Semantic Text Similarity); Token Classification (Morphological Tagging, Named Entity Recognition, Semantic Role Labeling)

For the **sequence classification** tasks, we take the pooled output of the BERT model (and ALBERT). We add dropout and an output layer. The number of output neurons and the activation function differs for each task.

**Sentence pair classifications** tasks employ the same approach as sequence classification tasks. The only difference is that we feed both sentences separated with special [SEP] token together into the model. This way, the model can profit from cross-attention between tokens from different sentences.

For the **token classification** tasks, we use the output embeddings associated with the input words ([CLS], [SEP] and other special output embeddings are ignored). When the input words are split to sub-word tokens, we take only the first sub-word tokens. For optimization, we use the Cross-entropy loss.

For all the tasks, the newly added layers are initialized randomly. We employ the Adam optimizer.

4.2 Named Entity Recognition

We use two different datasets to evaluate our model on the named entity recognition task. These are the following:

1. Czech Named Entity Corpus (CNEC) (Ševčíková et al., 2007) containing 4 688 training, 577 development and 585 test sentences. We use the CoNLL version of the dataset (Konkol and Konopík, 2013).
2. BSNLP 2019 shared task dataset (Piskorski et al., 2019) that consists of 196 train and 302 test sentences. We further split the test dataset into development and test parts resulting in development and test datasets of sizes 149 and 153 sentences, respectively. Additionally, we convert the original dataset into the same format as the CNEC, extracting entity classes only.

Independently on the dataset, we pre-process the sentences so that the maximum length of an example is 128 sub-word tokens. If the maximum length is exceeded, the residual part is used to create another data point. On the contrary, if the maximum length is not reached, the sentence is padded (padding is inserted at the end of the sentence). It is worth mentioning that exceeding the maximum length of a sentence occurs only for 44 times on the CNEC, which is negligible. On the other hand, on the BSNLP 2019, the length of the sentences differs a lot, and the maximum length is exceeded for a significant portion of the data. However, our experiments show that increasing the maximum sequence length does not improve the resulting F1 score. The architecture of the model follows the token classification settings described in Section 4.1. See Appendix B.1 for more details about the model and hyper-parameters.

4.2.1 Results

As an evaluation metric, we use F1 score computed on the entity level, while ignoring "O" (empty)
class. The results, stated with 95% confidence intervals, are summarized in Table 3.

4.3 Morphological Tagging

To evaluate our model on a morphological tagging task, we utilize four Universal Dependencies treebanks. These are namely: Prague Dependency Treebank 3.0 (PDT) (Bejček et al., 2013), Czech Academic Corpus 2.0 (Vildová et al., 2008), Czech Legal Text Treebank 2.0 (Krň et al., 2018) and FicTree (Hnátková et al., 2017). Together they comprise 103 143 train, 11 326 development and 12 216 test examples. Furthermore, we also perform our experiments on the PDT only to compare our model to the current SoTA. The PDT dataset then comprises 68 627 train, 9 285 dev and 10 163 test examples. The original datasets come as CoNLL files which we converted to a simplified format as in the case of the CNEC dataset (section 4.2). During this pre-processing step, we extracted only UPOS tags, which we use as labels. The architecture of the model follows the token classification settings described in Section 4.1. The number of output neurons is set to the number of possible UPOS tags. See B.2, for more details about the hyper-parameters and training process.

4.3.1 Results

Table 4 shows the achieved results with 95% confidence intervals. Results are stated in F1 score computed on a token level, ignoring the "O" (empty) class. As the table shows, our model Czert-B outperforms the other models on both datasets. Moreover, we outperformed the current SoTA (Straka et al., 2019) as well.

4.4 Semantic Role Labelling

In semantic role labeling we are looking for shallow semantic structure so the task can be formalized as classification of roles arguments of the predicates in the sentence. Therefore, a single example to be classified is the pair of predicate and argument where the predicate is a single word, and the argument is either word or a phrase. We are classifying the role of the argument towards the predicate. Our input representation is inspired by (Shi and Lin, 2019). We first tokenize the sentence with WordPiece. Then we feed the sentence into the network followed by the [CLS] token and the predicate token(s). Note that the predicate tokens have the same positional IDs as their occurrence in the sentence, but different segment ids. This way the predicate at the end of the sequence differs from its in-sentence representation only in segment embedding, so it contains all the information to encode the in-sentence context but it can be easily distinguished from other tokens by the segment embedding.

4.4.1 Results

We evaluate Semantic role labeling for the Czech language on the CoNLL 2009 dataset. The results are shown in Table 5; the dep-based column denotes the result achieved by Zhao et al. (2009). In gold-dep, we replicated their system but evaluated it with gold-standard dependency trees. Syntax-based F1 metric is computed on whole subtrees of dependency trees. To compute this for span based model, we need to project labels on dependency trees. We did not optimize this projection in any way. We just removed B- and I- prefixes, we copied the dependency annotation and ran the

4.5 Sentiment Classification

Sentiment Classification (SC) task (Liu, 2012) is a classification task where the goal is to assign a sentiment polarity of a given text. The positive, negative and neutral classes are usually used as the sentiment polarity labels. We perform the evaluation on two Czech sentiment classification datasets from Habernal et al. (2013), consisting of (1) Facebook posts and (2) movie reviews.

The Facebook dataset (FB) contains 10K users’ posts taken from nine Czech Facebook pages annotated with three classes.

We split the datasets into train, development and test parts with class distribution that follows the original datasets.

We fine-tune the models separately for each dataset. The architecture of the model follows the sequence pair classification setting described in Section 4.1. The number of output neurons is set to the number of sentiment polarity classes. Softmax normalization is applied to the output layer. We employ Cross-entropy loss. See B.4, for more details about hyper-parameters.

4.5.1 Results

We fine-tune the models (including the baselines) to achieve the best F1 score on the development data. Then, we use the best model settings to train a model on the train and development data. This model is evaluated on the test data and results are reported in Table 6 along with the initial learning rate and the number of epochs used for training. We repeat each experiment six times, and we report the average F1 score along with the 95% confidence interval.

4.6 Multi-label Document Classification

Multi-label Document Classification is a variant of classification problem where multiple labels can be assigned to each document. In this problem, there is no constraint on how many of the labels can be assigned to a given document.

We work with the Czech Text Document Corpus v 1.0 (Hrala and Král, 2013) to fine-tune and evaluate the models. The Czech News Agency provided almost 12 thousands of documents that formed the basis of this dataset. The agency journalists assign 60 categories (tags) to the documents as a part of their daily work. Following the approach from (Lenc and Král, 2018), we use only 37 most frequent categories for evaluation. More statistics are available in the paper.

Table 7: Results for Multi-label Document Classification on Czech Text Document Corpus v 1.0 dataset – AUROC and F1 measures. SoTA taken from (Lenc and Král, 2018).

### 4.6.1 Model Description and Fine-tuning

For **multi-label classification of documents** (MLC), we follow the sequence classification setting described in Section 4.1. The output layer is activated by the **sigmoid** function. The loss is the **Binary Cross-entropy** function. In the context of this task, documents are regarded as sentences trimmed to the maximum sequence length in tokens set to 512. We chose to pick the first N tokens in each document as our trimming strategy.

We run twenty 10-epoch-long training phases for each model and average the results. See B.6 for more details.

We use both standard **F1** and the **AUROC** (Melo, 2013) evaluation metrics. AUROC represents the overall ability of MLC models to distinguish between different classes without being biased by any constant threshold value. We use 95% confidence interval. We present the results in Table 7.

### 4.7 Semantic Text Similarity

We evaluate our model on semantic text similarity task on two different datasets.

1. **STS-SVOB** (Svoboda and Brychčín, 2018) contains two datasets: images descriptions (550 train and 300 test samples); and headlines (375 train and 200 test samples). We use the raw variant without any lemmatization or stemming.

2. **STS-CNA** was created during our experiments with this new model in cooperation with Czech News Agency and Charles University. STS-CNA contains s 138,556 hand-annotated sentence pairs (Sido et al., 2021).

### 4.7.1 Model Description and Fine-tuning

The architecture of the model follows the sequence pair classification setting described in Section 4.1. The number of output neurons is set to 1, and no activation function is applied to the output layer. We tried to keep hyper-parameters as close as possible between all experiments; however, we were forced to change them slightly in case of Czert-A and ALBERT-r. Also, the datasets have different nature; thus, we use different sets of hyper-parameters for each dataset. See B.5

We run ten experiments for each configuration and use 95% confidence interval. The tables Table 8 and Table 9 summarize the results. Table 8 shows that Czert-B model significantly outperforms the SoTA on SVOB-IMG dataset. In the SVOB-HL dataset, the models perform in par. We believe that the draw can be caused by reaching the annotation accuracy limit of this dataset.

We also observe a more stable and robust training on extremely small datasets; both Czert models are less prone to over-fitting than other tested models.

### 5 Discussion

We summarize the overall results of all evaluated tasks in Table 10. The first three columns contain the token classification tasks, the next two columns show results for sequence classification tasks, and the last column belongs to sequence pair classification task. We can observe that Czert-B model
We thoroughly evaluate our models on six common tasks: sentiment classification (SC) and semantic text similarity (STS). The increase is of ∼5% and ∼3% in both sentiment datasets and of ∼5% in one of the semantic similarity datasets. We also overcame SoTA in MLC.

6 Conclusion

In this work, we present two monolingual BERT-like models (BERT and ALBERT) for the Czech language. We train the models with the original MLM task and with a slightly modified NSP task. We thoroughly evaluate our models on six common tasks, and we compare them with other multilingual models. We include task-specific state-of-the-art models in our comparison. We outperform multilingual models with our newly trained Czert-B model on 9 out of 11 datasets. In addition, we establish the new state-of-the-art results on 9 datasets. The results show the strong performance of the Czert-B model on STS, MLC, SC, SRL, and MoT tasks.

As our paper confirms and as is shown in similar works, monolingual Transformer-based language models often overcome the multilingual ones.

Our models are publicly available for research purposes at our website and in the hugging face repository.

A Cluster Configuration

We use distributed training to set the weights of Czert. For distributed pre-training we rely on the Czech national cluster Metacentrum\(^1\). We employ 16 machines, each with two NVIDIA TESLA T4 graphic cards, which results in 32 T4s in total.

For the Czert-A model, we use standard Tensorflow (Abadi et al., 2015) distributed training, which is based upon the gRPC standard. It takes 12 days to training Czert-A with this setting.

The Czert-B model contains almost ten times as many trainable parameters as the Czert-A model. It proved impractical to train Czert-A with the tools provided by Tensorflow alone. We employ the MPI messaging standard that communicates over the OmniPath network with a speed of 100Gb/s. The Horovod (Sergeev and Balso, 2018) library handles all the synchronization transfers of our distributed training. We are able to reach the speeds of 2400ms per batch with this setting, which is approximately five times faster than with standard gRPC via TCP/IP. We are able to train the Czert-B model in 8 days.

B Fine-tuning and Hyper-parameters

B.1 Named Entity Recognition

In all of our experiments, we use Adam optimizer with a learning rate of 5e-5 and a linear decay to zero. Additionally, the Czert-B model uses a learning rate warm-up during the first epoch. Similarly to our NER experiments (Section 4.2s), we use a maximum sequence length of 128 sub-word tokens. The models are trained with batch size 64 for 13 epochs. For Czert-A it takes about 8 hours and 15 minutes on an NVIDIA Tesla-T4 GPU.

B.3 Semantic Role Labeling

For fine-tuning, we use Adam optimizer with a learning rate of 5e-5 and a linear decay to zero. We use a maximum sequence length of 128 sub-word tokens. We train the model on 2 Tesla T4 graphic cards with batch size of 64 for 12 epochs.

B.4 Sentiment Classification

We perform fine-tune training of the models by minimizing the Cross-Entropy loss function using the Adam (Kingma and Ba, 2014) optimization algorithm with default parameters (\(\beta_1 = 0.9, \beta_2 = 0.999\)) and with a linear learning rate decay (without warm-up). We try three different initial learning rates, i.e., 2e-6, 2e-5 and 2.5e-5 for at most 14 epochs. We use a max sequence length of 64, batch size of 32 for the FB\(^1\) dataset and a max sequence length of 512 and batch size of 14 for the CSFD dataset.

B.5 Semantic Textual Similarity

For the CNA dataset, we train two epochs using a batch of size 50, and LR 1e-5 with linear decay to zero for each model except Czert-A for which we used 5e-6 for four epochs, which lead to slightly better results.

For smaller datasets (SVOB-img and SVOB-hl) we used LR 5e-6 and train on 14k batches.

For each experiment, we used Adam optimizer, L2 weight normalization, and learning rate warm-up during the first 500 batches.

B.6 Multi-label Document Classification

For each experiment, we first run a linear grid search through learning rate parameter L = {2e-5, 4e-5, ..., 10e-4} and a decision \(D = \{true, false\}\) whether to use a linear learning rate decay\(^1\) or to

---

\(^{16}\)Arriving at 0 at the end of the last epoch.
keep the maximum learning rate constant until the last step. The learning rate achieved maximum after 500 steps of the warm-up phase. After the grid search was complete, we’ve run twenty 10-epoch-long training phases for each of the extended models and average the results.
Exploring German Multi-Level Text Simplification

Nicolas Spring, Annette Rios, Sarah Ebling
Department of Computational Linguistics, University of Zurich, Switzerland
{spring,arios,ebling}@cl.uzh.ch

Abstract

We report on experiments in automatic text simplification (ATS) for German with multiple simplification levels along the Common European Framework of Reference for Languages (CEFR), simplifying standard German into levels A1, A2 and B1. For that purpose, we investigate the use of source labels and pretraining on standard German, allowing us to simplify standard language to a specific CEFR level. We show that these approaches are especially effective in low-resource scenarios, where we are able to outperform a standard transformer baseline. Moreover, we introduce copy labels, which we show can help the model make a distinction between sentences that require further modifications and sentences that can be copied as-is.

1 Introduction

Simplified language is a variety of standard language characterized by reduced lexical and syntactic complexity, the addition of explanations for difficult concepts, and clearly structured layout.1 Among the target groups of simplified language are people with cognitive impairment and autism spectrum disorder, prelingually deaf and functionally illiterate people, and sometimes also foreign language learners and children (Bredel and Maaß, 2016).

Automatic text simplification (ATS), the process of automatically producing a simplified version of a standard-language text, was initiated in the late 1990s (Carroll et al., 1998; Chandrasekar et al., 1996) and has since then been approached by means of rule-based and statistical approaches. As part of the rule-based paradigm, the operations carried out typically include replacing complex lexical and syntactic units by simpler ones. The statistical paradigm so far has mainly conceptualized the simplification task as a case of monolingual (sentence-based) machine translation (MT), i.e., as one of converting standard-language into simplified-language sentences using MT techniques (Specia, 2010). However, while in bilingual parallel texts used for MT, the relation between source and target sentences is mostly 1:1, ATS usually requires n:m alignments with unaligned parts in-between.

ATS research has been documented for English (Zhu et al., 2010), Spanish (Saggion et al., 2015), Portuguese (Aluisio and Gasperin, 2010), French (Brouwers et al., 2014), Italian (Barlacchi and Tonelli, 2013), and other languages. Research on German is still sparse but has gained momentum in recent years due to a number of legal and political developments in German-speaking countries, such as the introduction of a set of regulations for accessible information technology (Barrierefreie-Informationstechnik-Verordnung, BITV 2.0) in Germany, the approval of rules for accessible information and communication (Barrierefreie Information und Kommunikation, BIK) in Austria, and the ratification of the United Nations Convention on the Rights of Persons with Disabilities (UN CRPD) in Switzerland.

In this paper, we report on work in automatic simplification of standard German into three separate simplification levels (A1, A2, B1) using a sentence-based MT approach. We show that the use of source-side labels indicating the targeted level of simplification benefited performance. Furthermore, pretraining the encoder and decoder on standard German also improved the performance of the ATS models. In our experiments, we noticed that MT models have a tendency to copy the source segments. While copies are sometimes desirable, we want to avoid this in cases where the original segment could benefit from further simplification.

1The term plain language is avoided here, as it refers to a specific level of simplification. Simplified language subsumes all efforts of reducing the complexity of a text.
We show that the use of special copy labels at training time can positively influence such behavior. In particular, the contributions of the paper at hand are the following:

- We demonstrate the use of source-side Common European Framework of Reference for Languages (CEFR) (Council of Europe, 2009) labels and a fine-tuning approach to boost text simplification performance for certain CEFR levels.

- We investigate the use of source-side copy labels to reduce the copying behaviour of text simplification models in situations where copying is not desirable.

The remainder of this paper is structured as follows: Section 2 describes existing datasets for text simplification for a variety of languages as well as established approaches to ATS. Section 3 describes our approach to multi-level text simplification for German. We discuss our experiments in Section 4 and conclude in Section 5 with further thoughts on improving ATS for German and current challenges to overcome.

2 Previous Work: Automatic Text Simplification

2.1 Data

ATS with sentence-based MT models relies on pairs of standard-language/simplified-language texts aligned at the sentence level. A number of parallel corpora have been created to this end. Gasperin et al. (2010) compiled the PorSimples Corpus consisting of Brazilian Portuguese texts (2,116 sentences), each with two different levels of simplifications (“natural” and “strong”), resulting in around 4,500 aligned sentences. Bott and Saggion (2012) produced the SimpLext Corpus consisting of 200 Spanish/simplified Spanish document pairs, amounting to a total of 1,149 (Spanish) and 1,808 (simplified Spanish) sentences (approximately 1,000 aligned sentences).

A large parallel corpus for ATS is the Parallel Wikipedia Simplification Corpus (PWKP) compiled from parallel articles of the English Wikipedia and the Simple English Wikipedia (Zhu et al., 2010), consisting of about 108,000 sentence pairs. Application of the corpus has been subject to criticism for various reasons (Štajner et al., 2018); the most important among these is the fact that Simple English Wikipedia articles are often not translations of articles from the English Wikipedia. Hwang et al. (2015) provided an updated version of the corpus that includes a total of 280,000 full and partial matches between the two Wikipedia versions.

Another frequently used data collection, available for English and Spanish, is the Newsela Corpus (Xu et al., 2015) consisting of 1,130 news articles, each simplified into four school grade levels by professional editors.

Klaper et al. (2013) created the first parallel corpus for German/simplified German, consisting of 256 texts each (approximately 70,000 tokens) downloaded from the Web. More recently, Battisti et al. (2020) extended the corpus with more parallel data, additional monolingual-only data (in simplified German), and new information on text structure (e.g., paragraphs, lines), typography (e.g., font type, font style), and images (content, position, and dimensions). The corpus is compiled from Web sources in Germany, Austria, and Switzerland. The sources mostly represent websites of governments, specialized institutions, and non-profit organizations. The documents cover a wide range of topics, such as politics (e.g., instructions for voting), health (e.g., what to do in case of pregnancy), and culture (e.g., introduction to art museums). The corpus contains 6,217 documents (5,461 monolingual documents plus 378 documents for each side of the parallel data). The vocabulary of the simplified German texts is smaller than that of the German texts by 51% (33,384 vs. 16,352 types), which is comparable to the rate of reduction reported for the Newsela Corpus (50.8%).

Säuberli et al. (2020) introduced a corpus of news items from the Austria Press Agency (Austria Presse Agentur, APA). At APA, four to six news items per day are manually simplified into two language levels, B1 and A2, following guidelines by capito, the largest provider of simplification services (translations and translators’ training) in Austria, Germany, and Switzerland. These news
items cover the topics of politics, economy, culture, and sports.

A number of tools exist for sentence alignment of parallel documents in the context of sentence simplification; among them are CATS (Štajner et al., 2018), MASSAlign (Paetzold et al., 2017), and LHA (Nikolov and Hahnloser, 2019). Spring et al. (2021) evaluated these alignment methods for German text simplification, together with SBERT (Reimers and Gurevych, 2020) and Vecalign (Thompson and Koehn, 2019). Both of the latter tools were originally designed in the context of multilingual alignment. Evaluation against a human-created gold standard showed that LHA yielded the most accurate sentence alignments.

2.2 Approaches

Specia (2010) introduced statistical machine translation (SMT) to the ATS task, using data from a small parallel corpus (roughly 4,500 parallel sentences) for Portuguese. Coster and Kauchak (2011) used the PWKP Corpus in its original form (cf. Section 2.1) to train an MT system. Xu et al. (2016) performed syntax-based MT on the English/simplified English part of the Newsela Corpus (cf. Section 2.1).

Nisioi et al. (2017) pioneered neural machine translation (NMT) models for ATS, performing experiments with LSTMs on both the Wikipedia dataset of Hwang et al. (2015) and the Newsela Corpus for English, with automatic alignments derived from CATS (cf. Section 2.1).

More recent contributions to ATS include explicit edit operation modeling (Dong et al., 2019), graded simplification (Nishihara et al., 2019), weakly supervised (Palmero Aprosio et al., 2019), and unsupervised approaches (Surya et al., 2019; Kumar et al., 2020).

Suter et al. (2016) introduced a rule-based ATS system for German. Their rules are based on linguistically motivated guidelines and their simplification system yielded outputs with a syntactic complexity comparable to a human translation.

Battisti et al. (2020) presented an approach to German ATS using recurrent neural networks with attention and incorporated back-translation (Sennrich et al., 2016) to generate additional synthetic training data from the monolingual part of their corpus.

Säuberli et al. (2020) presented the first approach to ATS for German using (sentence-based) NMT models. As data, they used the APA Corpus introduced in Section 2.1, amounting to approximately 3,500 sentence pairs.

Other contributions that are relevant to our work originate from the field of MT. Source-side labels have previously been employed in a variety of tasks such as domain adaptation (Kobus et al., 2017), multilingual translation (Johnson et al., 2017), and to improve training with back-translated data (Caswell et al., 2019).

2.3 Evaluation

The most commonly applied automatic evaluation metrics for text simplification are BLEU (Papineni et al., 2002) and SARI (Xu et al., 2016). BLEU, the de-facto standard for automatic evaluation of MT, computes token n-gram overlap between a hypothesis and one or multiple references. A shortcoming of BLEU with respect to ATS is that it does not punish hypotheses that are identical to the input. In contrast, SARI was introduced specifically for ATS and is designed to punish excessive copying behaviour. SARI considers the input and rewards tokens in the hypothesis that do not occur in the input but in one of the references (addition), as well as tokens in the input that are correctly retained (copying) or removed (deletion) in the hypothesis.\footnote{A copy or deletion is considered correct if the token is copied or deleted in at least one of the references.}

Table 1 displays scores for previous sentence-level ATS systems for different languages.

3 Text Simplification Along CEFR Levels for German

3.1 Data

The data used for the experiments reported in this paper consists of two collections:

The first part comprises an expanded version of the Austria Press Agency (Austria Presse Agentur, APA) corpus described by Säuberli et al. (2020) (cf. Section 2.1). Our updated version of this corpus consists of standard-language news items with their corresponding simplifications between August 2018 and April 2021. We extracted simplified German documents along with their standard German counterparts. This extraction yielded 2,410 document pairs for B1 and 2,347 for A2. As human text simplification work at the APA is ongoing, this corpus is expected to grow with time.

The second part of our data consists of the capito corpus. As a provider of simplification services,
capito produces a high number of professional simplifications for a variety of documents and text genres. This includes, but is not limited to, booklets, information texts, websites and legal texts, which are manually simplified into one or more levels following the capito guidelines. The simplification levels in this corpus include B1, A2 and A1. We extracted simplified German documents along with their standard German counterparts and metadata. Currently, the corpus contains 1,245 document pairs for B1, 1,885 for A2 and 879 for A1, however, since capito provides ongoing translation services, the number of documents is constantly increasing.

### 3.2 Sentence Alignment

Sentence alignment for ATS includes some phenomena that do not occur in this form in sentence alignment for translation. Whereas in translation, the standard case is often a simple 1:1 correspondence, alignment for text simplification can be considered n:m, meaning that a single alignment can consist of a varying number of segments on each side. This is due to phenomena such as sentence splitting and compression, additional explanations, as well as the fact that the order of information can change.

The results of NMT experiments are highly dependent on the available data. We extracted sentence alignments from our corpora using the LHA alignment method (Nikolov and Hahnloser, 2019), which was shown to yield the best results for simplified German (Spring et al., 2021) (cf. Section 2.1). For calculating the alignments, we used the Sentence Alignment Tools Evaluation Framework (SATEF),\(^5\) which yields n:m alignments, meaning that a single alignment can consist of a varying number of segments on each side. We aligned our documents in the direction from complex to simple. The number of documents differs considerably

\(^5\) Code is available from: https://github.com/kostrzmar/SATEF
depending on the CEFR level and the dataset, see Section 3.1. Furthermore, the APA Corpus does not contain any data for level A1. This manifests itself in the number of sentence alignments we were able to extract on this level. The largest number of alignments in our parallel corpus are for level A2, followed by about half as many for level B1. With 10,952 sentence alignments, A1 is the simplification level with the smallest amount of data available for model training, see Table 2 for an overview.

The sentence alignments with LHA on the APA data are publicly available.\(^6\)

### 3.3 Text Simplification

All the models we trained for our experiments shared the same architecture and hyperparameters. We trained transformer models (Vaswani et al., 2017) with five layers, four attention heads, 512 hidden units in the transformer layers, and a feed forward layer size of 2048. Embedding dropout and label smoothing were set to 0.3. We used early stopping according to BLEU on a held-out development set with a patience of 10. All models shared a 20k vocabulary between source and target. All our experiments were carried out in sockeye (Hieber et al., 2018).

We trained baseline models where we combined all available training data across all levels. These models had no explicit method to determine the desired level of simplification on the target side.

The diverse dataset allowed us to treat text simplification as a number of subtasks, where the model learns to simplify into different complexity levels, ranging from B1 to A1 according to the CEFR. To allow a model to make a distinction between the different levels of simplification, we used source-side labels indicating the desired CEFR level of the target segment (\(<a1>\), \(<a2>\), and \(<a3>\)). To better understand the copying behavior of our models, we trained our labeled models in two versions: 1) using a simple source-side label indicating the target CEFR level and 2) additionally using an explicit \(<copy>\) label instead of the CEFR level for all segments where source and target were identical. Apart from these modifications to the training data, all model hyperparameters were identical to the baseline models. We will refer to these models as “APA+capito multi” and “APA+capito multi copy”, respectively. Note that copying the source segment to the target is not wrong per se and that there are many cases where no further modification of a segment is needed, especially at higher CEFR levels. We hypothesize that the addition of these copy labels at training time allows the model to better recognize these cases even when they are not present at test time. At test time, all segments were translated with their CEFR label and no \(<copy>\) labels were present. We observed that training a simplification model with explicit \(<copy>\) labels reduced the number of untranslated segments where source and reference are not identical. We treated these types of copies as undesired.

All experiments previously described were performed in two variations. In the first variation, we trained the models from scratch on the simplification data. The second variation involved pretraining the encoder and decoder on a DE→EN or EN→DE translation task, respectively. This was motivated by the relatively low number of aligned segments we could use for our parallel training data. We trained two translation models with the same hyperparameters as the simplification models, but we used separate source and target vocabularies for encoder and decoder (German only). The parallel DE↔EN data for pretraining the NMT models (cf. Section 3.3) consisted of Europarl v10, Common Crawl, News Commentary v15, and the Tilde Rapid Corpus from WMT20.\(^7\) For the simplification models, we then initialized the parameters of the encoder with the encoder parameters of the DE→EN model. Likewise, we initialized the decoder parameters of the simplification models with the decoder parameters of the EN→DE model.\(^8\) The DE→EN, EN→DE and all simplification models used the same German subword vocabulary. We then fine-tuned these pretrained models on our text simplification data. We append the tag “fine-tuned” to the name of these models.

Finally, for the purpose of reproducibility, we trained a labeled simplification model on the publicly available APA alignments\(^9\) described in Section 3.2, referred to as “APA multi”.\(^10\)

For evaluation, we used a test set that consists of

\(^10\)Preprocessing and training scripts are available from: https://github.com/ZurichNLP/RANLP2021-German-ATS
500 parallel segments per level (A1, A2 and B1), randomly sampled from the combined corpus. The “APA multi” model was evaluated on a different test set, consisting exclusively of APA data.

3.4 Results

Our results can be found in Tables 3 and 4. In general, the models with target labels for the simplification levels performed better than the baseline both in terms of BLEU and SARI, with the notable exception of BLEU at level A2. Note that A2 was by far the most common simplification level in our dataset. The simple labeling approach of “APA+capito multi” was already effective and outperformed both baseline models on A1 and B1. But it was in turn outperformed by its fine-tuned counterpart “APA+capito multi fine-tuned” on B1, and by the fine-tuned model with copy labels, “APA+capito multi copy fine-tuned”, on A1. Pretraining the level-agnostic baseline model yielded improvements in terms of BLEU for A1 and A2 and only for A2 in terms of SARI.

When evaluating our labeled models with SARI, we could see improvements over the performance of the baselines for all models. Generally, SARI scores suggest that pretraining is especially effective when combined with labeling on levels A2 and B1. On A1, the simple labeling approach of “APA+capito multi” remained the most effective. It yielded an improvement of 6.86 points over the baseline. The best model for A2 and B1 was “APA+capito multi fine-tuned”, which yielded SARI scores improved between 5.49 (A2) and 7.55 (B1).

An analysis of the copying behaviour of the different models can be found in Table 5. The standard fine-tuned model generally had the strongest tendency to copy the source, however, the addition of copy labels significantly reduced the number of copied segments. This was also true for the non-pretrained model variants. Furthermore, the number of undesired copies (where source and reference are not identical) decreased with the use of copy labels (percentage decreases as indicated in Table 5). This was true for both the generic and the pretrained models. In general, the models tended to produce more copies for higher CEFR levels, which was consistent with the training data: In B1, or even A2, shorter segments are more often identical to their standard German counterparts than in A1.

Table 6 shows two examples of how the models with copy labels can avoid source copies. For both samples, “APA+capito multi fine-tuned” simply copies the input. “APA+capito multi fine-tuned copy” avoids this by using two different strategies. In the first example, it produces a segment with different structure and content, which is related to the source segment thematically. Such outputs are common across all models and can be seen as a result from the many-to-many nature of alignment for ATS and the elaborations that are common in text simplification. In the second example, the model produces a shorter simplification by removing some of the information present in the source segment. This ellipsis is another common phenomenon in text simplification.

The performance and copying behaviour of the “APA multi” model cannot be directly compared to the other models because it was trained on different data (exclusively the APA corpus) and uses a different test set.

4 Discussion

Comparing our results to Säuberli et al. (2020), whose experiments are similar to ours in terms of scope and data, it is clear that our baseline models are already quite strong. We find that source-side labels for target language levels generally improve BLEU and SARI scores and that the same is true for pretraining and fine-tuning. Interestingly, combining labels and pretraining results in lower gains in both metrics on A1 for the model without copy labels, indicating that these two approaches cannot always simply be combined. We also note that the scores on CEFR level A2 did not profit as much from the different strategies and we were not able to improve over the pretrained baseline model in terms of BLEU by using labels. We attribute this to the relatively large amount of training data for A2, meaning that specifically dealing with this low resource setting was not needed for this CEFR level. On the other hand, A1 and B2, for both of which there was substantially less data, benefit from labeling and pretraining.

Regarding the copying behaviour, we note higher numbers of direct source copies on the higher CEFR levels. We attribute this to the fact that simplifications on these higher levels typically tend to be closer to the original text in terms of lexical and syntactic complexity. This means that there are more standard language segments without any

5 Conclusion and Outlook

We were able to demonstrate the advantages of different approaches to German multi-level ATS. We established strong baselines on a generic simplification task across all CEFR levels and were able to further boost model performance for specific levels of simplification using source-side labels and a pretraining/fine-tuning strategy. We tested fine-tuning with labeled multi-level models. These approaches were generally more effective on the CEFR levels where we had more limited data, suggesting that they are especially useful in low-resource scenarios. We also investigated the use of copy labels at training time to mark segments where source and target segments are identical. At test time, this resulted in a lower number of copies overall and especially in the number of instances where the references differs from the source. This suggests that copy labels are a valid tool to reduce undesired copying behaviour in text simplification, though their influence on the quality of the output can likely only be determined by human evaluation.

Further work will be conducted on a more advantageous combination of the two approaches of
Table 5: The number of source copies produced by the models. Columns marked with an asterisk only count copies where the source is different from the reference (i.e., undesired copies). The APA multi model was trained and evaluated on different data and is not comparable to the rest of the models.

Exploring Reliability of Gold Labels for Emotion Detection in Twitter

Sanja Štajner
Symanto Research

sanja.stajner@symanto.com

Abstract

Emotion detection from social media posts has attracted noticeable attention from natural language processing (NLP) community in recent years. The ways for obtaining gold labels for training and testing of the systems for automatic emotion detection differ significantly from one study to another, and pose the question of reliability of gold labels and obtained classification results. This study systematically explores several ways for obtaining gold labels for Ekman’s emotion model on Twitter data and the influence of the chosen strategy on the manual classification results.

1 Introduction

Interest for automatic emotion detection has been gaining popularity in the last ten years (Acheampong et al., 2020, Figures 3 and 4). The span of its applications ranges from empathetic chatbots and virtual agents (Paiva et al., 2017; Rashkin et al., 2019; Lin et al., 2019b; Shin et al., 2019; Lin et al., 2019a; Ma et al., 2020) to social media and public opinion analysis (e.g. (Anstead and O’Loughlin, 2014; Wu et al., 2020; Loureiro and Alló, 2020)). Nevertheless, the task proved challenging, especially when attempted at purely textual utterances as opposed to the multi-modal ones (Poria et al., 2019), probably due to missing visual and audio cues (Acheampong et al., 2020).

Previous studies reported some of the challenges in automatic emotion detection from texts: different perspectives one may take (Buechel and Hahn, 2017b; Alm et al., 2005), missing context (Ôhman et al., 2020; Mohammad, 2012), non-literal meaning (Mohammad, 2012), high subjectivity of the task and low inter-annotator agreement even among trained annotators (Alm et al., 2005; Schuff et al., 2017). For example, the utterance “Italy defeats France in World Cup Final” (Katz et al., 2007) is most probably neutral from the writer’s (journalist’s) perspective, while evoking strong and probably opposite emotions among Italian and French readers (Buechel and Hahn, 2017b). The utterance “Time for shopping” might be neutral, or express evoke various emotions (e.g. joy, anger, fear) depending on the writer’s/reader’s associations and personal experiences with shopping.

The field of emotion detection from text, similar to many other areas of natural language processing, suffers from the absence of standards for human annotation, and systematic investigations of how different strategies for obtaining gold labels influence classification results. Notable exceptions are the studies by Mohammad and Turney (2013) and Buechel and Hahn (2017b). Mohammad and Turney (2013) found that asking annotators which emotion is the word associated with yields higher inter-annotator agreement than asking them which emotion the word evokes. This result indicated that annotating emotions from text’s perspective is less subjective than annotating them from reader’s perspective. Motivated by those results, Buechel and Hahn (2017b) investigated the influence of perspective on the inter-annotator agreement in emotion annotation at a sentence level.

A recent study by Northcutt et al. (2021) demonstrated that incomplete or suboptimal gold labels in benchmark datasets can steer research efforts in wrong direction as they reward systems that comply with such suboptimal labels. Obtaining the correct gold labels for emotion detection from texts should thus be of the utmost importance for the field.

This study’s contributions towards that goal are:

- An overview of previous efforts in human annotation of emotions in texts (Section 2).
- Single-label human annotation of Ekman’s emotions in English tweets by six trained annotators (Section 3).
### Table 1: Annotation procedures used in previous studies ("?" signifies that the particular aspect was not specified in the paper, "+1" in the #emotions column signifies the additional class for "other" or "no emotion").

- Detailed analysis of the collected human annotations and their comparison to the automatically assigned labels that are the current standard for obtaining gold labels on Twitter data (Section 4.1).
- Systematical investigation of several strategies for obtaining gold labels from manual annotations, and their influence on the reported manual classification results (Section 4.2).

### 2 Related Work

Several recent surveys (Acheampong et al., 2020; Alswaidan and Menai, 2020) and studies (Öhman et al., 2020; Bostan et al., 2020; Bostan and Klingler, 2018; Schuff et al., 2017) list previous work on emotion detection from texts and emphasise their differences in type of emotion taxonomy, task (single-label or multi-label), size of the dataset, text genre, granularity, topics, system architectures, and best results obtained with systems for automatic detection of emotions in texts.

However, none of the studies focussed on assessing the quality of benchmark datasets, or the influence of methods used for obtaining gold labels on the results of systems for automatic emotion detection from texts.

Drawing conclusions about influence of strategies for obtaining gold labels on the classification results by systematic exploration of the previous studies is not possible due to different text genres, number and type of annotators (trained vs. crowdsourced), annotation type (single-label vs. multi-label), granularity of annotations (word or sentence level, with or without surrounding context), emotion taxonomies, and the perspective taken. Table 1 presents annotation strategies used in some of the previous studies. For instance, in a multi-labelling task with 27 emotions (+ neutral) where each Reddit comment was annotated by three or five annotators out of a total of 82 crowdsourced annotators, the Cohen’s kappa (Cohen, 1960) was calculated by aggregating all pairs of annotations per instance and emotion (Demszky et al., 2020). In a single-labelling task with 15 emotions (+ no emotion) where each news headline was annotated by five out of 310 annotators, in contrast, the authors report the Fleiss’ kappa (Fleiss, 1971) as a measure of inter-annotator agreement (Bostan et al., 2020). In the XED dataset of movie subtitles, annotated with 8 emotions (+ neutral) in a multi-labelling task, some instances were annotated with fewer than three annotators (some even one annotator only), and the Cohen’s kappa was calculated for gold labels in the parallel dataset of movie subtitles in English and Finish (Öhman et al., 2020).

Some studies went beyond the “simple” emotion annotation, by requesting from annotators to annotate the intensity of the emotions, e.g. (Strapparava and Mihalcea, 2007; Aman and Szpakowicz, 2007; Buechel and Hahn, 2017a), the triples of who experiences which emotion and why (Kim and Klinger, 2018). In a recent study, Bostan et al. (2020) conducted the annotation of emotions, cues, intensities, experiencers, causes, targets, and reader’s emotions on news headlines.

A commonly used strategy for obtaining large training datasets for emotion detection in texts is
by automatically labelling tweets that contain hashtags that explicitly mention emotions or predefined emotion keywords. Wang et al. (2012) used 131 emotion hashtags as keywords for collecting 5 million tweets in seven emotion categories (joy, sadness, anger, love, thankfulness, surprise). They explored several different strategies for obtaining gold labels based on hashtags and found that most accurate gold labels are obtained if the keyword hashtag appears at the end of the tweet; keyword hashtags appearing anywhere else in the tweet were not found to be that relevant. Shahrai and Zaiane (2017) automatically annotated tweets with nine emotions (anger, fear, joy, love, sadness, surprise, thankfulness, disgust and guilt) based on 15 explicit hashtags appearing in them, resulting in Clean Balanced Emotional Dataset (CBET) with 27,000 annotated tweets (3,000 per each emotion). Mohammad (2012) compiled a corpus of 21,051 tweets which contained one of the six Ekman’s emotions (anger, disgust, fear, joy, sadness, surprise) as the last hashtag, and suggested to use it as an automatically assigned label that corresponds to the emotion experienced by the writer. One of the findings of that study was that such large, automatically-labelled training dataset can be used for emotion detection in other domains and text genres.

3 Methodology

3.1 Dataset

The dataset used in this study is a subset of TEC dataset (Mohammad, 2012), available through the Unify dataset (Bostan and Klinger, 2018). It consists of 35 randomly selected English instances for each of the six Ekman’s emotions (anger, disgust, fear, joy, sadness, and surprise) that contain at least six tokens. To select 35 instances of each of the six emotions, the gold labels of the original dataset were used, i.e. the automatically-assigned gold labels based on the last hashtag in the post, as described in the previous section, e.g. “We are fighting for the 99% that have been left behind. #OWS #anger” (Mohammad, 2012).

3.2 Annotation Procedure

Annotators. Each of the 210 tweets (35 per each emotion class) was annotated by six trained, paid annotators. Three annotators were male and three female. All annotators had at least a bachelor degree. Two of the annotators (one male and one female) were native speakers of English (UK); the other four annotators were proficient in English, and use it in their everyday work.

Guidelines. The annotators were instructed to choose, for each tweet, from a drop-down menu, one of the seven possible labels (ANGER, DISGUST, FEAR, JOY, SADNESS, SURPRISE, NEUTRAL), which best represents the emotion of the writer of the post, as the automatically assigned gold labels were expected to represent writers’ emotions as well (Mohammad, 2012).

Evaluation. The inter-annotator agreement, either between the gold label and one of the annotators, or between two annotators, was calculated in two ways: as accuracy (the percentage of cases in which the given labels match); and Cohen’s $\kappa$ (Cohen, 1960).  

3.3 Experiments

Two sets of experiments were conducted. In the first set of experiments, the results of the human annotation experiment were analysed and compared with the automatically obtained gold labels. The goals of this set of experiments were: (1) to investigate reliability of automatically obtained gold labels; and (2) to estimate complexity of the task for trained human annotators and find the main causes of their disagreements.

In the second set of experiments, several strategies for obtaining gold labels from human annotations, and their influence on the manual classification results were explored, given that previous studies used various strategies for obtaining gold labels from human annotations (Table 1, Section 2). The explored strategies for obtaining gold labels were: (1) based on the last emotion-hashtag (no human annotation required); (2) based on the annotations of just one trained annotator; (3) based on the majority label obtained from three human annotations; and (4) based on the majority label obtained from five human annotations.

4 Results and Discussion

The results of the two sets of experiments are presented and discussed in two separate subsections.

4.1 Annotation Analysis

The pairwise inter-annotator agreements for each pair of annotators, and for each annotator and the

\footnote{For calculation of Cohen’s $\kappa$, we used the implementation in sklearn library for python: https://scikit-learn.org/stable/modules/generated/sklearn.metrics.cohen_kappa_score.html.}

</tbody>
</table>

Gold labels, are presented in Table 2. As can be seen, the minimum, maximum, and average pairwise inter-annotator agreement is notably lower between any annotator and the gold labels than between any two annotators. The Cohen’s κ score between any annotator and the gold label corresponds to only a slight (strength of) agreement (0.00 ≤ κ ≤ 0.20), while the Cohen’s κ for any pair of annotators range from fair (0.21 ≤ κ ≤ 0.40) to moderate (0.41 ≤ κ ≤ 0.60) agreement, according to Landis and Koch (1977).

To investigate whether the annotation disagreements stem from poor quality of annotations, or from the natural complexity of the task, all labels assigned by all six annotators were manually checked. It was found that none of the annotators had more than 1% of erroneous annotations. The found errors were either due to labelling topic of the post instead of the writer’s emotion (SURPRISE labels), or due to labelling posts based on the words that occur in them instead of the writer’s emotion (SADNESS labels). The rest of the annotation disagreements were the result of the natural complexity of the task (Section 4.1.2).

The fairly low agreement among the annotators indicates that the task of detecting Ekman’s emotions in tweets is challenging and/or subjective. This is in line with previous studies which reported that emotion detection from text is a complex task that results in low inter-annotator agreements regardless of the emotion taxonomy used (Alm et al., 2005; Schuff et al., 2017; Kim and Klinger, 2018; Bostan and Klinger, 2018; Öhman et al., 2020; Acheampong et al., 2020).

The very low agreement between the annotators and the gold labels, in turn, indicates potential problems with the strategy of automatically assigning gold labels for emotion in tweets (according to the last hashtag of the tweet). This is in line with the results reported by Demszky et al. (2020) where the transfer-learning based system obtained noticeably lower results on the TEC dataset (F1-score of ≈0.5) than on the other two Twitter datasets where the gold label were obtained by manual annotations (F1-scores of ≈0.8 and ≈0.7).

4.1.1 Reliability of the Gold Labels

To explore the main causes of disagreements of the annotators with the automatically assigned gold labels, the percentage of instances on which certain number of annotators assigned the same label as the gold one was calculated for each emotion category separately (Table 3). In as many as 42.4% of the cases, none of the six trained annotators assigned the same label as the gold one was calculated for each emotion category separately (Table 3). In as many as 42.4% of the cases, none of the six trained annotators assigned the same label as the gold one. All six annotators assigned the same label as the gold one in only 7.6% of the cases. While the latter can be a consequence of a high subjectivity of the task, the former indicates that the automatically assigned gold labels might not be reliable.

In the per-class analysis (Table 3), FEAR and SURPRISE stand out as gold labels for which in as many as 71.4% and 45.7% of the cases, respectively, none of the six annotators assigned the gold
# Example Gold Assigned

Table 4: Examples of complete disagreement of annotators with the gold labels FEAR and SURPRISE. The number in parenthesis after the label signifies the number of annotators who assigned that label.

Table 5: Most frequently assigned sets of labels.
other disagreements in that group were between ANGER and SADNESS, ANGER and DISGUST, and JOY and SURPRISE (Table 5).

The most surprising combinations, among the most frequently encountered ones, were \{JOY, SADNESS\} (in 2.4% of all instances) and \{JOY, SADNESS, NEUTRAL\} (in 4.8% of all instances). By manual inspection of all those surprising combinations, it was discovered that they were not a result of erroneous annotations, but were rather assigned to one of the two following types of posts: (1) posts that can be associated with either joy or sadness depending on the writer’s association with the mentioned action (examples 1 and 2 in Table 6); (2) posts that contain one part that conveys writer’s sadness and other that conveys writer’s joy (examples 3–5 in Table 6). Disagreements that stem from the first type of posts cannot be avoided. Disagreements that stem from the second type of posts, in contrast, could be avoided by more fine-grained emotion annotation where annotators also mark the causes for each found emotion in the sentence, as it was done in studies by Kim and Klinger (2018) or Bostan et al. (2020), mentioned in Section 2.

### 4.2 Comparison of Different Strategies

To systematically analyse the influence of different strategies for obtaining gold label on the manual classification performances, the Cohen’s \(\kappa\) and accuracy of each remaining annotator (whose annotations were not used for obtaining the gold labels) against the gold labels were calculated. As the focus of this study is on single-label classification task, the majority vote was used as the gold label (other strategies mentioned in Table 1 would lead to multiple gold labels per instance). As mentioned in Section 3.3, four strategies were explored: automatically obtaining gold labels based on the last hashtag (0 annotations), having one human annotator to provide the gold label (1 annotation), having three human annotators to provide the gold label as the majority label (3 annotations), and having five human annotators to provide the gold label as the majority label (5 annotations). In the last two strategies, it is not always possible to obtain the majority label, i.e. if all three annotators assign different labels (for the strategy where gold labels are obtained based on three human annotations), or if two distinct labels were assigned each by two annotators (for the strategy where gold labels are obtained based on five human annotations). The minimal, maximal, and average percentage of instances (out of 210) that did not have a majority class are given in Table 7.

Cohen’s \(\kappa\) and accuracy were computed for each annotator against the gold labels only for those annotators whose annotations were not used for obtaining the gold labels, e.g. if the gold labels were obtained by using annotations of the annotators 1, 2, and 5, then the Cohen’s \(\kappa\) and accuracy against the gold labels were calculated only for the annotators 3, 4, and 6. That resulted in 20 data points for the strategy of obtaining gold labels from three human annotations (all combinations of three annotators from a total of six annotators), and six data points for the strategies of obtaining gold labels from one or five human annotations. The cases without majority class (when obtaining gold label from three and five annotations) were excluded.

The influence of the strategy for obtaining gold labels (involving zero, one, three, or five annotators) on the observed manual classification performances (Cohen’s \(\kappa\) and accuracy) of the rest of the annotators is clearly visible in Figure 2. As the quality of annotations was previously manu-

ally checked (Section 4.1), the higher classification performances in Figure 2 (the upper right corner of the plot) correspond to better quality of gold labels. According to these results, assigning gold labels based on the majority vote of three or five annotators lead to noticeably higher quality than assigning them based on the annotations of one annotator only. Assigning gold labels automatically, based on the emotion explicitly mentioned in the last hashtag in the tweet, leads to significantly lower quality than any other strategy. Box-plots in Figures 3 and 4 show more detailed results of this analysis. Strategies for obtaining gold labels from three or five human annotations both result in moderate to high inter-annotator agreements according to Cohen’s $\kappa$ score, and similar average values of those agreements.

The results of this analysis indicate that for obtaining good quality gold labels for Ekman’s emotions on English Twitter data it is not necessary to hire more than three trained human annotators. Would the same hold for crowdsourced annotations and different emotion taxonomies is something that needs to be explored in future studies.

5 Final Discussion and Conclusion

This study addressed the issue of reliability of gold labels for emotion detection in English tweets.

The results indicated that automatically obtained gold labels (based on the last emotion-hashtag of the tweets) are not reliable, mainly due to the last emotion-hashtag often representing either the topic of the post and not the emotion experienced by the writer, or the emotion that the post is expected to evoke in a particular group of readers. These results call for caution if such large automatically annotated datasets are used for training automatic emotion detection systems, or for testing them, as a significant portion of instances contain suboptimal gold labels.

The analysis of most common disagreements among the annotators revealed that, surprisingly, joy and sadness are often assigned to the same post by different annotators. A manual inspection of those cases revealed that they are results of either lack of context and knowledge about writer’s position about a certain topic, or writer’s expression of both sadness and joy in different parts of the post.

The analysis of impact of strategy used for obtaining gold labels on the manual classification results and quality of the test dataset indicated that three trained annotators are sufficient for providing gold labels by their majority vote.

Ethics/Impact Statement

This study is expected to have a broader impact on the field of automatic emotion detection in texts by raising awareness about the complexity of the task, and encouraging other NLP researchers to further explore annotation procedures and the qual-
ity of the gold labels in datasets used in automatic emotion detection.

The use of suboptimal annotation schemes and procedures, that do not account for natural complexities of the task, may lead to a high number of incorrect or incomplete labels in compiled datasets. The use of such datasets to train and test NLP models further leads to rewarding the models which are not actually performing well on the final goal but are, instead, good at learning and propagating the errors found in the training datasets (Northcutt et al., 2021). This might be particularly dangerous in the case of automatic emotion detection, as such models might be used in the real-world scenarios for a direct communication with real users, e.g. in empathetic chatbots. If those systems fail to grasp the actual emotional state of the user, especially in the case of individuals who are at-risk conditions in terms of mental health, they may cause further harms for such users. Furthermore, apart from the accurate recognition of the emotional experiences, such systems need to adequately respond to those users that go through emotional upheavals. Thus, special attention should be paid in the development of proper empathetic reactions of chatbots to prevent the potential harm to vulnerable populations.

Acknowledgements

I would like to express my gratitude to Justyna Hedler for her help in conducting human annotation experiment, Seren Yenikent for valuable discussions about emotion detection in psychology, Francisco Rangel for supporting this work, and the six annotators for the high quality of annotations.

Abstract

Automatic detection of the Myers-Briggs Type Indicator (MBTI) from short posts attracted noticeable attention in the last few years. Recent studies showed that this is quite a difficult task, especially on commonly used Twitter data. Obtaining MBTI labels is also difficult, as human annotation requires trained psychologists, and automatic way of obtaining them is through long questionnaires of questionable usability for the task. In this paper, we present a method for collecting reliable MBTI labels via only four carefully selected questions that can be applied to any type of textual data.

1 Introduction

The Myers-Briggs Type Indicator (MBTI) model (Briggs-Myers and Myers, 1995) is one of the most widely used non-clinical psychometric models (Štajner and Yenikent, 2020). It classifies people into two groups across four dimensions: extraversion/introversion (E/I), sensing/intuition (S/N), thinking/feeling (T/F), and judgement/perception (J/P). This leads to a total of 16 personality types. The first three dimensions are based on the theoretical work of Carl Jung (1921), while the fourth dimension was added later by Myers and Briggs-Myers (1995). The MBTI personality framework has already been used for decades in educational and industry settings, e.g. for finding jobs that best resonate with the person’s preferences for information processing (S/N and T/F dimensions), finding work organization types that best resonate with the person’s preferred judgement processes (J/P dimension) thus leading to better job satisfaction, and for better matching work environments with the person’s preferences (E/I dimension) to lower employee turnover (Briggs-Myers and Myers, 1995).

The original MBTI questionnaire contains 93 questions and is not freely available.1 Due to the popularity of MBTI framework (it is estimated that more than 2 million US adults complete the inventory every year),2 there is a number of freely available alternative MBTI questionnaires on the internet, with the 16personalities test3 being one of the most popular ones. According to the Myers-Briggs Foundation4 and the 16personality test website,5 both questionnaires satisfy the accepted standards for test validity and reliability. Nevertheless, the MBTI questionnaires have received a noticeable criticism from the academic community (Pittenger, 1993; Boyle, 1995) for not relying on a scientifically proven (i.e. data-driven) background, but rather on qualitative measures such as observation and introspection. The other common criticism is the binary nature of the questionnaire as it is known that the majority of people usually lies somewhere in the middle of the scales (Pittenger, 1993).

The questionnaire-based personality detection has several weaknesses: it requires trained human assessors; it is prone to social desirability bias (Krumpal, 2011) and reference-group effect (Heine et al., 2002); it is questionable if answering questionnaires is a natural way of showing ones personality (as opposed to free writing or behaviour “when nobody watches”). To detect MBTI typologies in a more natural way and without necessity for trained human assessors, many studies have attempted at building systems for automatic detection of MBTI personality types from text in the last several years. Attempts have been made for automatic detection of MBTI personality types from: tweets written in English (Plank and Hovy, 2015), six other Western European languages (Ver-professional/versions-of-the-mbti-questionnaire/)

4myersbriggs.org
5https://www.16personalities.com/articles/reliability-and-validity
hoeven et al., 2016), and Japanese (Yamada et al., 2019); English posts collected from Personality Cafe forum\(^6\) available in Kaggle;\(^7\) and English Reddit comments (Gjurković and Snajder, 2018; Gjurković et al., 2020). Despite being trained on large amounts of textual data (over one million), and modelled as four binary classification tasks, the best systems performed only slightly better than the random and majority-class baselines, regardless of the architecture used.

Some studies suggested that tweets might not contain sufficient amounts of MBTI signals (even after concatenating up to 150-200 tweets per user) due to the nature of Twitter posts (Celli and Lepri, 2018; Štajner and Yenikent, 2020, 2021). Another issue with all those studies and obtained results might be that the systems are supervised and were trained with gold labels obtained via MBTI questionnaires that suffer from all earlier mentioned weaknesses. In our recent study (Štajner and Yenikent, 2021), we found a low association between the MBTI types obtained via questionnaires and the MBTI signals found in the short texts written by participants (tweets and free texts on carefully chosen topics). At the same time, the inter-annotator agreement of two expert annotators assigning MBTI types based on those free texts was quite high (Štajner and Yenikent, 2021).

**Contributions.** To avoid all previously mentioned problems in automatic MBTI detection from texts, in this study, we propose a carefully designed set of four questions with answers on a 1-5 scale (Section 3) that aim to capture the main MBTI characteristics without taking much time from participants, and can be administered together with any open-end questions without need for trained human assessors. The validity of our questionnaire has been assessed via expert human annotation following previously proposed annotation methodology (Štajner and Yenikent, 2021). The agreement between the answers to the newly proposed questions and the expert human annotations was found to be similar as between two trained annotators (Section 5.2). Another advantage of the proposed method is that it goes beyond binary typology, by offering a 5-point scale for each MBTI dimension. This creates a possibility for filtering out those instances written by people who exhibit similar amount of signals from both polarities. As it is known that many people have characteristics of both polarities across MBTI dimensions (Pittenger, 1993), such filtering of training datasets might lead to better performances of automatic systems for MBTI detection from texts by removing noise.

2 Related Work

Plank and Hovy (2015) were the first to explore the use of Twitter data for obtaining a large-scale dataset for open-vocabulary automatic detection of MBTI personality traits. They collected a corpus of 1.2M English tweets automatically labelled for gender and MBTI type. To identify the users for whom an MBTI type can be automatically assigned, the authors relied on mentions of any of the 16 MBTI types plus the word “Briggs”. Additionally, each user was labelled as female or male whenever it was discernible; those users for whom the gender was not discernible were excluded from the study. For each selected Twitter user, the authors collected up to 2000 most recent tweets (to be included, each user had to have at least 100 tweets). Plank and Hovy (2015) found that the distribution of MBTI types across the selected Twitter users significantly differs from the distribution of MBTI types across the general US population. The authors further trained binary classification models (for each MBTI dimension separately) using various features and model architectures. The best systems outperformed majority-class baselines only for I/E and T/F dimensions.

Verhoeven et al. (2016) used a similar strategy for obtaining large-scale MBTI datasets for six other languages: German, Italian, Dutch, French, Portuguese, and Spanish. As opposed to the work of Plank and Hovy (2015), the triggers for identifying users whose MBTI types can be automatically assigned were mentions of one of the 16 personality types and the word “personality” or pronouns and verb forms such as “I am” or “I have”, for each of the six languages. All retrieved contexts were manually checked for whether or not they describe the personality of the writer of the post. For all users whose posts passed this check, the gender was annotated based on the user’s name, handle, description, and profile picture (Verhoeven et al., 2016). Distributions of MBTI types across Twitter users of the six languages were found to be similar, with only a few exceptions (Verhoeven et al., 2016). The authors also trained binary classifiers using the dataset with 200 concatenated tweets for each user

---

\(^6\)https://www.personalitycafe.com/

\(^7\)https://www.kaggle.com/datasnaek/mbti-type
and LinearSVC classifier with binary word and character n-gram features. Similar as for English (Plank and Hovy, 2015), in most of the languages, the best classifiers outperformed the majority-class baselines only for E/I and T/F dimensions.

Gjurković and Šnajder (2018) compiled a large-scale MBTI dataset from English Reddit comments by relying on flairs—short introductions of users on various subreddits—which, in the case of the MBTI-related subreddits, usually contain the users’ MBTI results. In the subsequent study (Gjurković et al., 2020), dataset was further enriched with demographic information about the users (age, gender, location, and language), and the labels for two other personality models. The distribution of MBTI types in this dataset also significantly deviated from the general US population (see Figure 3 in Section 6 for comparison of MBTI type distribution among different populations/datasets).

Automatic assignment of MBTI type to each user in all above-mentioned studies is based on automatic extraction of contexts in which a certain MBTI type is mentioned. Without manual inspection of each such mention—which was only reported for the study by Verhoeven et al. (2016)—the assigned labels might not be reliable, as they may refer to someone else mentioned in the tweet and not the writer of the tweet, or they might be a part of a larger phrase, e.g. “I think/believe I am an INTP” or “I expect to get ESFJ as the result if I do personality assessment”.

To the best of our knowledge, the only study in which MBTI labels were obtained by explicitly asking participants to report their MBTI type, if they had done an MBTI personality test in the past, is our recent study (Štajner and Yenikent, 2021). The Amazon Mechanical Turk workers were also asked to describe their favourite type of vacations and preferred hobbies in minimum 300 characters each. We found that this type of texts (responses to carefully selected open-end questions) contain more MBTI signals than tweets (even if concatenated together for each user). We further proposed detailed guidelines for MBTI personality annotation from textual data, and showed that expert human annotators have a high level of agreement among themselves on obtained textual answers when following provided guidelines. At the same time, we found that the annotators have a low level of agreement with the MBTI types reported by participants (based on their previous MBTI personality testing via popular questionnaires), which might be an indication that MBTI results obtained via questionnaires do not resonate well with the MBTI signals found in more natural textual forms.

The current study aims to overcome previously reported issues by proposing four questions with the answers on a 1–5 scale to obtain MBTI labels that better resonate with the expert human MBTI annotations on short texts.

3 Questionnaire

The whole questionnaire consisted of one optional question “You might have obtained your MBTI type in the past via questionnaires. If you know your MBTI type, please type it here”, four compulsory demographic questions, four compulsory questions with answers on a 1–5 scale that aimed to capture the participants MBTI type, and two compulsory open-end questions. Demographic questions encompassed gender, age, whether or not English is their native language, and the highest level of education obtained (Figure 1). The gender question had four possible answers: female, male, other, prefer not to specify. Five age groups were offered to choose from: 18–25, 26–35, 36–45, 46–55, and over 55.

After answering demographic questions, parti-
pants were provided with four questions that aimed to capture their MBTI type, and were asked to provide an answer on a 1–5 points scale. Those four questions are the central contribution of this study. By following the idea that aspects of leisure time represent the most natural version of personality, as it is directed by high degrees of intrinsic motivation (Štajner and Yenikent, 2021), the questions are focused on typical leisure time activities—hobbies and vacations. This also gave us the opportunity to utilize the previously proposed open-end questions (Štajner and Yenikent, 2021) in the validation process (Section 5). In deciding the content of the questions for each individual dimension, we followed the main definitions provided by Briggs-Myers and Myers (1995). Although each MBTI dimension corresponds to multiple practical and behavioral characteristics, the core theoretical focus for every dimension is consistent.

The first question (for the E/I dimension) was designed with the idea of capturing whether the person prefers to be surrounded by people and social interactions, on one end of the scale (1 = extraverted), or to spend quiet and calm time by themselves, on the other end of the scale (5 = introverted). The second question (for the S/N dimension) aims to capture the characteristics of the tasks people would prefer to process, concrete or intuitive, by asking whether they prefer technical and hands-on hobbies (1 = sensing) or abstract and imaginative (5 = intuitive). The third MBTI dimension (T/F) is fundamentally about how people make their decisions, whether based on rational or emotional motives. As people do not engage with strict decision-making processes during their free time, which is ultimately based on their personal interests, the question measured the preference for rational (1 = thinking) or emotional (5 = feeling) reasoning for liking a certain hobby. The fourth question aimed to capture the preference for spontaneous and flexible (1 = perceiving), or a well-planned (5 = judging) schedule at vacations.

We initially prepared two questions per each MBTI dimension and performed a pilot study with 30 participants to choose those questions (Figure 2) that better correspond to the MBTI types provided by the participants, and the MBTI annotations by two annotators.

Finally, participants were asked to answer to two open-end questions, which we previously proposed (Štajner and Yenikent, 2021) as the optimal questions for annotating MBTI types from texts:

- Describe which kind of vacations you typically enjoy and why.
- Describe what type of hobbies you enjoy and why.

The two questions were preceded by the following instructions: “The following questions aim to understand your life style preferences. While answering, please write down the first things that come to your mind without much contemplation.” To be accepted, each answer needed to contain a minimum of 300 characters.

4 Challenges in Data Collection

Data was collected via Amazon Mechanical Turk (AMT) platform. We prepared the questionnaire as Google Forms and provided the link to it in the HIT of the AMT platform. We experimented with various setups in the platform: different values for monetary compensations, allowing only those participants with high scores on previous tasks, different times for validation of the answers and payment. The only variable that noticeably influenced the time needed for obtaining completed HITs was whether or not we restrict the participants according to their performance on the previous HITs. Without any restrictions, we were
obtaining approximately 50 completed HITs per hour. The main bottleneck in the whole procedure was the need for manually checking “honesty” of the answers to the open-end questions.

We manually checked all answers by particularly focusing on checking whether or not: (1) all personality questions contained the same answer (although theoretically possible that a person has the same answer to all four questions, it is very likely that this behaviour instead signifies that the AMT worker just wanted to finish the task as soon as possible and get the monetary compensation); (2) the answers to the open-end questions make sense, i.e. are not just a random sequence of 300 characters; (3) the answers to the open-end questions are copied from the internet; (4) the same worker has already completed the task, and if they did, we checked whether the answers to both multiple-choice and open-end questions were similar in both completed HITs. We found that approximately one third of the completed HITs contained answers that were copied from the internet. Those HITs were disregarded and those workers did not obtain monetary compensation to prevent them from doing it again. In those cases where more than one HIT was completed by the same worker, if the answers were similar, we paid the monetary compensation for all of them and maintained only one randomly chosen HIT for our dataset. In those cases where the answers in the HITs of the same worker had many significant differences, we paid the monetary compensation, but excluded all HITs from that worker from the dataset.

5 Validation

We performed two types of validation of our questionnaire. First, we calculated the agreement of the answers to our personality questions with the MBTI labels provided by the participants, for those cases where the MBTI label was provided (Section 5.1). Given that the MBTI labels obtained by using popular questionnaires might not be reliable for MBTI type detection from textual utterances (Štajner and Yenikent, 2021), the results obtained through this validation method should be taken with the grain of salt. Second, we validated our questionnaire via manual annotation of MBTI types on the answers to the open-end questions (Section 5.2).

5.1 Agreement with the MBTI Types

Given the wide popularity of the MBTI framework in non-research communities, we expected that a substantial number of AMT workers had taken the MBTI or 16Personalities tests before. In total, 340 participants responded to the optional MBTI question, with the following distribution of the MBTI traits: 87 extraversion / 253 introversion, 249 sensing / 91 intuition, 148 thinking / 192 feeling, and 206 judging / 134 perceiving.

We compared the MBTI types provided by AMT workers and the respective answers to our personality questions. To be able to compare them, we converted the 5-point scores into binary ones to match with the MBTI binary typology. For every dimension, the scores of 1 and 2 were merged as one polarity (e.g. extravert), and 4 and 5 were merged as the other polarity (e.g. introvert). The remaining 3s were considered as middle scores and were treated differently in two setups: (1) always counted as correct, regardless of the MBTI type provided by the AMT workers; (2) excluded from the analysis. In the second case, the total number of excluded cases per each dimension was: 79 (23.2%) for E/I; 76 (22.4%) for S/N; 67 (19.7%) for T/F; and 54 (15.9%) for J/P.

The middle scores either represent the cases in which participant equally exhibits characteristics of both polarities, or they indicate indecisiveness. Both types of participants could score as either of the two polarities in the MBTI questionnaires as those only offer two options. Therefore, the results of the first setup could be seen as an upper bound, and the results of the second setup a lower bound of the validity score. The exact result of the validation procedure cannot be calculated due to the limitation of the MBTI labels to capture middle cases which are common (Pittenger, 1993).

The percentage of cases in which the collected answers to our personality questions correspond to the MBTI type provided by the AMT workers is given in Table 1.

5.2 Agreement with Human Annotations

We asked two paid expert annotators, well-versioned in MBTI framework from psychology perspective, to read 30 answers to the Vacations question and 30 answers to the Hobbies questions, and annotate each of them with one of the polarities (e.g. E or I), or the label MIDDLE if they see equal amount of signs for both polarities. The annotators
were provided with the previously proposed annotation guidelines (Štajner and Yenikent, 2021) and instructed to annotate the answers to the Vacations question only for the E/I and J/P dimensions, and the answers to the Hobbies questions only for the S/N and T/F dimensions.

The 30 answers per each open-end question were randomly selected with the constraint that 10 or those answers are from workers who chose 1 or 2 as the answers to the two respective personality questions, 10 answers are from workers who chose 3 as the answers to the two respective personality questions, and 10 answers are from workers who chose 4 or 5 as the answer to the two respective personality questions.

We compared the labels obtained by human annotation (in a ternary classification task) with the labels obtained by transforming the answers to the personality questions into three classes: 1 and 2 to one polarity; 4 and 5 to the other polarity; and 3 to MIDDLE. Human annotations corresponded to the automatically obtained labels in 66.7-90.0% of the cases, depending on the annotator and the dimension in question. Several examples from this experiment are given in Table 2. Given the complexity of the task and the results of the agreement between the two trained annotators on a similar task (Štajner and Yenikent, 2021, Table 7), we find
Figure 3: Distributions of MBTI dimensions across different populations/datasets (presented in percentages of all respective users): general US population (Briggs Myers et al., 1998), Twitter users (Plank and Hovy, 2015), Reddit users (Gjurković et al., 2020), Amazon Mechanical Turk users who completed our HIT (MTURK-MBTI corresponds to those users who reported their MBTI type and is based on the MBTI type they provided, while MTURK-Q corresponds to all users and is based on the answers they chose on the scale 1–5).

6 Dataset Statistics

The total number of users whose answers we collected via Amazon Mechanical Turk platform, after the manual quality check (Section 4) was 1038.

Distributions of labels for each dimension separately, for the whole dataset (MTURK-Q) and the portion that contained MBTI types entered by AMT workers (MTURK-MBTI) is provided in Figure 3 together with the distribution of labels in different populations/datasets mentioned in Section 2. As can be observed, the distributions of labels for the S/N dimension vary significantly across different datasets, with our dataset being the only one that follows a similar distribution as the one found in the general US population. For the E/I dimension, distribution of labels in all datasets deviate from the distribution in the general US population. As already mentioned in some of the previous studies (Plank and Hovy, 2015; Verhoeven et al., 2016; Štajner and Yenikent, 2020), this is not surprising, as it is known that introverts prefer online communication (Goby, 2006). For the T/F and J/P dimensions, all datasets roughly follow the distribution in the general US population.

Figure 4: MBTI distribution (340 users).

these results satisfactory.
While being reported among the least frequent ones in the general US population (Briggs Myers et al., 1998),

Distributions of the answers to our personality questions and demographics questions are presented in Figures 5 and 6.

7 Conclusions

In this study, we proposed a set of four questions for quickly obtaining MBTI labels that better correspond to the expert human annotations of MBTI traits from short texts than the commonly used MBTI labels obtained via lengthy questionnaires. Apart from being faster to administer and allowing for obtaining large quantities of short texts on various topics, the proposed method also offers a more fine-grained MBTI typology, overcoming thus the common objections about the binary nature of MBTI questionnaires. This is particularly important for advancing research efforts in automatic MBTI personality detection from texts, as those instances that come from people that exhibit equal preferences to both polarities could be filtered out from the training data, thus lowering the noise in the models. Finally, it seems that proposed way of compiling MBTI dataset via Amazon Mechanical Turk platform leads to obtaining labels with distributions closer to those of the general US population.

Watching a Language Model Learning Chess

Abstract
We analyse how a transformer-based language model learns the rules of chess from text data of recorded games. We show how it is possible to investigate how the model capacity and the available number of training data influence the learning success of a language model with the help of chess-specific metrics. With these metrics, we show that more games used for training in the studied range offers significantly better results for the same training time. However, model size does not show such a clear influence. It is also interesting to observe that the usual evaluation metrics for language models, predictive accuracy and perplexity, give no indication of this here. Further examination of trained models reveals how they store information about board state in the activations of neuron groups, and how the overall sequence of previous moves influences the newly-generated moves.

1 Introduction
Language models are now used for a variety of applications that are not, or not directly, related to Natural Language Processing tasks, and process data that is not text Parmar et al. (2018); Huang et al. (2018); Dhariwal et al. (2020). Lu et al. (2021) used a so-called Frozen Pretrained Transformer (FPT) to study finetuning on a variety of sequence classification tasks spanning numerical computation, vision, and protein fold prediction.

In this article, we use state-of-the-art methods for language models in an area that at first glance does not seem to be an application area for them, namely the area of computer chess. This is because clear rules determine what happens here, rather than the ambiguities and vagueness that characterise language.

Brown et al. (2020) demonstrated, among other things, that a language model with increasing model capacity is able to learn the rules of arithmetic to a certain degree by training it with the data of crawled websites. In the process, elementary operations were learned in a certain number space, but not beyond. Is this limitation due to the lack of capacity of the model, insufficient training time or training data that did not contain sufficient information?

In Nogueira et al. (2021), it was demonstrated that regardless of the number of parameters and training examples, Transformer Vaswani et al. (2017) models are unable to learn addition rules that are independent of the length of the numbers seen during training.

To test the ability of language models to learn rules, and assess the influence of model size, training time and available training data, we use the commonly-stressed field of “computer chess” as an example. We investigate whether a language model is able to learn the rules of chess only from the records of games played by humans.

The test area is well suited for studying the training process of language models, since training data is available in large quantities here thanks to the recording of chess games on the booming internet chess servers. Another reason is that the quality of the language model can not only be assessed with the usual evaluation metrics for language models such as perplexity, but also with the help of the chess rules to check whether correct games are generated.

Chess as an AI testing ground has also been very popular for decades, and it regained strong focus a few years ago, thanks to the work of Deepmind1 Silver et al. (2018, 2017); Tomašev et al. (2020) together with the game of GO. There, only starting from the rules with new techniques of reinforcement learning, a chess engine was created that sur-

---

1https://www.deepmind.com/
passed everything that had previously existed in terms of playing strength.

In Schrittwieser et al. (2020), as a continuation of the previous work, knowledge of the rules is now not even assumed. When evaluating Go, Chess and Shogi, without knowledge of the rules of the game, the new algorithm MuZero achieved the superhuman performance of AlphaZero\textsuperscript{2} of the earlier work, which was trained with the rules of the game.

We will use a completely different approach as a starting point to create a system that discovers the rules of chess itself. Only transcripts of games played will be used to train language models. We will then inspect the models to ascertain how the system has learned the rules of chess.

2 Formulation of the Problem

We formulate the problem of learning to play chess within the framework of the usual methodology for language models. A language model is made capable of writing texts by training it with data comprising natural language. It achieves this by completing given passages of text, inserting word by word or part of word by part of word that is likely to be next.

In recent years, major progress has been made in this field thanks to the use of neural networks. These very powerful models are not only able to form syntactically correct sentences, but also to keep the context correct across several paragraphs, thus producing texts that are almost indistinguishable from those written by humans.

This has become possible because the new model architectures called Transformers Vaswani et al. (2017); Alammar (2018) are able to capture dependencies in the texts over long distances, and sufficient training material is also available from the WWW. In order to have a supervised training setting, the systems are either fed with text as input to guess the next word (casual language modelling), or words in a whole sentence are masked, which the model then has to reconstruct (masked language modelling). The best-known representative of the first type is the family of GPT models Radford et al. (2018, 2019); Brown et al. (2020) and for that of the second type BERT Devlin et al. (2018) and its many relatives.

We will use the GPT2 model in different model sizes as a basis and train them with chess data. This data is often in the so-called Portable Game Notation (PGN) format\textsuperscript{3}. These are text files containing some metadata, such as the names of the players, the date, the ELO rating\textsuperscript{4} and more, and the transcription of the actual game in Standard Algebraic Notation\textsuperscript{5}. This part is a string that can be seen like a sentence of a natural language. The individual moves form the “words” of the sentence.

Example:

\texttt{“d4 d5 Nf3 Nf6 e3 Bf5 Nh4 Bg6 Nxe6 hxg6 Nd2 c6 Bd3 Bd6 e4 dxe4 Nxe4 Rxh2 Ke2 Rfxh1 Qxh1...”}

Adding a new word to the \texttt{SAN} string is equivalent to making a chess move. The context that a language model has in the form of the preceding words for prediction contains all of the information needed to generate the state of the chessboard. Accordingly in principle it should be possible to create a model that predicts all legal moves of a position with positive probability and all illegal moves with probability near 0.

3 Data and Pre-Processing

For training the language model, we need a large amount of game data containing legal moves. We can download these from the internet chess server Lichess\textsuperscript{6}, for example. All games played on the server since 2013 are offered there, grouped by month. A compressed PGN file is available for each month. Overall, over 400 GB of compressed data with over 1.7 billion games played.

This is a sufficiently large amount of data, even if the amount becomes much smaller after pre-processing (e.g. removing metadata). Considering that the original GPT2 language model was trained with 40GB of internet text, we have sufficient room to experiment with different amounts of data during training.

The quality of the games played plays a subordinate role in this research, as it is initially only about learning the rules. However, it would be possible to filter games via the metadata of the ELO values of the players and examine the influence on the playing strength. However, in order to avoid games that were abandoned early on, sometimes after only one move on the server, we will use a minimum length

\textsuperscript{3}http://www.saremba.de/chessgml/standards/pgn/pgn-complete.htm

\textsuperscript{4}https://en.wikipedia.org/wiki/elo_rating_system

\textsuperscript{5}https://www.chessprogramming.org/AlgebraicChessNotation

\textsuperscript{6}https://database.lichess.org/
for filtering. The pre-processing of the batch of data is undertaken with a command line programme for manipulating the PGN files, which masters almost all of the required steps. pgnextract\footnote{https://www.cs.kent.ac.uk/people/staff/djb/pgn-extract/} can perform the required transformations in a reasonable time even with large amounts of data.

In these cleansings, all move numbers, results, comments, variations, etc. are removed from the games to obtain only the pure string with the SAN notation. One line per game is written to a file. All games with fewer than 20 moves are also filtered.

4 Related Work

A very similar approach was followed in Noever et al. (2020). With slightly different pre-processing, a model also based on GPT2 was trained from game data (11,000 games and 2.19 million games). After 30,000 training steps, plausible looking games could be generated, but with about 10 percent illegal moves in the games. It was also clearly observed that fewer errors occurred in the early stages of the game, which is obvious due to the lower context required. In our experiments, we will investigate positions after different number of moves from the starting position.

Jhamtani et al. (2018) use text generation not to generate the games themselves, but rather to generate comments in text form. A specially created data set and an LSTM (Hochreiter and Schmidhuber, 1997)-based neural network are used for training.

In our work, as in Kaplan et al. (2020); Henighan et al. (2020) we will also investigate the relationship between the development of test loss in language models as a function of model size, computing capacity and data volume. In their work, power laws were found to be observed very precisely over seven orders of magnitude, showing that the result benefits from a scale up as long as the sizes are increased simultaneously and there is no bottleneck at one. If the model sizes in terms of the number of parameters are increased by eight times, the amount of data has to be increased by eight times. We will investigate the relationships with chess-specific metrics, such as the number of correctly-generated moves.

Before we start fine-tuning the model with the games data, we would like to test whether the GPT2 models of different sizes trained with English language files are inherently capable of continuing chess games. Since the training texts comprising web crawls certainly contained chess games in algebraic notation, this could be possible.

Sequences generated with the GPT2 small, for example, if started with “e4 d5”, look like this: “e4 d5 e5 e8 f8) e5 e3 f8 e9 f8 f8) 9 0-0-0-0-0-.”. While this looks a little like a game of chess, but they are hardly correct moves.

Games generated with the medium GPT2 model look like this, for example: e4 d5 18. f6 Ne5 19. Nf3 Nd4 20. Rg1 Nd6 This looks more like chess notation, but it still does not contain correct moves. This example also shows a problem that the model has with the notation, given that games are published very differently on the web and therefore also in the GPT2 training data. They are partly with numbering and partly without, which is also reflected in the example.

The Large Model and the XL Model do not give better results. We suspect that this is due to insufficient and inconsistent lot data in the training data set. A larger model capacity does not bring any progress here.

5 Training and Evaluation of the Models

The hardware used for the training was a Kubernetes cluster Brewer (2015) with NVIDIA RTX 3090 GPUs, each with 24 GB of video RAM and 256 GB of main memory.

For the implementation, the Transformers\footnote{https://huggingface.co/transformers/} package Wolf et al. (2020) from HuggingFace\footnote{https://sgugger.github.io/the-1cycle-policy.html} based on Pytorch Paszke et al. (2019) was used.

The learning rate search was conducted according to Smith (2018). We start fine-tuning the model as the learning rate increases from very low to very high, and stop when the loss starts to truly become out of control.

Fastai Howard and Gugger (2020) was used for the training, using the 1-cycle-policy Smith and Topin (2019).\footnote{https://sgugger.github.io/the-1cycle-policy.html}

With batch sizes just fitting on the GPU memory, the models were saved after some epochs of training for the evaluations.

When language models generate sequences of words, the same sequence will always emerge if the word with the highest probability is always chosen next. Furthermore, the models often tend to repeat sequences of words. This also applies to the
generation of chess games here. Therefore, random mechanisms such as top-k sampling Fan et al. (2018) and top-p sampling Holtzman et al. (2019) are used to generate the games. These techniques reduce the tendency of repetition, although it can still occur, as Welleck et al. (2020) have investigated.

To evaluate the models, games are generated in different ways:

- From a list of typical opening positions after two moves.
- From positions of games from a game data set after a given number of moves.
- From randomly-generated positions after a given number of moves.

For all of these games, the average number of correct moves generated is counted. These three chess-specific metrics for assessing the generated moves pose different challenges to the language model. For the first evaluation criterion, it is easiest to generate legal moves, since all test positions were included in a large number of the training data games, and therefore it is sufficient for the model to remember the data. A generalization in the form that the rules of chess were actually learned is only necessary for very long generated move sequences.

The second method presents more of a challenge, increasing as the length of the given number of moves increases. Since the game data set used for the test is not included in the training data, as the length of the given moves increases, increasingly more positions will appear that the model has never seen before. Therefore, the model has to learn the rules to generate valid moves.

The third metric uses starting positions generated by a random sequence of moves. A large proportion of these moves have therefore never appeared in human games, nor in the test data set. Furthermore, the move patterns that appear are very different from those in human games, as well as from those in conventional chess programs. It is therefore very difficult for the model to generate regular moves for these sequences. Even for humans, handling such random positions is very difficult. Chase and Simon (1973) has found in experiments with chess grandmasters and amateurs that while good chess players can easily remember typical positions, they have problems with random positions.

For each trained model, the training loss, validation loss, accuracy predicting the moves in the data and perplexity are also calculated.

6 Results

For encoding, we use byte pair encoding, and therefore a typical chess game of 50 moves from both sides requires about 200 tokens for encoding the whole game. However, a game can be much longer. We use a maximum sequence length of 256 and cut of the rest of the moves.

We trained different model sizes of GPT2 (small, medium, large) with different numbers of games (99,604, 577,202, 2,163,417 games) to investigate the influence of the two factors on the learning process. To assess the results, the models were each subjected to an evaluation after a few epochs, using the evaluation metrics described in the previous section. Appendix A-1 shows how the predictive accuracy of the language model evolves with the number of GPU training hours.

The small amount of training data leads to a strong increase in accuracy for all three model sizes after only a few days of training. With more data, no model shows this increase. The different models seem to learn at about the same rate, with the small model being slightly slower.

Alternatively, if we look at perplexity as an evaluation measure, the same picture emerges. All models with a small training data set lead to a faster drop in perplexity, which indicates a better prediction of the language model. All other combinations of model size and amount of data seem to perform the same.

We now want to investigate whether the models with little data are able to learn the chess rules faster and whether it truly makes no difference with the other combinations.

With the chess-specific metrics, we can get to the root of this, and look at the performance of the models as a function of training time.

From five typical opening positions after one move by both sides, five games were generated with the models with top-p sampling (p=0.92), and then it was checked how many moves were correct until the first incorrect move was made. The average of these 25 games was calculated. Appendix A-2 shows how this performance for the respective models developed with the training time.

Top-p sampling is used to check the models’ ability to produce not only the most likely move,
but also other valid moves. In a chess position, more than one move is usually possible.

For each combination of models and data set, the result was plotted over the training time and a logarithmic fit was drawn. No data are available for the GPT2 large model with the larger amount of data because hardly any models could be trained in the available time period due to the long training time per epoch.

In contrast to the accuracy, this measure shows that the models with a small amount of data perform significantly worse.

The best values are delivered by the medium model with medium data volume. This is in sync with the observation in Kaplan et al. (2020) that model size and data volume should be increased together for good results.

The second metric is a more demanding task, as the games are not generated from a typical starting position after one move, but rather from positions after ten moves, taken at random from games played. These games were not from the training data set.

Games are generated from 100 random positions using top-p sampling (p=0.92), and then tested to see how many moves were correct from this position, whereby the mean value is then calculated. Appendix A-3 shows how this performance for the respective models developed with the training time. Again, a logarithmic fit was drawn.

For this task, all models benefit from more training data, although there are no differences in model size.

As a third metric, we have chosen a task that is even more challenging, and it should make it clearer whether the task was solved based on learned rules rather than pure memorisation of variants.

Again, starting with top-p sampling (p=0.92), 100 games were generated from one position after ten random moves, and then checked to see how many moves were correct from this position, whereby the mean value was then calculated. Appendix A-4 again shows how this performance for the respective models developed with the training time.

It can be seen that this task is much more difficult, as the models now only manage to correctly execute sequences of a few moves on average. However, the same effect can be seen as with the two previous metrics, namely that all models benefit from a larger amount of data. In terms of model size, there are few differences.

7 How Is Chess Knowledge Stored in the Model?

So far, we have explored how language models benefit from more parameters in the model and more training data when learning chess rules. Now we want to ascertain whether there are patterns in how the information of the chess rules is stored in the parameters of the models. We will use different visualisations for this purpose.

For this purpose, different approaches help to visualise language models. On the one hand, we look at the influence of different inputs on the generated words/moves, as shown in Arrieta et al. (2020); Li et al. (2015), and on the other hand, we can look at the activation of the different neurons in the models, as shown in Karpathy et al. (2015); Poerner et al. (2018); Dalvi et al. (2019).

When properly visualised and studied, neuron activations can reveal the roles played by individual neurons and groups of neurons. We use the Eccox library10 Alammar (2021) for analysis.

In order to combine the groups of neurons involved in the same tasks, factorisation methods for matrices are used, whereby the library used employs NMF for this purpose.

Let us look at the inner workings of a trained model for moves from some sample positions. The first position is from the opening phase and it is a special situation where only one legal move is possible (Fig. 1).

If we look at the influence of the individual parts of the sequence in Fig. 2, the moves that led to position Fig. 1, on the new move, we see that the last parts have the strongest influence, but otherwise the entire sequence also influences the output.

The colour code shows the strength of the influence, and alternatively we can also show the influence of the individual parts as a percentage (Fig. 3).

How certain is the model that the generated move is a correct one?

For this purpose, we look at the probabilities that the model assigns to the individual possible tokens at the end of the last layer of the generator part. The move is generated in two parts, and it shows a high probability of the generated move for both

10https://www.eccox.io/
Let us now look at the activations of the neurons and try to see how the model stores information about the chessboard from the move sequences. In order to generate valid moves, the language model needs a representation of the chessboard and its pieces in the states of the neurons.

If we look at the activation of the neurons by group, we see that one group (red in Fig. 5) is active on the parts of the text responsible for the row information on the chessboard, and another for the column and piece information (blue in Fig. 5). The other two are active at the beginning or end of the sequence.

Let us now look at another position, which comes from the so-called “Game of the Century”\(^1\). In the complicated position from the middle game in Fig. 6 with many possible moves, the model reaches its limits. It recognises that a piece on the d-file was captured last and wants to capture it back with Rxd or Qxd. However, there is no valid move for this in this position. The representation on the board was not correctly mapped in the neurons here, so no valid moves are generated.

The probability for possible next tokens in the last layer of the network is also distributed over

---

\(^1\)https://en.wikipedia.org/wiki/The_Game_of_the_Century_(chess)
many candidates (Fig. 7).

As in position 1, virtually the entire sequence of previous moves has an influence on the new move to be generated, as can be seen in Fig. 8.

In this example, again the specialisation of groups of neurons on the row information and the figure and column information can be seen. However, the activations are lower at the beginning of the sequence.

8 Conclusion and Future Work

In the two example positions, it can be seen that the whole sequence has an influence on the generated move, which is necessary to generate correct moves.

By looking at the activation of neurons, we could see that the information about the row, column and type of figure is stored in different groups of neurons. Thus, the model seems to organise the storage of the information necessary to represent the state of the board. So the training could benefit from a longer string representation of the games such as the long algebraic notation since the mechanics of moves are more directly accessible. Because rows, columns, and pieces are all represented as separate tokens.

In order to study the learning process for larger models and larger data sets we would like to use distributed training with Falcon (2019) with higher computational capacity, and the optimizations proposed in Rajbhandari et al. (2020); Rasley et al. (2020); Zhang and He (2020); Ren et al. (2021); Tang et al. (2021); Rajbhandari et al. (2021); Li et al. (2021).

We have only investigated the learning of the rules of the game here. Accordingly, investigating the possible playing strength of the language models as a function of the training data quality would be an interesting extension of the investigations. The influence of the selection of the training data according to the playing strength of the players involved and the model size would have to be considered here.

Abstract

The last several years have seen a massive increase in the quantity and influence of disinformation being spread online. Various approaches have been developed to target the process at different stages from identifying sources to tracking distribution in social media to providing follow up debunks to people who have encountered the disinformation.

One common conclusion in each of these approaches is that disinformation is too nuanced and subjective a topic for fully automated solutions to work but the quantity of data to process and cross-reference is too high for humans to handle unassisted. Ultimately, the problem calls for a hybrid approach of human experts with technological assistance.

In this paper we will demonstrate the application of certain state-of-the-art NLP techniques in assisting expert debunkers and fact checkers as well as the role of these NLP algorithms within a more holistic approach to analyzing and countering the spread of disinformation. We will present a multilingual corpus of disinformation and debunks which contains text, concept tags, images and videos as well as various methods for searching and leveraging the content.

1 Introduction

The topic of fake news and intentional spread of disinformation has been gaining increasing prominence over the last decade. The distinction of terminology and attempts to classify various erroneous or misleading statements online is constantly evolving but disinformation, as shown in Fallis (2015), has recently settled as the commonly accepted term to describe the intentional and systematic spread of incorrect information.

The spread of this incorrect information is strongly reliant on social media, causing a strong emotional reaction and quick propagation before its inaccuracy can be effectively exposed. This means that in most cases minimal effort is put into crafting the disinformation, instead relying on speed, volume and reuse of slightly modified pre-existing materials. There are, of course, always new disinformation materials popping up but they are in the minority and should they gain traction, they will very quickly get picked up, modified slightly and reused.

A very stark example of this kind of interaction was provided in the early months of the Covid pandemic as reliable scientifically-tested information was still rather scarce and the void was filled by a wide variety of rapidly-spreading fake and unsupported claims. This can be viewed both from the perspective of journalists mobilizing to counteract the spread and from that of researchers looking into assisting their efforts e.g. in identifying spread of disinformation that has already been debunked as in Singh et al. (2021) or in tracking the comparative effect of disinformation and debunking tweets as in Jiang et al. (2021).

This means that combating the spread of disinformation can happen on a variety of levels. One option is to identify the creator and limit their reach - a replacement will pop up eventually but rebuilding a presence in the social network requires time and resources. Alternatively, it is possible to identify a piece of disinformation early in its spread and expose it to the people who interact with it before it really gains traction. Finally, it is possible to monitor social media for trending topics and work on creating convincing well-supported debunks to new disinformation that has gained popularity. An ideal approach would combine all three aspects in some manner.

Finally, the reality is that while disinformation might typically involve minor or simple modifi-

1https://weverify.eu/blog/speeding-up-the-debunking-process/
cations, it is still intentionally crafted to be misleading and is constantly evolving and adapting. This makes completely automated approaches to combating it impractical. Meanwhile, the sheer volume of information that needs to be tracked, analysed and correlated makes a completely manual approach equally impractical. The solution will inevitably then involve a hybrid approach.

To that end, we present a data set based on a collection of fact-checker created debunks of pieces of disinformation that has been extended with additional metadata. Several forms of advanced search functionality have been developed on top of it in order to make discovering relevant content in the data set as straight-forward as possible. This will allow fact-checking experts to easily check for previous work on disinformation they encounter, point to previous instances of it being used and react quickly to its spread in order to counter it early on.

2 The Data Set

The data set used for our experiments is based on a snapshot of the Database of Known Fakes (DBKF). It is a collection of debunking content from highly respected fact-checking organizations around the world extended with additional metadata related to said debunks in order to enable the advanced search and correlation functionality we present here.

Figure 1 shows an overview of the major types of objects contained within the DBKF and the connections between them. At its core, the data model of the data set is based around the Claim and Claim-Review format defined within schema.org which is already familiar to and used by many fact-checking organizations.

The core objects defined within the schema.org specification are a Claim (a short statement summarizing the target of the debunk) and ClaimReview (a typically article-length debunk of the claim being discussed). As can be seen in Figure 1, these two objects are extended with additional explicit objects. The two most important additions areAppearances and Evidences - the former are links to posts where a specific Claim is being made and the latter are external content supporting the explanation and reasoning contained within a debunk.

Appearances are automatically expanded to include additional metadata available at the external website (more on that in Subsection 3.1) and a number of state-of-the-art systems are used to enrich the objects further (more on that in Subsections 3.3 and 4.2). Some of this metadata is more detailed and contained within specialized objects such as Image, Video, Concept and Annotation (which is an instance of a concept at a specific location in a document’s text).

At the time of writing, the data set contains

- **Claims**: 32,138
- **Debunks**: 32,220
- **Appearances**: 74,099
- **Evidences**: 348,100
- **Concepts**: 110,158
- **Annotations**: 359,032
- **Images**: 9,774 links to an image of which 9,217 unique image urls
- **Videos**: 9,866 links to a video of which 9,745 unique video urls

but the numbers are always growing as new input is being collected from many fact checking and debunking organizations daily.

Figure 2 provides a specific example of a debunk that might be retrieved by the system (pre-advanced enrichment steps). The claim is that an immigrant destroyed a statue in Italy, three appearances provide links to three tweets that made that claim, the debunk disproves the claim and explains what actually happened while the evidences support that explanation.

2.1 Sources

The contents of the data set are sourced from organizations in the Facebook third-party fact-checking program. At the time of writing the data set contained data from 17 separate organizations in at least 13 languages and based on disinformation encountered in over 20 different countries.

Due to the variety in article formatting and institutional approaches to writing the debunks, there is some significant variety in the details of the retrieved debunks but the objects in the high level model presented in Section 2 are present for all

---

2. https://schema.org/Claim
simplification of existing debunking content and serve as a comprehensive repository.

3 Enrichment

This section will go over the additional enrichment steps that are used to take the DBKF beyond a simple collection of existing debunks and unlock the ability to do advanced searching and correlation by expanding the metadata available on the debunks. This contains the additional metadata added to Appearance and Evidence objects, language tagging of all texts and named entity recognition.

3.1Appearances and Evidence

When originally extracted from the debunking articles, appearances and evidences are just plain urls. These objects are expanded to include additional metadata, whenever possible. This has multiple goals:

1. Extract text, images, videos, author information, publication time, etc. to be used in searching, filtering and analysis

2. Archive the link so that it is still accessible should the original be removed (often the case with disinformation that gets debunked)

3. If the link is already an archive, extract the original url for domain analysis purposes

The retrieval of this metadata is, of course, not always possible. Aside from the common case of a link being removed or simply inaccessible, there is also no guarantee how the target website will be formatted. To that end we have chosen...
to focus metadata expansion on a few social media websites that are particularly common (Twitter, Facebook, YouTube), popular archive websites (perma.cc, archive.org, archive.is, etc.) and websites that follow the Google guidelines for publishing news articles with properly tagged metadata. This allows us to collect at least some metadata for over 90% of appearances.

3.2 Language Recognition

Language detection is a simple task but an important first building block for some of the more complex enrichment steps presented later such as for selecting the appropriate NER pipeline in subsection 3.3. For this reason we ran the texts of claim, debunks and appearances through a well-tested language detection algorithm- Shuyo (2010).

It is worth noting that while language detection is not an especially difficult task, the contents of the data set are quite varied in a number of ways - quite a variety of languages, mixed-language texts, various lengths (from few words to multi-page articles). This all means that some amount of errors will inevitably be introduced at this step of the process.

In Figure 3 we can see the language distribution produced by the algorithm. The distribution of languages corresponds to what we expect to see based on the fact-checking sources present in the data set. English, Spanish, German and French are currently the major languages and there is a long tail of languages where the total number of available debunks is much lower.

It is worth keeping in mind that the distribution is both a reflection of currently active fact-checking organizations and the specific sources that are processed and ingested in the system. This is to say that the situation is quite fluid and more languages can become relevant in the future.

3.3 Locations and Concepts

The language tagging of all text in the data set allows the final step in metadata enrichment - named entity recognition carried out over the corpus. This task was further divided in two, based on the needs of the users and analysis of available algorithms. After reviewing the literature on comparative analysis of available algorithms Schmitt et al (2019), we ran some additional comparisons of different approaches since the diverse nature of our data set and unconventional target concepts make comparison over standard data sets less feasible.

Table 1 shows a comparison between an in-house developed NER pipeline targeted at the publishing domain, which is based on GATE\(^6\) using a subset of the Wikidata\(^7\) data set (referred to as CES - Concept Extraction Service), the default spaCy pipeline\(^8\) and the NER functionality of Google Cloud\(^9\). The comparison was carried out over a variety of language although the CES algorithm was only used on English texts.

<table>
<thead>
<tr>
<th></th>
<th>Detected</th>
<th>P (strict)</th>
<th>P (partial)</th>
</tr>
</thead>
<tbody>
<tr>
<td>CES</td>
<td>156</td>
<td>0.74</td>
<td>0.95</td>
</tr>
<tr>
<td>spaCy</td>
<td>171</td>
<td>0.66</td>
<td>0.83</td>
</tr>
<tr>
<td>Google Cloud</td>
<td>190</td>
<td>0.59</td>
<td>0.81</td>
</tr>
</tbody>
</table>

The conclusion is that CES, while limited to only English, has a notable performance advantage. Meanwhile the spaCy pipelines and Google Cloud offering are roughly on par but both support a larger variety of languages.

For that reason, CES was used to do NER of location mentions over the data set. It was decided that the better performance in correctly identifying location mentions offsets the limiting of that enrichment to only English. Conversely, the general "concept" tags rather typical POL entities are more useful when applied to as many of the texts as practical.

A word of caution on the applicability of simple numerical comparison in the case of general con-

\(^{6}\)https://gate.ac.uk/
\(^{7}\)https://www.wikidata.org/
\(^{8}\)https://spacy.io/usage/models/
\(^{9}\)https://cloud.google.com/natural-language
cept recognition. The case of disinformation spread is a very challenging one for the NER task since the uniquely identifying concepts associated with given misinformation are quite varied and much less well-defined than the typical POL formulation of the task. Words like "immigrant", "hospital", "lemon", "vaccine", "5G" and many others have actually proven quite important but their popularity and usefulness is actually quite limited in time. To that end we placed particular importance on the system's ability to identify such concepts when they first begin to gain prominence.

4 Search

The final step in unlocking the full potential of the data set is to enable powerful search functionality that can make discovering existing debunk information and locating similar cases of disinformation in the past as quick and easy as possible. This kind of searching should utilize the full capability of the collected and enriched data set and can be used as a stepping stone to semi-automated and automated systems such as early detection of disinformation and chat bots. It is also a first step to being able to detect larger trends within the data such as tracking the spread of a particular disinformation claim across countries or watching a particular piece of disinformation change and evolve in response to fact-checker debunkers.

There are several aspects of this search functionality that build on each other. Firstly, we will describe the full-text and faceted search then near-duplicate detection based on visual similarity and multilingual search that uses latest neural machine translation. Subsection 5.1 will also briefly discuss what we envision these search capabilities building to in the future.

4.1 Facets

The basic functionality needed by expert fact-checkers is the ability to quickly look for debunkers related to the claim they are currently investigating using keywords or even phrases. To this end, we have implemented a full-text search based on the Elasticsearch engine. Results from the full-text search are presented, based on the user preference, either by the relevance score returned by Elasticsearch, or by date of publication. In order to fully exploit the information collected from the sources, as well as the metadata and enrichments created while populating DBKF, we have implemented faceted search. The facets currently support filtering and slicing DBKF content or search results by: language, author, debunk publisher (source), time of publication, locations and concepts. For example, using the full-text search with the "5G" keyword, together with facets can help debunkers quickly find the false claims that were circulating in different languages on the subject during a specified timeframe. Similarly, fact-checkers can use facets to quickly check what locations are mentioned in "vaccine" (selected from the concept facet) related disinformation. The ability to search DBKF with the help of facets can be beneficial not only to verification professionals but also to researchers in the field of disinformation, social scientists and policy makers.

4.2 Visual Similarity

Searching based on visual similarity relies on the research performed by Kordopatis-Zilos et al. (2019) and is carried out by using the near duplicate detection (NDD) service. This service supports indexing and searching for both images and videos based on visual similarity between the contents. This means that every image or video discovered within appearance and evidence objects is automatically indexed within the NDD service in order to be available for visual similarity searches.

When a visual search is initiated by the user, the image or video they provide is also indexed into the NDD service and then all returned results are tied back to their corresponding debunkers within the DBKF. This effectively enables us to discover debunkers that contain similar images and videos even if they have been reuploaded or slightly modified which are the typical way bad faith actors reuse them for spreading disinformation.

It is worth noting that once indexed, an image or video does not need to be stored in its original form and, in fact, due to concerns about storage and distribution rights of digital content, they are usually not stored locally. Instead, the final representation of the visual object is a single vector in a highly-dimensional space which cannot be used to recreate the original digital object. In practice, this means that the visual similarity service can discover connections to similar content but cannot show that content to the user.

As a practical step to combat the frequent disap-
pearance of content tied to disinformation, we work with internet archiving websites to preserve any Appearance when we initially encounter it. These websites have a procedure for the content owner to have the a specific archived item removed but in practice while the social media post often disappears within months, the archiving organizations are rarely contacted to have the archived content removed. So as a response to a visual similarity search, we provide the similar item, a link to its original url and a url to an archiving website making it quite likely but not guaranteed that the user can view the original image or video.

There are other image and video processing services available for integration with the contents of the DBKF such as automated image forensic analysis Zampoglou et al. (2016) and deep fake detection Charitidis et al. (2020) but those are more suited to producing evidence to support debunks than for searching the data set. That said, it is possible to extend the metadata associated with debunks to reflect the kind of visual manipulations encountered within a piece of disinformation and make that available for search as another facet similar to the ones described in Subsection 4.1.

4.3 Multilingual

The newest kind of search functionality enabled in the DBKF focuses on the multilingual aspect of the data set. Its intent is to vastly improve the ability to track the spread of disinformation in international situations.

The search utilizes the latest advances in neural machine translation and the translation is based on M2M-100 - a many-to-many multilingual translation model presented in Fan et al. (2020). It supports bidirectional translation between any pair of over 100 languages and shows a marked improvement in translation between non-English languages when compared to English-centric model. English is often not the first language in which disinformation appears so this is a very useful feature for our use case.

As shown in Figure 4, we have chosen to focus on the eight major languages of the data set. This is a reflection of the analysis shown in Figure 3 about the current distribution of data in the data set. A major advantage of the M2M-100 model is that it allows seamless adaptation to changes in the available data.

To quickly summarize the workflow presented, the search first identifies the language of the query. If it is a supported language, it translates it into all other supported languages and sends off a multi-expression query to be processed. Otherwise it forwards it without modifications. The search returns the results in order of relevance without regard to which translation they have matched.

The decision to not translate queries in unsupported language is a reflection of the limitation of the search. If the search query is too short or ambiguous (a not unlikely situation), the language tag will be unreliable and the translations will likely be of equally low quality.

5 Conclusion and Future Work

In conclusion, the DBKF already contains a large amount of data extended with useful metadata and powerful search capability. This can make it a powerful tool in the arsenal of fact-checkers and also allows its incorporation in counter-disinformation campaigns where people are targeted with evidence of a claim’s falsehood before they spread it unknowingly. The contents of the database are also constantly growing with the automatic ingestion of new content. Future developments can include.
the addition of new fact-checking sources, support for metadata-expansion of more types of social media posts and further building on the modeling and search functionality.

5.1 Multimodal Search

One improvement of particular interest is the option to enable a true multimodal search over the data set. As discussed in Section 4, we already have full-text, faceted, image and video search so the next step would be to combine them into a single endpoint. This would enable to effortlessly search for debunks relevant to a social media post, essentially the automatic ability to ask "Is this post repeating known disinformation?"

The challenge is actually combining the various results in a meaningful way. The various modalities operate on completely different scales, not to mention that they are all optional and possibly multi-valued e.g. how do you compare a post with a sentence of text, three concepts, a location mention and five images to a debunk that has three pages of text, seventy concepts, no images and two videos? It is by no means an insurmountable obstacle but extensive experimentation and careful fine-tuning will be required to produce intuitive and helpful results.

5.2 Model Extension

There are various ideas for adding additional aspects to the data model. One idea briefly mention in Subsection 4.2 is tagging debunks based on the type of disinformation techniques they represent e.g. deep fake videos, out-of-context images, etc. Work has began on building a vocabulary for disinformation techniques but we are consulting with fact-checking experts to align it to their expectations and needs.

The more interesting but complex direction of expansion would be to incorporate deeper understanding and tracking of disinformation campaigns into the model. This would allow to explicitly connect individual debunks into the larger trends they are coming up against.

Abstract

We study the task of learning and evaluating Chinese idiom embeddings. We first construct a new evaluation dataset that contains idiom synonyms and antonyms. Observing that existing Chinese word embedding methods may not be suitable for learning idiom embeddings, we further present a BERT-based method that directly learns embedding vectors for individual idioms. We empirically compare representative existing methods and our method. We find that our method substantially outperforms existing methods on the evaluation dataset we have constructed.

1 Introduction

Chengyu (成语, literally meaning “set phrases”) are a type of idiomatic expressions in Chinese that usually consist of four Chinese characters. They are mostly derived from ancient Chinese literature and many of them are based on historical stories. The semantic meanings of Chengyu are often non-compositional and sometimes metaphoric. For example, the Chengyu 瓜田李下 literally means “melon field, beneath the plums,” but its idiomatic meaning is to warn people to avoid situations where a person may be easily suspected of wrongdoing. Chengyu are commonly used in modern Chinese language, and using computational methods to understand Chengyu plays an important role in Chinese language understanding. For example, a recent work studied how to improve essay writing with recommending Chinese idioms (Liu et al., 2019), and others studied how to improve reading comprehension by correcting usage of Chinese idioms (Wang et al., 2020) and differentiating synonyms of Chinese idioms (Long et al., 2020). In this paper, we refer to Chengyu as Chinese idioms, although there are also other types of idioms in Chinese.

Recent years have witnessed the success of deep neural networks for many NLP tasks. A central idea behind deep neural networks for NLP is to use dense embedding vectors to represent language units including words, phrases and sentences, and such embeddings have been shown to be useful for many tasks such as sentiment analysis (Yu et al., 2017), question answering (Hao et al., 2017) and machine translation (Zhou et al., 2016). We therefore believe that it is also desirable to derive embedding vectors for Chinese idioms that can accurately capture their semantic meanings. However, it is not clear whether existing methods for Chinese word embeddings are effective in deriving good Chinese idiom embeddings, and there are at least two reasons for this.

First, existing Chinese word embedding evaluation datasets do not have sufficient coverage of idioms. For example, in the commonly used WordSim-240 (Wang et al., 2011) and WordSim-296 (Chen et al., 2015) datasets for Chinese word relatedness, no idiom is found. More recently, Huang et al. (2019) released a COS960 dataset with similarities of Multiword Expressions (MWEs). Although COS960 covers 150 Chinese idioms, this is still a relatively small number, and only 20 MWE pairs in COS960 consist of both idioms. For the word analogy task, another commonly used evaluation task, Chen et al. (2015) created the first Chinese dataset with 1,125 analogies, but no idiom is included. Li et al. (2018) released a large and balanced dataset CA8 for word analogy. Although CA8 has 400 entries that contain idioms, this is still a relatively small number, and only 20 MWE pairs in COS960 consist of both idioms. For the word analogy task, another commonly used evaluation task, Chen et al. (2015) created the first Chinese dataset with 1,125 analogies, but no idiom is included. Li et al. (2018) released a large and balanced dataset CA8 for word analogy. Although CA8 has 400 entries that contain idioms, they only cover 32 unique idioms and no idiom pairs are included. With this lack of coverage of idioms in existing evaluation datasets, we cannot judge whether existing Chinese word embedding methods work well for Chinese idioms.

Second, it is reasonable to suspect that existing word embedding methods for Chinese have
limitations that make them less suitable for Chinese idioms. For non-contextualized word embedding methods such as Continuous-Bag-Of-Words (CBOW) and Skip-Gram with Negative Sampling (SGNS), they treat contexts as bags of words, but given the complex meanings of Chinese idioms, learning their embeddings from bag-of-word representations of contextual words without considering the order and interactions between these contextual words may not be sufficient. Existing pre-trained non-contextualized Chinese word embeddings are also usually trained with a relatively small context window, but the semantic meaning of a Chinese idiom is often based on a larger context where the idiom appears. In fact, it has been observed that larger context windows result in more topicality (Levy and Goldberg, 2014; Bansal et al., 2014), and we suspect that for learning Chinese idiom embeddings a larger context window helps. Therefore, existing pre-trained non-contextualized Chinese word embeddings may not capture the semantic meanings of Chinese idioms well. On the other hand, recent contextualized word embedding methods such as BERT (Devlin et al., 2019) and its variants (e.g., ERNIE (Zhang et al., 2019)) consider longer contexts and use attention mechanism to model interactions between words, but since they do not focus on learning word embeddings, they do not learn a single embedding vector for each Chinese idiom. Although we can aggregate the character-level representations of the characters inside an idiom and treat the aggregated representation as the idiom embedding, since many Chinese idioms' semantics are non-compositional, this simplified approach is likely not ideal.

In this paper, we study the problem of learning and evaluating Chinese idiom embeddings. To overcome the first challenge stated above, i.e., the lack of suitable evaluation dataset for Chinese idiom embeddings, we construct an evaluation dataset that contains Chinese idiom synonyms and antonyms. We also define two evaluation metrics to measure how close the ground truth idiom synonyms are in an embedding space in order to quantify the quality of the embedding space. To overcome the second challenge stated above, i.e., the potential limitations of existing word embedding methods for Chinese idioms, we propose to adapt a method (Tan and Jiang, 2020) for Chinese idiom recommendation to learn idiom embeddings. This method learns a single embedding vector directly for each idiom and encodes the contextual information using BERT.

With the evaluation dataset we have created, we empirically compare a SGNS-based non-contextualized word embedding method for Chinese, two variants of BERT for Chinese, and our Chinese idiom embedding method. We find that based on the two metrics we have defined to measure closeness of synonyms in an embedding space, our method performs substantially better than existing methods. We also find that our method can better distinguish idiom antonyms from idiom synonyms than existing embedding methods. We also conduct further analysis to demonstrate that embedding methods that rely more on Chinese character information show advantages only when the synonyms share many common characters.

The contributions of our work are twofold: (1) We construct an evaluation dataset to facilitate the evaluation of Chinese idiom embeddings. Code and data are released on github. (2) We present a BERT-based method that directly learns Chinese idiom embeddings, and we empirically compare this method with existing Chinese word embedding methods to demonstrate both the importance of learning a single embedding vector for an entire idiom and the importance of using BERT to encode the context when learning these idiom embeddings.

2 Related Work

Word Embeddings

Word embedding is an important technique in NLP. It computes dense meaning representations for discrete words. It is built upon the distributional hypothesis that linguistic items with similar distributions have similar meanings. Several methods have been proposed to learn non-contextualized word embeddings efficiently, including Continuous Bag-Of-Words (CBOW), Skip-Gram with Negative Sampling (SGNS) and GloVe (Pennington et al., 2014). In this paper, we use an SGNS-based Chinese word embedding method as a representative non-contextualized word embedding method for evaluation. Contextualized word embeddings such as ELMO, GPT and BERT have been developed in recent years and shown their high effectiveness for many NLP tasks. In this paper, we use two representative BERT variants, BERT-wwm and ERNIE, to evaluate Chinese idiom embeddings derived from pre-trained Chi-
Chinese BERT models.

**Evaluation of Chinese Word Embeddings** For word embeddings, existing evaluation methods can be categorized into intrinsic and extrinsic methods (Schnabel et al., 2015). Commonly used intrinsic methods include word similarity and word analogy, while extrinsic methods rely on downstream NLP tasks (Pennington et al., 2014). In this paper, we use an intrinsic method to evaluate Chinese idiom embeddings.

Several benchmark datasets for evaluating Chinese word embeddings have been released (Wang et al., 2011; Finkelstein et al., 2001; Jin and Wu, 2012; Chen et al., 2015; Guo et al., 2014; Huang et al., 2019; Li et al., 2018). But as we pointed out in Section 1, existing datasets have low coverage of Chinese idioms.

**Neural Network Models for Chinese Idiom Understanding** Despite the importance of Chengyu in Chinese language understanding, there have been only a few pieces of work on Chengyu using neural models (Jiang et al., 2018; Liu et al., 2019; Zheng et al., 2019). Chinese Chengyu Recommendation (CCR) has been addressed in recent years (Liu et al., 2019; Jiang et al., 2018; Zheng et al., 2019). In this paper, we adapt a method for CCR (Tan and Jiang, 2020) to learn Chinese idiom embeddings.

### 3 Construction of the Evaluation Dataset

A standard intrinsic task for evaluating word embeddings is word similarity (Bakarov, 2018; Wang et al., 2019). For Chinese idioms, a natural choice of idiom pairs that are semantically similar are synonyms or near-synonyms. Although previously Wang et al. (2013) constructed a Chinese idiom knowledge base that contains idiom synonyms, this knowledge base is not publicly available. On the other hand, there exist online resources containing synonyms and near-synonyms of Chinese idioms. We choose two websites, kxue.com (快学网) and Baidu Baike (百度百科), as the sources from which to crawl idiom synonyms and near-synonyms. We also collect idiom antonyms from these two websites because an antonym of an idiom is often topically related to that idiom and therefore may be also close to that idiom in an embedding space. However, we expect a good idiom embedding method to be able to separate antonyms from synonyms.

**Idiom Vocabulary:** According to Wang et al. (2013), there are in total around 38k Chinese idioms, among which around 3.5k are commonly used. In order to obtain a vocabulary of Chinese idioms with high coverage, we merge the idioms found in the following four resources: (1) Chengyu Daquan5, (2) Xinhua Chengyu Dictionary6, (3) Chengyu Cloze Test7, and (4) ChID.8 This gives us a Chinese idiom vocabulary with 33,237 idioms.

**ChIDsyn:** As we have pointed out earlier, we believe idiom synonyms can help us evaluate idiom embeddings. To construct a large dataset of Chinese idiom synonyms, we crawled synonyms from two websites: (1) Kxue.com is an online Chinese thesaurus. It has a dedicated page where Chinese idiom synonyms are listed. Each entry in this list consists of a key and a value, where the key is a Chinese idiom and the value is one or more other Chinese idioms that are near-synonyms of the key. We crawled all the entries from this idiom synonym page on kxue.com.8 Baidu Baike is an online encyclopedia in Chinese. For each idiom, there is a section called 成语辨析 (Chengyu Differentiation) that lists its synonyms and antonyms.9 We crawled the synonyms of those idioms in our vocabulary that can be found on Baidu Baike. In total, we obtained around 30k entries of Chinese synonyms. We then removed those idioms in the data that are not in our idiom vocabulary as described earlier. In the end we obtained a total of around 21K entries in our synonym dataset, where each entry consists of a query idiom and a set of other idioms that are the query idiom’s synonyms or near-synonyms.

We observe that a significant portion of the synonyms share common characters with the query idioms. For example, 山盟海誓 (oath of eternal love) and 海誓山盟 are treated as near-synonyms.

---

5<https://github.com/zhengcj1/ChID-Dataset>
7<https://github.com/bazingagin/chengyu_data>
8<https://github.com/zhengcj1/ChID-Dataset>
in our dataset, but these two idioms contain exactly the same set of Chinese characters. In fact, they are variants of the same basic form. Another example is 挨家挨户 (door to door) and 挨门挨户, which share three common characters. In general, it is not uncommon for Chinese idioms to have such variants due to historical reasons such as misuse (including literary malapropism). Although these are valid near-synonyms, we suspect that they may affect the evaluation of idiom embeddings. This is because those idiom embeddings that rely more on character-level information are likely to gain advantages when evaluated on these near-synonym pairs sharing common characters. For example, if an idiom embedding is obtained by averaging the character embeddings of its component characters, then it is very easy for this type of idiom embeddings to recognize that 山盟海誓 and 海誓山盟 are near-synonyms (because they would have the same average character embedding), but we would not be able to know whether such embeddings truly capture the semantic meanings. We also suspect that for those idioms that have near-synonyms sharing common characters, their semantic meanings are more likely to be compositional and thus less idiomatic. For example, for the idiom 挨挨挨户, the character 挨 means “in sequence” and both 家 and 户 mean “household.” The meaning of the idiom, which is “door to door,” can be directly inferred from the meanings of the characters. Therefore, when the character 家 (household) is replaced with the character 门 (door), the meaning of the idiom remains the same.

Consequently, we move those synonyms that share at least two common characters with the query idioms into a separate dataset, which we will not use as the main evaluation dataset. The remaining synonyms always have no more than one common character with their query idioms. We refer to this cleaned synonym dataset as ChIdSyn, and the separate dataset containing synonyms sharing two or more common characters is referred to as ChIdSyn-com. We will use ChIdSyn-com for additional analysis in our experiments. Statistics of ChIdSyn and ChIdSyn-com can be found in Table 1.

**ChIdAnt:** From the same two websites, we have also collected around 10K entries in an antonym dataset which we refer to as ChIdAnt. Similarly, each entry in this dataset consists of a query idiom and its antonyms. Although antonyms are idioms having opposite meanings, they are often topically closely related. For example, the idiom 饱学之士 means “a scholarly man,” and its antonym 胸无点墨 means “uneducated.” We can see that their meanings are topically closely related. We therefore suspect that they are still close in an embedding space, but ideally a good idiom embedding method should be able to distinguish the synonyms of a query idiom from its antonyms. Table 1 gives some statistics of ChIdAnt.

Existing Chinese word embedding methods can be used to derive idiom embeddings. However, as we have discussed in Section 1, they may not be ideal for learning Chinese idiom embeddings. In this section, we first briefly review existing Chinese word embedding methods and how we use them to obtain idiom embeddings. We then present a method to learn Chinese idiom embeddings based on BERT. Our proposed method is adapted from a method for Chinese idiom recommendation (Tan and Jiang, 2020).

#### 4 Learning Chinese Idiom Embeddings

Continuous Bag-Of-Words (CBOW) and Skip-Gram with Negative-Sampling (SGNS) (Mikolov et al., 2013) are two most commonly used efficient log-linear prediction models for learning non-contextualized word embeddings. CBOW tries to predict a word based on its context, where the context is represented as the average word embeddings within the contextual window. In contrast, SGNS tries to predict the contextual words of a given word, and negative sampling is used to reduce the computational cost.

Both CBOW and SGNS have been used to learn Chinese word embeddings (Chen et al., 2015; Li et al., 2018). Chinese is an ideographic language with no explicit word delimiter between words (Li and Yuan, 1998). Chinese segmentation tools are
therefore used to identify word boundaries when learning Chinese word embeddings. On the other hand, Chinese words consist of characters, which have their own semantic meanings. Therefore character information has been incorporated to improve Chinese word embeddings (Chen et al., 2015). In addition, inspired by N-gram SGNS for English (Zhao et al., 2017; Bojanowski et al., 2017), which predicts contextual N-grams rather than contextual words, Li et al. (2018) trained Chinese word embeddings using N-gram SGNS and found that both N-gram and character features bring significant and consistent improvement.

However, Chinese idioms are not always treated as words by Chinese segmentation tools. They are sometimes separated into multiple words. Therefore, only a subset of the idioms in our idiom vocabulary can be found as words in existing pre-trained non-contextualized Chinese word embeddings, and we are only able to perform evaluation on this subset of idioms.

4.2 BERT and Its Variants

Recently, contextualized word embeddings have shown to be highly effective for many NLP tasks. BERT (Devlin et al., 2019) is probably the most commonly used contextualized word embedding model. The original BERT model is pre-trained using the Masked Language Model (MLM) task and the Next Sentence Prediction (NSP) task. Since the original BERT was proposed, there have been some variants of it proposed, including BERT with whole word masking (BERT-wwm) (Cui et al., 2019) and ERNIE (Zhang et al., 2019) that incorporates a multi-stage knowledge masking strategy which adds word-level masking, phrase-level masking and entity-level masking.

The original Chinese-BERT starts from embeddings of individual Chinese characters at the bottom layer. When BERT-wwm or ERNIE is applied to Chinese, although words are identified and masked using Chinese segmentation tools, the model still does not learn embedding vectors directly for entire words. Therefore, to obtain an embedding for an idiom, we need to aggregate the component characters’ embeddings. In this paper, we take the vector representations of individual characters at the top layer of BERT, and average these character representations as the embedding for the entire idiom.11

11We have also experimented with another setting where

![Figure 1: Model structure for BERT with SGNS. The red flow shows the path for the target idiom while the light blue flows show paths for negative sampled idioms used for the learning.](image)

4.3 Learning Idiom Embeddings with BERT

As we have pointed out earlier, existing non-contextualized Chinese word embedding methods model contextual words in a bag-of-word manner, which is suboptimal for encoding the contextual information. Chinese-BERT and its variants can better encode the contextual information using the Transformer architecture, but they do not learn a single embedding vector for an entire Chinese idiom, and therefore they are not ideal either because idioms often have non-compositional semantics. We propose to combine BERT contextual encoding with single embedding vectors for Chinese idioms.

Specifically, to train idiom embeddings, we perform the task of idiom prediction based on its context. Given an idiom \( v \) appearing in a context window \( c = (w_{-k}, \ldots, w_{-2}, w_{-1}, [\text{MASK}], w_1, w_2, \ldots, w_k) \), where \( w_i \) are the contextual words and [MASK] replaces the idiom \( v \) in the original text, the task aims to predict \( v \) based on \( c \). To do so, our idea is to assume that \( v \) has an embedding vector \( e_v \) to be learned. We then use BERT to derive a hidden representation \( h \) that represents \( c \) and use \( h \) and \( e_v \) to derive a log-linear score to indicate how likely \( v \) fits into the context \( c \).

Note that the task described above is similar to the prediction task used by CBOW, but instead of simply using the average word embedding to represent the context \( c \), our method uses BERT to encode \( c \). The task described above is also similar to the Masked Language Model task of BERT, but we mask and predict whole idioms rather than we use the [CLS] token’s representation at the top layer as the idiom representation. We found this to perform worse than using average character embedding.
individual characters.

Concretely, to use BERT to encode the sequence \(c\), following standard practice, we prepend the token [CLS] to the beginning of \(c\) and append [SEP] to the end of \(c\). We also include position embeddings. For segment embeddings, we treat the sequence \(c\) as a single segment. Let \(h_{\text{CLS}} \in \mathbb{R}^d\) denote the hidden vector produced by the last layer of BERT representing [CLS], and \(h_{\text{MASK}} \in \mathbb{R}^d\) the similarly produced hidden vector representing [MASK]. We then define the following vector \(h\) to combine \(h_{\text{CLS}}\) and \(h_{\text{MASK}}\) into a single vector representation because both are important for representing the context \(c\): 

\[
h = W h_{\text{CLS}}; h_{\text{CLS}} \odot h_{\text{MASK}}; h_{\text{CLS}} - h_{\text{MASK}},
\]

where \(\odot\) is element-wise multiplication between two vectors and \(W \in \mathbb{R}^{d \times 4d}\) is a matrix to be learned.

We then use a standard log-linear model based on the dot product between \(h\) and \(e_v\) to train our model. To use the hidden representation \(h\) of the context to predict the idiom \(v\), we take its idiom embedding \(e_v\), apply Layer Normalization (Ba et al., 2016) \(LN\) on it. We also adopt negative sampling to select negative Chengyu. The learning objective is defined as

\[
-(\log \sigma(LN(e_v)^	op h) + \sum_{v' \in N_v} \log (-LN(e_{v'})^	op h)),
\]

where \(N_v\) contains a fixed number of negative samples for each Chinese idiom, and \(\sigma(\cdot)\) is the sigmoid function. Besides the transformation \(W\) and \(LN\), during the training process, the BERT layers will be finetuned and the whole vocabulary will be learned from random initialization. The model structure is illustrated in Figure 1.

5 Experiments

5.1 Experiment Setup

Evaluation metrics: Recall that our main evaluation dataset is the ChIdSyn dataset that contains entries of query idioms and their near-synonyms, where these near-synonyms share at most one common character with the query idiom. We design two evaluation metrics to measure whether near-synonyms in ChIdSyn are close to each other in an embedding space. (1) \textit{Recall@K}: Given a query idiom \(v_n\), we rank all idioms based on their idiom embeddings’ cosine or Euclidean distances with the query idiom’s embedding. Let \(R^{(K)}_{v_n}\) represent the top-\(K\) ranked idioms. Let \(S_{v_n}\) denote the set of ground truth near-synonyms of \(v_n\). \textit{Recall@K} is defined as

\[
\text{Recall@K} = \frac{1}{N} \sum_{n=1}^{N} \frac{|S_{v_n} \cap R^{(K)}_{v_n}|}{|S_{v_n}|},
\]

where \(N\) is the total number of query idioms in ChIdSyn. (2) \textit{Coherence@K}: However, it is not guaranteed that all near-synonyms of a query idiom \(v\) are identified in the online resources we crawled, i.e., some of the top-\(K\) ranked idioms may be indeed near-synonyms but are not found in the ground truth near-synonym set. To overcome this limitation, we can measure whether a query idiom and its ground truth near-synonyms share many common “similar” idioms. In this way, even if a real near-synonym \(u\) of idiom \(v\) is missed from the ground truth, if \(u\) is found to be similar to both \(v\) and its ground truth near-synonyms, it will contribute positively to the metric. We therefore define the following metric, which we call \textit{Coherence@K}:

\[
\text{Coherence@K} = \frac{1}{N} \sum_{n=1}^{N} \frac{|\bigcap_{u \in S'_{v_n}} R^{(K)}_{u}|}{|\bigcup_{u \in S'_{v_n}} R^{(K)}_{u}|},
\]

where \(v_n\) is a query idiom, \(N\) is the total number of query idioms, \(S'_{v_n} = \{v_n\} \cup S_{v_n}\) (i.e., \(v_n\) together with its ground truth near-synonyms), and \(R^{(K)}_{u}\) is the top-\(K\) similar idioms to \(u\), where similarity can be based on either cosine or Euclidean distance.

Methods to be compared: We empirically compare the following embedding methods: (1) \textit{SGNS} and its variants: We use Chinese word embeddings released by Li et al. (2018), which are trained using the Skip-Gram with Negative Sampling method. There are a few variations of these embeddings. \textit{SGNS+B} uses bigram prediction, \textit{SGNS+C} incorporates character information, and \textit{SGNS+B+C} uses both bigram prediction and character information. Li et al. (2018) also experimented with different genres of text for training. In this paper, we use their pre-trained word embeddings trained on the literature genre because this provides fair comparison with our method, which is also trained on Chinese text in the literature genre. (2) \textit{BERT-wwm}: This refers to averaging the top-layer character representations after using the pre-trained Chinese-BERT-wwm (Cui et al., 2019) to process an idiom. (3) \textit{ERNIE}: This refers to averaging the top-layer character representations after using Chinese ERNIE (Zhang et al., 2019) to process an
We first present the results of all the methods we compare using the metrics Recall@K and Coherence@K on ChIdSyn, see Table 2. We can draw the following major conclusions from the table: (1) If we compare Ours-16 with the SGNS methods, we can see that Ours-16 clearly outperforms these SGNS methods. Recall that we use a similar context window size as the SGNS methods. The main difference of Ours-16 from the SGNS methods is that we use Chinese-BERT to encode the context whereas the SGNS methods do not model the interactions between the contextual words. This implies that when learning Chinese idiom embeddings, it is important to model the order of and interactions between the contextual words. (2) Comparing Ours-16 with BERT-wwm and ERNIE, we can see that Ours-16 also substantially outperforms these two BERT-based methods. Recall that the main difference of our method and these BERT methods is that we directly learn a single idiom embedding vector whereas for these BERT methods we need to aggregate character embeddings to derive idiom embeddings. The results suggest that many Chinese idioms’ semantic meanings cannot be simply derived from their character embeddings and therefore it is important to associate a Chinese idiom with a single embedding vector and to learn this embedding vector from the contexts of this idiom. (3) Ours-32 performs clearly better than Ours-16. This suggests that a larger context window is very useful for learning Chinese idiom embeddings, which have not been found to be the case for word embeddings (Lison and Kutuzov, 2017).

Besides the major conclusions drawn above, we can also see from the two tables that: (1) For the SGNS methods, adding character information may actually either hurt the performance or improve the performance very little. In other words, there is no consistent observation that character information helps for Chinese idiom embeddings, which is not the case for Chinese word embeddings (Chen et al., 2015; Zhao et al., 2017). This verifies our hypothesis that existing conclusions drawn from evaluating Chinese word embeddings may not apply to idiom embeddings. (2) For the two BERT-based methods, we can see that ERNIE performs clearly better than BERT-wwm. It is worth noticing that ERNIE uses Baidu Baike in which most idioms have entries and
would be treated as entities by the entity-level mask. Intuitively, the embeddings extracted using ERNIE should be better than BERT-WWM, whose CWS tools may not be able to recognize all the idioms.

5.3 Further Analysis

In this section, we conduct some further comparison and analysis using ChIdSyn-com and ChIdAnt.

Synonyms with Common Characters: Recall that we identified a set of near-synonyms that share two or more common characters. We suspect that these idiom synonyms are easier to be identified if the idiom embeddings rely more on character-level information. To verify this hypothesis, we compare the various methods using Recall@K based on cosine distance on ChIdSyn-com. The results are shown in Table 3. We can see that indeed those existing methods that rely more on character-level information, namely, SGNS+C, SGNS+B+C, BERT-wwm and ERNIE generally perform better than the other methods, including our methods. This verifies our hypothesis above. Note that because the synonyms in ChIdSyn-com share many common characters, being able to identify them does not imply that the embeddings truly capture the semantic meanings of the idioms. Since SGNS+C, SGNS+B+C, BERT-wwm and ERNIE actually do not perform well on ChIdSyn, we argue that they are effective only for synonyms sharing many common characters, and this implies that they rely on superficial patterns to encode idioms.

Antonyms: Recall that earlier we raised the hypothesis that good idiom embedding methods should be able to distinguish antonyms from synonyms, although both can be topically related to the query idioms. In fact, a previous study by Samenko et al. (2020) also found that embeddings contain information that distinguishes synonyms and antonyms. Inspired by them, we think that the separability of near-synonyms and antonyms may reflect the quality of the learned embeddings. We therefore visualize the distributions of cosine distances (i.e., 1 minus cosine similarity) of idiom near-synonym pairs and antonym pairs in Figure 2, using ChIdSyn and ChIdAnt. We can see from the figure that our methods Ours-16 and Ours-32 clearly has a distinguishable cosine distance distribution for antonyms compared with synonyms, whereas for the other methods the two distributions are less distinguishable. This again demonstrates the advantage of our idiom embedding methods.

6 Conclusion

In this paper, we constructed a new evaluation dataset that contains Chinese idiom synonyms and antonyms to facilitate the evaluation of Chinese idiom embeddings. We presented a method that learns Chinese idiom embeddings by predicting idioms based on BERT-encoded contexts. We also propose two metrics to measure closeness of synonyms in the embedding space. Our method performs substantially better than existing methods.

Abstract

Understanding idioms is important in NLP. In this paper, we study to what extent a pre-trained BERT model is able to encode the meaning of a potentially idiomatic expression (PIE) in a certain context. We make use of a few existing datasets and perform two probing tasks: PIE usage classification and idiom paraphrase identification. Our experiment results suggest that BERT indeed is able to separate the literal and idiomatic usages of a PIE with high accuracy. It is also able to encode the idiomatic meaning of a PIE to some extent.

1 Introduction

Understanding idiomatic expressions is important for NLP tasks such as sentiment analysis (Balahur et al., 2010; Williams et al., 2015) and machine translation (Isabelle et al., 2017; Shao et al., 2018). However, due to the non-compositionality of idioms, it remains a challenge to model the semantic meanings of idioms effectively (Sag et al., 2002; Shwartz and Dagan, 2019).

BERT is a contextualized pre-trained language model that has been widely used and proven to be highly effective for many NLP tasks (Devlin et al., 2019). To better understand how BERT works, recently the community has adopted the approach of probing, where a probing task is designed to test whether BERT encodings contain sufficient information to perform the task well. Examples of probing tasks include POS tagging and parsing (Hewitt and Liang, 2019; Wu et al., 2020) as well as semantic reasoning tasks such as understanding numbers (Wallace et al., 2019).

It is therefore also natural to ask whether BERT encodes any knowledge about the usage and meanings of idioms, given that BERT was trained on huge corpora, which must contain many idiomatic expressions. However, this problem has not been well explored. To the best of our knowledge, the closest existing work is by Shwartz and Dagan (2019), who studied whether pre-trained (static and contextualized) word embeddings can detect meaning shift and implicit information of phrases, with the help of several probing tasks. However, we believe there is a need for further exploration. We note that Shwartz and Dagan (2019) did not specifically focus on idioms; only one of the six probing tasks was directly related to idioms, and only idiomatic noun compounds were studied. Since English idioms have different syntactic structures, it would be useful to experiment with a higher coverage of different types of idioms.

In this paper, we focus on probing BERT to understand whether BERT embeddings can encode the meanings of a diverse range of different types of idioms. We propose two probing tasks to test whether BERT understands idioms. First, given a context containing a potentially idiomatic expression (PIE), the task is to decide whether the meaning of the PIE is literal or idiomatic, based on the BERT-encoded contextualized embedding of the PIE. We hypothesize that if pre-trained BERT could perform the task well, it would indicate that BERT knows the difference between literal and idiomatic usages of the same expression based on its context. For this task, we use a large dataset recently released by Haagsma et al. (2020), which covers 1756 unique idioms and 50K contextual sentences, much larger and more diverse than the idiomatic noun compounds dataset used by Shwartz and Dagan (2019). However, this task is not sufficient to show whether BERT truly understands the idiomatic meaning of a PIE. In order to test this, we design a second probing task based on existing idiom paraphrase datasets. The task is to select the correct paraphrase of an idiom among a set of candidate phrases based on the cosine similarity between the idiom’s BERT embedding and these...
candidate phrases’ BERT embeddings. We hypothesize that if the correct paraphrase could be ranked higher than other irrelevant phrases, it would indicate that BERT indeed understands the idiomatic meaning of the idiom.

It is important to note that our objective is not to improve the performance of the two tasks by designing effective learning methods; rather, the objective is to use these two tasks to probe pre-trained BERT in order to understand how much BERT encodes the meanings of idioms. Therefore, the models for the two probing tasks are simple models without many parameters to be learned.

Through our empirical study using both the original BERT and ERNIE2 (Sun et al., 2020) (an improved version of BERT), we find that compared with non-contextualized embedding representations of PIEs, contextualized BERT and ERNIE2 embeddings of PIEs can clearly achieve higher accuracy for PIE usage classification, with an accuracy level around 90%, suggesting that BERT can use the context to accurately guess whether an expression is used literally or idiomatically. For paraphrase identification, we find that BERT and ERNIE2 perform significantly better than a random baseline, although the absolute performance is still considered low. Since paraphrase identification is itself challenging, to put things in perspective, we also compare with paraphrase identification for general multi-word expressions (MWEs). Contrary to our expectation, we find that identifying paraphrases for general MWEs does not necessarily fare better than for idioms. Further analysis reveals that this is because BERT contextualization actually hurts paraphrase identification for general MWEs but not so for idioms.

2 Related Work

2.1 Probing Tasks

The notion of probing (Ettinger et al., 2016) or a probing task (Conneau et al., 2018) refers to the use of a classification problem to reveal whether certain linguistic properties of sentences are captured in the input embedding representations of the sentences fed into the classification model. There have been studies investigating what properties of a sentence its embedding might have contained (Ettinger et al., 2016; Shi et al., 2016; Adi et al., 2017). The properties being probed include semantic roles (Ettinger et al., 2016), negation scopes (Ettinger et al., 2016), constituents (Shi et al., 2016), part-of-speech tags (Shi et al., 2016), sentence lengths (Adi et al., 2017), word orders (Adi et al., 2017), agreement information (Giulianelli et al., 2018) and tense of the main clause (Bacon and Regier, 2018). With the emergence of contextualized embeddings such as BERT (Devlin et al., 2019) and ELMO (Peters et al., 2018a), researchers have also applied probing tasks to word-level contextual representations (Tenney et al., 2019), attention mechanisms (Clark et al., 2019) and syntactic knowledge (Peters et al., 2018b; Hewitt and Manning, 2019). Probing phrasal representations to study lexical composition has also attracted attention. Jawahar et al. (2019) found that the compositional scheme underlying BERT mimics classical, tree-like structures. Shwartz and Dagan (2019) conducted a series of experiments and concluded that lexical composition can shift the meanings of the constituent words and introduce implicit information. Yu and Ettinger (2020) reminded us that phrase representation in transformer models still relies heavily on word content, with little evidence of sophisticated composition of phrase meaning like that done by humans. Our work differs from these existing studies in that we focus on idiomatic expressions rather than any phrases, and we use a recently released large-scale idiom dataset to facilitate our study.

2.2 Potentially Idiomatic Expressions

Potentially Idiomatic Expressions (PIEs) originate from multiword expressions (MWEs) which have both an idiomatic interpretation and a literal interpretation, for example, *spill the beans*. Identifying the correct meaning of a PIE in a certain context is crucial for many downstream tasks including sentiment analysis (Williams et al., 2015), automatic spelling correction (Horbach et al., 2016) and machine translation (Isabelle et al., 2017). There has been both supervised (Sporleder and Li, 2009) and unsupervised (Haagsma et al., 2018; Kurfalı and Östling, 2020) approaches to solve this problem. For example, Feldman and Peng (2013) treated idiom recognition as outlier detection, which does not rely on costly annotated training data. Peng et al. (2014) incorporated the affective hypothesis of idioms to facilitate the identification of idiomatic operations. Different from these studies, our object is not to improve the performance of idiom recognition but rather to use the task as a probing task to understand the capabilities of BERT to en-
code idioms. With newly created large scale dataset MAGPIE (Haagsma et al., 2020), we can further investigate how contextualized word representations works for idiomatic expressions and literal ones.

2.3 Paraphrase Identification

Paraphrase identification aims to determine whether a pair of language units such as sentences have the same meaning (Kauchak and Barzilay, 2006) or whether a given paraphrase candidate can replace a given language unit in its context without changing overall semantic meaning of the text (Yimam et al., 2016). Idiom paraphrasing is a challenging task that has been attracting continuous attention from the community. For example, Liu and Hwa (2016) investigated the effectiveness of a phrasal substitution method to replace idioms with literal expressions, indicating that high quality paraphrasing of idiomatic expressions can be achieved. Yimam et al. (2016) researched a paraphrase-scoring annotation task and showed that the contexts have an impact on the ranking of paraphrases. Haagsma et al. (2018) looks at the literal representation of the PIE’s figurative sense (similar to dictionary definitions of an idiom’s meaning, which can also be treated as paraphrase) to facilitate potentially idiomatic expression classification. Different from the studies above, in this paper, we focus on understanding whether pre-trained BERT models encode the semantic meanings of idioms, using idiom paraphrase identification as the probing task. We adopt three phrase-level paraphrase datasets for our probing task. Using this task, we probe how contextualization in transformers may affect the semantic relatedness of phrases.

3 Probing Tasks

We design two probing tasks to answer two research questions: (1) Can BERT distinguish the idiomatic usage of a PIE from its literal usage? (2) Can BERT understand the idiomatic meaning of an idiom? Both questions are related to the capabilities of BERT to understand idioms, but the second task is more demanding than the first. The two tasks also share similar objectives as the probing tasks designed by Shwartz and Dagan (2019), which aimed to test whether pre-trained word embeddings can detect the shift of meaning of a phrase from its component words, and whether pre-trained word embeddings understand the implicit meaning of a phrase. However, they are conducting probing at word level, which focuses on whether the meaning of a word in a noun compound (NC) is literal. The dataset only has 90 noun compounds (Reddy et al., 2011). Although they try to augment the dataset using Tratz (2011), the dataset is still limited to 3K. The paraphrase identification task used by them also uses compounds and addresses whether the paraphrase describes the semantic relation between two words of a noun compound (Hendrickx et al., 2013).

In this paper, we use a much larger dataset called MAGPIE (Haagsma et al., 2020) that covers much more potentially idiomatic expressions for phrase-level literal-idiomatic classification. To make the task more challenging, we choose to split the data such that the idiomatic expressions in the training, development, and test sets do not overlap. We further adapt several paraphrase datasets (Liu and Hwa, 2016; Yimam et al., 2016; Pershina et al., 2015) to compare phrasal semantic relatedness for idioms. We compare the effect of BERT encodings at different layers for the two probing tasks to better understand the effect of contextualization.

3.1 PIE Usage Classification

Many MWEs can be interpreted either literally or idiomatically. In some literature, these expressions are defined as potentially idiomatic expressions (PIEs) (Sporleder and Li, 2009; Haagsma et al., 2018, 2020). For example, “spill the beans” can either be used literally to refer to the action of spilling beans or in its idiomatic sense to refer to disclosing some secrets. However, current approaches are investigating this problem with the limitation to one or more syntactic patterns. In this paper, we propose to use the latest large scale dataset MAGPIE to probe how BERT is capturing the difference of literal and non-literal usage of a PIE.

Task Definition. Given a piece of context denoted as \( w_1, w_2, \ldots, w_n \) containing a PIE with \( m \) words, \( w_i, \ldots, w_{i+m-1} \), the task is to decide whether the PIE is used with its literal meaning or its idiomatic meaning. Performance is measured by accuracy. It is important to note that since our goal is to test whether pre-trained BERT can already encode such knowledge, we do not train a classifier per idiom. Instead, we train a single binary classifier using a set of training PIEs and their labeled contexts, and test the classifier on a separate set of different test PIEs and their contexts.
Data. We use the MAGPIE dataset (Haagsma et al., 2020), which is the largest-to-date corpus of English PIEs and labeled instances of both their literal and idiomatic usages in different contexts. The corpus comprises 1756 unique PIEs and more than 50K contexts, an order of a magnitude larger than previous similar resources. Annotations of MAGPIE included various aspects: annotation (dis)agreement, distribution of idiom types, sense distributions across types, composition of the ‘other’-category, and influence of genre. An example of MAGPIE is given in Table 1. In this paper, we further analyse what might be the reason of BERT’s advantage in connection with annotation agreement.

Table 1: An example from MAGPIE dataset with details of annotations.

| Context: | Think of a sunflower turning its flower head towards a source of light — and therefore of energy. The sunflower does not learn by experience to turn its head more effectively as it matures, or not to turn at all if it is repeatedly electrically shocked every time it does so. |
| Annotation: | Label: literal | PIE: turn head |
| | Confidence: 0.75 | Genres: W nonAc: nat science |
| | Judgment Count: 4 | |
| | Variant Type: combined-inflection | Label Distribution: {‘idiomatic’: 0.25, ‘literal’: 0.75} |

3.2 Idiom Paraphrase Identification

In this paper, to further understand whether BERT has learned the idiomatic meaning of phrases, we propose the Idiom Paraphrase Identification probing task to check whether contextualized representations of PIEs encoded by BERT have shifted meanings that are closer to their paraphrases.

Task Definition. Given a piece of context denoted as \((w_1, w_2, \ldots, w_n)\) containing a PIE \(w_i, \ldots, w_{i+m-1}\) where the PIE is known to be used idiomatically, and given a set of candidate phrases \(\mathcal{P} = \{p_1, p_2, \ldots, p_k\}\), where each \(p_i \in \mathcal{P}\) is a MWE and one of them is a paraphrase of the given idiom, the task is to identify the correct paraphrase from \(\mathcal{P}\). We cast this task as a ranking problem and use Mean Reciprocal Rank (MRR) to measure the performance.

Data. We combine different resources described below to create the data needed to perform this paraphrase identification task. Specifically, we create three datasets: (1) Idioms-MWEs, (2) MWEs-MWEs, and (3) Idioms-Idioms. Details of the collection of these three datasets are listed below:

- **Idioms-MWEs**: We use the idiom paraphrase dataset created by Liu and Hwa (2016). Each instance in this dataset is a context sentence containing an idiom together with a phrase that can substitute the idiom in the context. The dataset was created by shortening the definitions of these idioms from a dictionary and performing appropriate grammatical and referential transformations to ensure that the idiom substitution fits seamlessly into the original context. The paraphrases have also been verified and refined by human annotators. This gives us a dataset with high quality paraphrases of idiomatic expressions. The dataset contains 171 unique idioms, each with a single context sentence and a paraphrase.

- **MWEs-MWEs**: Since paraphrase identification itself is likely a challenging task even for non-idiomatic MWEs, in order to put things in perspective, we also make use of another paraphrase dataset that contains pairs of MWEs that are paraphrases. Yimam et al. (2016) investigated the impact of context for the paraphrase ranking task using both multi-word expressions and single words. The dataset covers 17k data points (2k MWEs and 15k single word) annotated through crowd-sourcing. The 2k MWEs are of particular interest to us in this probing task. We processed the original dataset by retaining only those paraphrase pairs with a human agreement score of 4, which gives us a final set of 176 entries of a MWE in a context as well as their paraphrases. We find that these 176 entries do not overlap with the PIEs in the MAGPIE dataset, suggesting that these MWEs are likely all non-idiomatic expressions. By performing paraphrase identification on this dataset, we can get a sense of the expected performance for paraphrase identification on phrases that are not idiomatic.

- **Idioms-Idioms**: Pershina et al. (2015) presented idiomatic expressions as a new domain for short-text paraphrase identification and
This Cuban Black Bean recipe is pretty much as easy as beans get and they are SO delicious.

If only I could soup up this computer to run just a little faster.

She constantly complains of boredom as her presence at home is merely decorative, while her husband is heavily involved in his scholarly interests.

Table 2: Paraphrase evaluation datasets. We select one example from each dataset.

For each dataset, we list its size and one example in Table 2.

To create the set of candidate paraphrases, we simply pool the paraphrases of all the entries of the three datasets together as the set of candidate paraphrases for all instances.

4 Experiments

For each of the two probing tasks above, we use pre-trained BERT\(^2\) and ERNIE2\(^3\) to process each context \((w_1, w_2, \ldots, w_n)\). Following standard practice, we prepend the [CLS] token to the beginning of the sequence and append the [SEP] token to the end. The sequence is then fed into an L-layer BERT. Let \(h^k_i \in \mathbb{R}^d\) denote the hidden vector produced by the \(k\)th layer of BERT representing \(w_i\). When \(k = 0\), \(h^0_i\) denotes the combined representation of the word embedding, the position embedding and the token type embedding before it is fed into the transformer-based encoder.

For each PIE, we get a sequence of hidden vectors at the \(k\)th layer for the \(m\) tokens inside this PIE as follows: \(p^k = (h^k_i, h^k_{i+1}, \ldots, h^k_{i+m-1})\). We will use these contextualized BERT embeddings of the PIE as input to the model for the probing tasks. Note that when training the model for a probing task, BERT is not fine-tuned.

For both probing tasks, we experiment with both the original BERT (Devlin et al., 2019) and ERNIE2 (Sun et al., 2020), which supports phrase masking by using lexical analysis and chunking tools to get the boundary of phrases in the sentences. Our code and data are released on github\(^4\).

4.1 PIE Classification

After we get the hidden representation \(p^k = (h^k_i, h^k_{i+1}, \ldots, h^k_{i+m-1})\) of the PIE, we further encode the sequence into a single vector using a bidirectional LSTM encoder. We then treat this vector as input to train the binary PIE usage classifier using a linear classifier.

We show the accuracy of the trained PIE usage classifier on both the development set and the test set in Table 3. We include a baseline BL-majority that always predicts the usage to be idiomatic. This is because we observe that there are more instances in this dataset labeled as idiomatic than literal. We also include another baseline BL-GloVe, which uses the static GloVe word embeddings (Pennington et al., 2014) to replace the BERT encoded representations. For BERT embeddings, we include

\(^2\)huggingface.co/bert-base-uncased

\(^3\)huggingface.co/nghuyong/ernie-2.0-en

\(^4\)https://github.com/VisualJoyce/CiYi
the results using the bottom layer (Layer-0) and the results using the final layer (Layer-12). Including Layer-0 is for us to observe how the static embeddings of BERT have performed.

From the table, we can draw the following conclusions: (1) The baseline method **BL-majority** achieves an accuracy above 50%. This shows that the dataset is not balanced, with more instances of idiomatic usage. (2) Using Layer-0 of BERT and ERNIE2, i.e., using only static word embeddings, we can see that the performance is always above 80% and is very close to **BL-GloVe**. This suggests that even the static word embeddings contain some prior knowledge about whether the expression is literal or idiomatic. (3) Using Layer-12 of BERT and ERNIE2, we can see that the accuracy of PIE usage classification significantly increased compared with using Layer-0. In fact the absolute accuracy level is quite high, reaching 90%. This confirms that with BERT contextualization, the embeddings of the PIE better reflect the usage of the PIE, allowing the classifier to easily predict whether the PIE is used literally or idiomatically. This shows that BERT can indeed encode the knowledge about the usage of a PIE.

Table 3: PIE classification accuracy.

Given the large gap between the classification accuracy using Layer-0 and Layer-12, next we exper-
iment with other intermediate layers of the Transformer architecture for BERT and ERNIE2. The results are shown in Figure 1a. From the figure we find that starting from around Layer-4 the performance stabilizes and the last layer is not necessarily the one with the best performance. This shows that BERT requires just a few rounds of contextualization to encode the idiom usage information.

To better understand how BERT contextualization improves PIE usage classification, we further zoom into the two different types of errors: (1) literal usage mistakenly classified as idiomatic usage, and (2) idiomatic usage mistakenly classified as literal usage. We show the numbers of these error cases in four confusion matrices in Figure 1b (one confusion matrix for one of Layer-0, Layer-4, Layer-8 and Layer-12), where the lower-left corner shows the first type of errors and the upper-right corner shows the second type of errors. In Figure 2, we further show the precision, recall and F1 scores across all the layers by either choosing idiomatic or literal as the positive label. We observe that interestingly the error reductions from Layer-0 to Layer-12 comes mostly from the group literal-idiomatic where literal expressions are wrongly predicted to be idiomatic. We hypothesize that this is because without contextualization, some of the words in these PIEs tend to indicate that the PIEs are used idiomatically, probably because these words have appeared often in other idiomatic expressions in the training data; but after considering the specific contexts these PIEs are placed in, i.e., with BERT contextualization, the model recognizes that these contexts are semantically similar to the literal meanings of the tokens inside these PIEs, and therefore predict the usage as being literal. This shows that with more contextualization, BERT embeddings help the most in recognizing literal usages of PIEs.

We further ask the question whether those instances where BERT embeddings did not do well for the PIE usage classification task are those instances where human annotators’ agreement is also low. To answer this question, we show the average annotation agreement scores on the test set for correctly predicted instances and incorrectly predicted instances. The statistics are shown in Figure 3. The red line shows the average agreement score over all test instances, the green line shows the average agreement score over those instances whose ground truth labels are “idiomatic”, and the blue line shows the average agreement score over those instances with the ground truth label “literal”. We can see that human annotations have a clearly higher degree of agreement on those idiomatic usages of PIEs, but a lower agreement when a PIE is likely used literally. The four bars in Figure 3 shows the average agreement scores of correctly and incorrectly predicted instances, grouped by the ground truth labels. We can see that clearly those incorrectly predicted instances (shown in light gray bars) have clearly lower human agreement scores compared with the correctly predicted ones. This verifies our hypothesis that the model tends to make mistakes on those instances which humans also find hard.

Table 4: MRR scores for paraphrase ranking.

For the paraphrase identification task, after we get the hidden representation $p_k$ of the PIE in its context, we take the average of these vectors to obtain a single vector. For each candidate paraphrase, we perform the same encoding, without any context, and then take the average of the produced hidden vectors. Finally, we rank the candidates based on the cosine similarity between the PIE’s embedding and the candidate’s embedding.

The Mean Reciprocal Rank (MRR) scores are
listed in Table 4. For comparison, we consider a baseline that randomly ranks the candidates. We can observe the following from the table: (1) BERT and ERNIE2 can perform better than the random baseline on Idioms-MWEs, although the absolute values of MRR are low. This shows that BERT contextualized embeddings can still encode the idiomatic meanings of idioms to some extent. (2) We also observe that identifying paraphrases for general multi-word expressions (MWEs-MWEs), which are likely not idiomatic, is not easier than for idioms. This is counter-intuitive and we will show further investigation below. (3) Identifying paraphrase idioms of idioms (Idioms-Idioms) is a bit harder than identifying general multi-word-expression-based paraphrases. This maybe because the candidate idioms are not contextualized, and therefore their embeddings do not reflect their idiomatic meanings.

To better understand why paraphrase identification for general MWEs has even lower performance than for idioms, we again test the performance using different layers of BERT/ERNIE2 embeddings. The results are shown in Figure 4a. Now it is clear that with non-contextualized embeddings (i.e., Layer-0), paraphrase identification for general MWEs is actually much easier than for idioms. This is intuitive because the meaning of non-idiomatic MWEs can be derived from their component words and therefore contextualization is not needed. The figure also shows that with more contextualization, performance of paraphrase identification for general MWEs is largely hurt, but this is not the case for idioms. It’s also interesting that, for Idioms-Idioms, the MRR scores do not change much with layers. We think this may due to both an idiom and its idiomatic paraphrase share less overlap with the context.

Noticing that the performance of paraphrase identification for Idioms-MWEs surpasses MWEs-MWEs at Layer-8, i.e., when there is some degree of contextualization, we conduct some further analysis to understand why. Specifically, given a query idiom (or query MWE) $q$, its context $c$, and its ground truth paraphrase MWE $p$, we would like to check if $p$ tends to have common words with $q$ and $c$, respectively. Our hypothesis is that if $p$ shares common words with $c$, then contextualized word embeddings are helpful because they encode the context $c$. We show our analysis in Figure 4b. In the left hand side of the figure, the light gray bar shows the percentage of test instances in the MWEs-MWEs dataset where the query MWE $q$ shares at least one common word with the ground truth paraphrase $p$, and the dark gray bar shows the percentage of test instances in MWEs-MWEs where the context $c$ shares at least one common word with the ground truth paraphrase $p$. The right hand side of the figure shows the same percentages for the Idioms-MWEs dataset. We can see that for MWE-MWE paraphrase pairs, it is less...
common for the ground truth paraphrase to share a common word with the context of the query phrase, compared with Idiom-MWE paraphrase pairs. This is reasonable because for an idiom, its idiomatic meaning is often not directly linked to the semantic meanings of their component words, and therefore words in the idiom itself may not overlap with words in its paraphrase; on the other hand, the context where an idiom appears may imply the idiom’s idiomatic meaning, and therefore may have word overlap with the paraphrase. The statistics shown in Figure 4b shows that because for MWEs, their paraphrases are less likely to share common words with the contexts where the MWEs appear, contextualization done by BERT therefore not only is not so useful but also may harm the performance of paraphrase identification.

5 Conclusion

In this paper, we use two probing tasks to study whether BERT understands English idioms. In conclusion, we find that BERT is able to detect idiomatic usages of a PIE with a high accuracy, and with more contextualization as the layer increases, BERT helps the most in recognizing literal usages of PIEs. However, this only proves that BERT is effective in detecting meaning shift for idiomatic expressions. To further probe if the shifted meanings are closer to their paraphrases, we adopt the paraphrase identification task by gathering three different types of paraphrase pairs, MWEs-MWEs, MWEs-Idioms and Idioms-Idioms. Our experiments show that BERT is able to encode the idiomatic meaning to some extent. However, contextualization may have different effects for MWEs and idioms, which still requires further exploration to fully explain.

Abstract

Neural Topic Models are recent neural models that aim at extracting the main themes from a collection of documents. The comparison of these models is usually limited because the hyperparameters are held fixed. In this paper, we present an empirical analysis and comparison of Neural Topic Models by finding the optimal hyperparameters of each model for four different performance measures adopting a single-objective Bayesian optimization. This allows us to determine the robustness of a topic model for several evaluation metrics. We also empirically show the effect of the length of the documents on different optimized metrics and discover which evaluation metrics are in conflict or agreement with each other.

1 Introduction

Topic models (Blei, 2012) are probabilistic generative models that aim at identifying the underlying themes, or topics, in a collection of documents. Although they are used in a vast range of applications, from text exploratory purposes to information retrieval tasks (Boyd-Graber et al., 2017), most of the investigations disregard the elements that influence the results generated by the models and, in particular, what is the effect on their performance.

Several works explore topic modeling over a range of different models, topics, and measures, but usually focus on classical topic models (Greene et al., 2014; Stevens et al., 2012), e.g. Latent Dirichlet Allocation (LDA) (Blei et al., 2003) or Non-negative Matrix Factorization (NMF) (Lee and Seung, 2000), and solely on a single evaluation measure (Stevens et al., 2012; O’Callaghan et al., 2015).

Doan and Hoang recently made an effort to benchmark neural topic models, however, the authors seem to disregard the importance of the hyperparameter selection. In fact, the evaluations of topic models are usually limited to the comparison of models whose hyperparameters are fixed. Yet, the hyperparameters that control the models can have a great impact on their performance. Therefore, fixing them prevents the researchers from discovering the best topic model on a given dataset. In the latest years, Neural Topic Models (NTM) (Zhao et al., 2021; Dieng et al., 2020; Bianchi et al., 2021a,b) have gained popularity, due to their flexibility and scalability. The problem of finding the best hyperparameter configuration has become even more compelling, since topic models based on neural networks are usually controlled by a high number of hyperparameters.

In this paper, we perform an empirical analysis of recent NTMs by optimizing the hyperparameters of the models with respect to different metrics. We aim to investigate if there exists a potential relationship between hyperparameters, document length and performance measures, to finally understand under which conditions we can exploit at best the potentiality of each model. In particular, the following research questions have been addressed:

RQ1: To what extent are Neural Topic Models robust across different evaluation metrics?
RQ2: Does the document length affect the Neural Topic Models on different performance measures?
RQ3: Does the optimization of a model’s hyperparameters for a given performance metric imply good performance on other measures?

To this purpose, we use Bayesian Optimization (BO) (Archetti and Candelieri, 2019), a well-known and efficient strategy for hyperparameter tuning, to determine the optimal hyperparameter settings for four different evaluation metrics of five state-of-the-art NTMs. The hyperparameter optimization allows us to guarantee a fair comparison.
between the models and investigate their behavior with different hyperparameter settings.

2 Methodology

In this work, we conduct an empirical comparison of different state-of-the-art NTMs. We adopt a single-objective Bayesian Optimization approach, using the comparative framework topic modeling OCTIS (Terragni et al., 2021a), to optimize the hyperparameters of five different topic models with respect to four different evaluation metrics. Each metric investigates a different aspect of a model. Bayesian Optimization (Archetti and Candelieri, 2019; Kandasamy et al., 2020) is a Sequential Model-Based Optimization (SMBO) strategy that allows us to optimize all the hyperparameters by treating the topic model as a black-box function. The model is in fact viewed just in terms of its input (the hyperparameters) and its output (the distribution of the topics over the vocabulary and the topic distribution for each document).

BO uses the model’s configurations evaluated so far to approximate the value of the performance metrics with respect to the model’s hyperparameters and then selects a new promising configuration to evaluate. The two key components are the probabilistic surrogate model aimed at approximating the performance metrics to optimize, and the acquisition function that uses the mean of the surrogate model and the confidence (i.e. its standard deviation) to select the next configuration.

Optimizing a model’s hyperparameters not only allows us to investigate the robustness of a model over different evaluation metrics (RQ1), but we can also investigate the performance of the optimized evaluation metric on datasets with different features (RQ2) and the relationship between the optimized evaluation metric and the other metrics (RQ3).

2.1 Topic Models

In our investigation, we focus on the following recent state-of-the-art topic models based on a neural variational frameworks. We consider Neural LDA (Srivastava and Sutton, 2017, NeurLDA), Product-of-experts LDA (Srivastava and Sutton, 2017, ProdLDA), the Embedded Topic Models (Dieng et al., 2020, ETM), and finally we use a variant of the family of Contextualized Topic Models, namely the Zero-shot Contextualized Topic Model (Bianchi et al., 2021b, CTM).

All these neural models are based on the Variational Autoencoder (VAE) presented in Miao et al. The neural variational framework trains an inference network to map the bag-of-words (BoW) document representation into a continuous latent representation. A decoder network reconstructs the BoW by generating its words from the document representation. This document representation is $K$-dimensional, where $K$ is the number of topics.

NeurLDA and ProdLDA (Srivastava and Sutton, 2017) explicitly approximate the Dirichlet prior using Gaussian distributions, instead of using a Gaussian prior. In addition, ProdLDA replaces the word-topic distribution in LDA with a product of experts (Hinton, 2002).

CTM (Bianchi et al., 2021b) extends ProdLDA by replacing the BoW document representation of the input with the corresponding pre-trained contextualized representations of the documents. These representations derive from contextualized language models, e.g. BERT (Devlin et al., 2019).

Concerning ETM (Dieng et al., 2020), words and topics are represented in the same embedding space. The word-topic distribution is proportional to the exponentiated inner product of the topic embedding and each word embedding. ETM can automatically learn the word embedding representations or use pre-trained word embeddings. Following the original paper, we will refer to the former version of the model as ETM, while the one that uses pre-trained word embeddings (PWE) will be referred to as ETM-PWE.

We also consider the well-known Latent Dirichlet Allocation (Blei et al., 2003, LDA) as a baseline. LDA is a probabilistic model that describes a corpus through $K$ topics, seen as distributions of words over a vocabulary $W$. A document is assumed composed of a mixture of topics following a Dirichlet distribution, where a topic drawn from the mixture is assigned to each word of the documents.

2.2 Evaluation Metrics

We consider four evaluation metrics that investigate different aspects of a topic model.

F1 refers to the Micro-F1 measure, the weighted average of the F1 measure for each class. We train a linear support vector machine (SVM) that predicts the document’s class using the topic distribution $\theta$ of each document (given by each topic model) as
its feature representation (Terragni et al., 2020a).

**IRBO** (Bianchi et al., 2021a; Terragni et al., 2021b) is a measure of topic diversity (0 for identical topics and 1 for completely different topics). It is based on the Ranked-Biased Overlap measure (Webber et al., 2010). Topics with common words at different rankings are penalized less than topics sharing the same words at the highest ranks.

**NPMI** (Lau et al., 2014) measures Normalized Pointwise Mutual Information of each pair of words \((w_i, w_j)\) in the 10-top words of each topic. It is a topic coherence measure, that evaluates how much the words in a topic are related to each other.

**KL-B** (AlSumait et al., 2009; Terragni et al., 2020b) is the Kullback-Leibler distance of a topic to a “background” topic, a topic found equally probable in all the documents. Meaningful topics appear in a small subset of the data, thus higher values are preferred.

### 3 Experimental Setting

#### 3.1 Datasets and Preprocessing

To analyze the impact of the length of the documents with respect to several models and performance measures, we consider two different datasets: 20Newsgroup\(^2\) (20NG), where each document is characterized by a long text, and M10 (Lim and Buntine, 2014), which is composed of titles of scientific papers, and therefore it represents a case study of short texts.

We adopt a common preprocessing procedure\(^3\): punctuation removal, lemmatization, removal of English stop-words and unfrequent words, removal of documents with less than 3 words (for M10) or 5 words (for 20NG). The stopwords list is the one provided by MALLET\(^4\). Each dataset is split into training (70%), validation (15%) and test set (15%). Table 1 shows the datasets statistics.

#### 3.2 Bayesian Optimization and Model Settings

We optimize the models’ hyperparameters using BO for each evaluation metric. We trained each model 30 times and considered the median as the evaluation of the function to be optimized. The initial configurations are randomly sampled via Latin Hypercube Sampling and equal to the number of the hyperparameters to optimize plus 2 (to provide enough configurations for the initial surrogate model). The total number of BO iterations is 30 for LDA and 120 for the other models. We use Random Forests as the surrogate model and the Upper Confidence Bound (UCB) as the acquisition function.

We report the models’ hyperparameters and their corresponding ranges in Table 2.

</tr>
</tbody>
</table>

Table 2: Hyperparameters and ranges.

Regarding LDA, we optimize the hyperparameters \( \alpha \) and \( \beta \) priors that the sparsity of the topics in the documents and sparsity of the words in the topic distributions respectively. These hyperparameters are set to range between \( 10^{-4} \) and 10 on a logarithmic scale.

The hyperparameters of the neural models are mainly related to the architecture of the network. For all the neural models, we optimize the dropout...
(ranging between 0 and $1 - 10^{-6}$) and the momentum (ranging between 0 and 1). We optimize the learning rate, that is set to range between $10^{-4}$ and $10^{-1}$, on a logarithm scale. We also consider different variants of activation functions and optimizers.

Regarding NeurLDA, ProdLDA, and CTM in particular, we optimize the number of layers (ranging from 1 to 5), and the number of neurons (ranging from 100 to 1000). For simplicity, each layer has the same number of neurons. Finally, we also consider the hyperparameter learn priors that controls if the priors are learnable parameters.

Following (Bianchi et al., 2021a), we use the contextualized document representations derived from SentenceBERT (Reimers and Gurevych, 2019). We use the pre-trained BERT model fine-tuned on the natural language inference (NLI) task.\(^5\)

Considering ETM and ETM-PWE, in addition to the hyperparameters mentioned above, we only optimize the number of neurons (ranging from 100 to 1000). We follow the original implementation, for which the number of hidden layers is set to 1. For ETM-PWE, we use pre-trained word2vec word embeddings (Mikolov et al., 2013), trained on the Google News corpus (3 million 300-dimension English word vectors).

For the neural models, we set the batch size to 200 and we adopted an early stopping criterion for determining the convergence of each model. We set the remaining model parameters to their default values. To have a fair comparison, we set the number of topics to be discovered equals to the number of classes available in each dataset, i.e. 10 for M10 and 20 for 20NG. For running the experiments, we use the open-source library OCTIS (Terragni et al., 2021a), which already integrates the implementations of the considered models and metrics. It is available at the following link: https://github.com/mind-lab/octis.

### 4 Empirical Analysis and Discussion

#### 4.1 Robustness of Neural Topic Models (RQ1)

In table 3 we report the median of the four evaluation metrics for each topic model obtained by the best hyperparameter configuration. Rows represent the optimized metric (marked as metric*), while columns denote the median of the evaluated metric. The overall best values for each metric and dataset are reported in bold. First of all, we can observe that there is not a model that outperforms the others for all the considered metrics. In fact, it seems that each topic model works better for a specific metric.

In particular, LDA is the topic model that obtains the best performance in terms of KL-B*, thus obtaining topics that are significant rather than background topics. While, the topic models based on the neural variational framework defined in (Srivastava and Sutton, 2017), i.e. NeurLDA, ProdLDA, and CTM, are the ones that obtain the highest diversity. Regarding the topic coherence, CTM obtains the best topic coherence for both datasets. In fact, it improves the performance of ProdLDA (second-best model for the topic coherence) through the incorporation of the contextualized pre-trained representations of the documents. Finally, ETM-PWE outperforms the other models in terms of F1*, probably due to the contribution of the pre-trained word embeddings.

Provided that each topic model seems to reach the best performance only in a specific metric, it follows that they cannot simultaneously guarantee optimal performance for the other metrics. We will further investigate the trade-off between different metrics in Sections 4.2 and 4.3. A complete overview of the best configuration of hyperparameters discovered by BO for all the models and for all the considered evaluation measures is reported in Tables 4, 5, 6, 7, 8 and 9. This would allow a user to choose a promising hyperparameter configuration for the evaluation metric of their interest.

\(^5\)https://huggingface.co/sentence-transformers/bert-base-nli-mean-tokens
4.2 Impact of the Document Length (RQ2)

We can derive other insights by analyzing Table 3 and comparing the two datasets. In particular, we highlight that for LDA the document length seems to be an invariant when optimizing on the KL-B* metric. This insight can be grasped by considering the KL-B* of LDA (i.e. 2.343 for M10 and 2.299 for 20NG) that, not only are the best performance when compared to the other models, but they suggest that LDA performs well independently on the document length and therefore it guarantees optimal KL-B* both on short and long documents.

Another important insight is about the F1 measures obtained by LDA (0.472 and 0.469), ETM (0.534 and 0.453), and ETM-PWE (0.585 and 0.471), which seem to be not affected by the length of the documents. On the other hand, the results for the F1 measure for NeurLDA, ProdLDA, and CTM (which are based on the same architecture) are affected by the documents’ length, obtaining the best performance for short texts. In these cases, when the models achieve a high F1 on short documents (0.420 by NeurLDA, 0.539 by ProdLDA, and 0.563 by CTM), the performance on short documents is lower (0.339 by NeurLDA, 0.373 by ProdLDA, and 0.361 by CTM).

When optimizing for the IRBO* metric, all the models succeed in obtaining almost completely diverse topics, both for long and short texts. The performance of IRBO* for LDA* is slightly affected when dealing with short texts. Finally, we remark that CTM obtains an excellent topic coherence for both datasets, but, on the other hand, the remaining models seem to be particularly affected when dealing with short texts, assuming NPMI values inferior to 0.

4.3 Metrics-Metrics Correlations (RQ3)

In Figure 1, we report the correlations between the evaluation metrics when a single-objective optimization policy is performed. The rows of the correlation matrices denote the optimized metrics (F1*, IRBO*, KL-B*, and NPMI*), while the columns the non-optimized evaluated measures (F1, IRBO, KL-B, and NPMI). According to these results, we can observe if optimizing a model for a specific metric allows us for an increasing or

decreasing performance of the other metrics. In Figure 1, we report the Spearman correlation coefficients between metrics using all the runs of a given experiment.

Concerning LDA, when the model is optimized for the KL-B*, NPMI*, or F1*, then the IRBO is positively correlated with these metrics. It is then sufficient to optimize one of the other metrics to get also diverse topics. This occurs in particular for the KL-B* and NPMI* on long documents (0.87 and 0.98 respectively). It is also interesting to notice that optimizing for KL-B* does not imply a maximization for the F1 and NPMI on long texts. To achieve better topic coherence and classification, we should consider background topics as well.

Focusing on NeurLDA, ProdLDA, and CTM, we do not observe substantial differences between long and short documents. IRBO* is not strongly correlated with the other metrics, especially for long documents. This can be grasped by observing the coefficients IRBO* vs F1, KL-B, and NPMI reported in Figure (1f), (1h) and (1d). On the contrary, optimizing NeurLDA, ProdLDA, and CTM for F1*, NPMI* or KL-B* guarantees, in most of the cases, a good performance on all the metrics both for short and long documents (Figure (1e), (1f), (1g) and (1h)).

Concerning ETM, the difference between long and short documents is clear: the optimization of a given metric can be detrimental to the majority of the other metrics when dealing with short documents. In fact, the optimization of ETM w.r.t. IRBO* and NPMI* originates correlation values with all the other metrics that are close to zero or negative (Figure 1i). On the other hand, F1* and KL-B* seem not to be affected by the difference of the datasets. This suggests that maximizing KL-B* or F1* implies good performance also for other purposes. Focusing on long documents (Figure 1j), the optimization of ETM w.r.t. F1*, KL-B*, and NPMI* originates positive correlation values for all the other metrics. On the other hand, we can highlight that optimizing the topic diversity IRBO* does not allow us to simultaneously obtain good performance on topic coherence (NPMI) on long documents. Regarding ETM-PWE, we do not notice a clear difference between the two datasets. The introduction of the pre-trained word embedding into the training process of the model seems to be beneficial for all the metrics.

To summarize, optimizing the neural models according to the IRBO* is not always convenient and may lead to incoherent topics or poor document classification performance. Another important insight concerns the optimization of F1*, which usually guarantees to maximize IRBO, KL-B, and NPMI, for both short and long documents, except for LDA.

5 Conclusions and Future Work

In this paper, we presented an empirical analysis of Neural Topic Models to determine the relationship between hyperparameters, document length and performance measures. Three main research questions have been addressed for understanding under which conditions such Topic Models could work for guaranteeing their best performance.

The main findings could help both practitioners on tuning the models according to their objectives and researchers to explore the role of hyperparameters and document length with respect to any given performance measure. Regarding the future work, the problem of hyperparameter optimization by considering multi-objective optimization (Horn and Bischl, 2016) will be addressed for understanding to which extent multiple metrics could be optimized according to the length of the documents and the hyperparameters of the models.

Abstract

Recognizing named entities in short search engine queries is a difficult task due to their weaker contextual information compared to long sentences. Standard named entity recognition (NER) systems that are trained on grammatically correct and long sentences fail to perform well on such queries. In this study, we share our efforts towards creating a cleaned and labeled dataset of real Turkish search engine queries (TR-SEQ) and introduce an extended label set to satisfy the search engine needs. A NER system is trained by applying the state-of-the-art deep learning model BERT to the collected data and its high performance on search engine queries is reported. Moreover, we compare our results with the state-of-the-art Turkish NER systems.

1 Introduction

Named entity recognition (NER) aims to identify the predetermined entity categories (person, organization, location, etc.) accurately in a given text. NER studies which is one of the most widely studied subjects in the field of natural language processing (NLP), has been started for English and spread over a range of languages including Turkish (Yeniterzi, 2011). Initial NER studies for Turkish used small labeled datasets that contain grammatically correct and typo-free sentences. Since manual labeling is a time-consuming and a costly process, gathering larger datasets and manually labeling them has not been feasible. With the increase of internet use, correctly classifying named entities has become a crucial need especially for social media entries and search engine (SE) queries. In search engines, identifying entities such as famous persons, places or dates in user queries is crucial in order to accurately determine the information to be displayed to the user and response with the right information. For example, if the user is searching for a famous person, SE should return the Wikipedia information about the person. Moreover if this famous person is an artist, the identified named entity assists in conveying the details of his/her movie/album/artwork details. Similarly, it is important to determine the location in the query for which we want to know the weather.

The state-of-the-art Turkish NER tools fail to perform well on search engine queries due to two main reasons. The first reason is that most of the NER tools that have been developed for Turkish so far generally carry out categorization studies with three classes (Person, Organization and Location). Naturally, a three-class model cannot detect all the named entities in a SE query that is required to create a successful SE response. For this reason, it has become a necessity to determine the entity types specific to the SEs and to make a special development for these types. The second reason is that NER tools are dependent on the texts and domains they are trained on. NER tools, which are usually trained in canonical and grammatically correct long sentences, do not succeed in short SE queries that contain abbreviations and spelling errors and mostly consist of two or three words. As the short inputs have poor contextual knowledge compared to long sentences and often include misspellings, existing NER tools are observed to perform poorly on these type of texts and the success rates are far below the desired levels.

Although the first attempts for Turkish NER systems are dominated by rule-based systems (Kıčük and Yazıcı, 2009), CRF-based models (Yeniterzi, 2011; Seker and Eryiğit, 2012; Yeniterzi et al., 2018) came to the fore in the forthcoming studies. In all of these studies, a relatively small dataset consisting of about 30K sentences, clean in terms of spelling and grammar, is used (Tur et al., 2003) and models are based on three classes (person, location, organization). Recently, models using deep learning methods (Demir and Ozgur, 2014; Aras et al., 2021), especially Bidirectional Long Short-Term
Memory (BLSTM), became more popular (Güneş and Tantuğ, 2018).

Even though the accuracies of these NER studies are high in their test sets, the performance drop is dramatical on social media (e.g., Twitter) and SE queries (Çelikkaya et al., 2013; Küçük and Steinberger, 2014). For this reason, studies are carried out to collect dedicated data for social media texts (Okur et al., 2016). The most recent studies in Turkish NER field utilize Transformers and BERT based models (Yıldırım, 2019; Akdemir and Güngör, 2019; Aras et al., 2021).

In this paper, we focus on the recognition of a selected group of named entities for Turkish search engine queries. In the study, Yaani\(^1\) search engine entries are collected, the categories for the SE needs are determined and a labeling study is carried out using an in-house annotation tool. The data consisting of a total of 100\(K\) SE queries is labeled by more than one person and a verification study is carried out with the obtained outputs. In addition, a high-performance NER tool is developed by training the Transformers-based BERT (Devlin et al., 2018) model, which is one of the most successful approaches and widely used in current NLP studies, with our labeled dataset, and an accuracy of 90.41% is achieved.\(^2\)

2 Dataset Creation Process

For data-driven NER systems to perform well on real world scenarios, it is of crucial importance to have training data that has a similar distribution with the real world data. In order to satisfy this constraint, we carried out an extensive data collection and labeling process for a NER system specific to SE queries. We collected a dataset of 100\(K\) queries that are submitted to Yaani search engine for a specific period of time without having a constraint related to short/long queries. Next, we cleaned the malicious content and normalized the spelling errors manually. Finally, we removed the duplicates which resulted in a dataset with \(97,428\) queries.

2.1 Determining Entity Classes

Active usage of widgets and snippets is a particular way of enhancing user experience in search engines. Currently, most of the well-known search engines respond to user queries via widgets and snippets which convey information requested by the user in a concise and compact manner. The main motivation behind this study is the extraction of relevant information obtained from user queries and activate related widgets and snippets accordingly. At the time of this study, recognition of named entities specific to particular widgets such as weather, currency converter, maps and info boxes (i.e., Wikipedia results) have been focused.

Due to the inadequacy of the standard three-class model for a SE specific NER model; we examined 48 different entity categories provided by Shrinked TWNERTC Turkish NER Data \(^3\) (Şahin et al., 2017) and selected the following seven main categories to cover different agents such as weather, maps, and currency inquiries. These classes are as follows;

- **Person**: All type of proper names for persons
  Ex: Mustafa Kemal Atatürk, Prof. Dr. Ali Ünal

- **Organization**: All type of entities that have an organization or that are organized such as government institutions, firms, hospitals, universities, soccer clubs, festivals Ex: Walter Reed Askeri Hastanesi (Walter Reed Military Hospital), İstanbul Üniversitesi (İstanbul University)

- **Location**: All places that have a physical position like countries, cities, villages, etc. Ex: İstanbul, Van Gölü (Van Lake), Hollywood

- **Date**: All date/time entries plus important dates like "mother’s day" etc. Ex: 15.02.2020, 15 Ekim (November, 15th), M.Ö 500 (500 B.C.), 1870

- **Measure**: All entities that are in the global standard, the International System of Units (SI), such as, kg, lt, etc. Ex: 1700 metrekare (square meters), 2 lt (liters), 300 metre (meters)

- **Currency**: All currency entities plus commodities such as gold, silver and cryptocurrency Ex: 19 milyon TL (milion Turkish Liras), 20 bitcoin, 10 gram altın (gram of gold)

- **Production_art_music**: All entities that are produced like films, series, songs, books, etc.

\(^1\)yaani.com.tr
\(^2\)The data is freely available for academic purposes. Please contact the authors for dataset acquisition.
2.2 Labeling Process

Following the category determination, we organized a team of twenty people for data labeling. We shared a labeling guide in which we itemized the tagging criteria and provided positive and negative examples. We also asked annotators to complete a demo task before initializing the main project. By the help of the demo outputs, we revised the labeling guide and finalized the rule set as follows:

- A NE should be labelled to include the longest phrase that can be retrieved. **Ex:** Bursa Büyükşehir Belediyesi (Bursa Metropolitan Municipality) should be labeled as **Organization** as a whole instead of labeling only Bursa as **Location**.

- Successive NEs of the same type should be labeled individually if separated by "," or "and". **Ex:** Washington DC White House should be labelled seperately in Washington DC'deki Beyaz Saray'a nasıl giderim (How can I go to the White House in Washington DC), instead of selecting it as a whole phrase such as White House in Washington DC.

- While labeling person NEs, if the title phrase does not have another NE, the whole title will be labeled as **Person**. **Ex:** İçleri Bakamı (Minister of Interior) Soylu will be labeled as a whole as **Person** but as the query Bursa Büyükşehir Belediyesi Başkanı (Mayor of Bursa Metropolitan Municipality) Alinur Aktaş has an **Organization** NE in the phrase Bursa Büyükşehir Belediyesi (Bursa Metropolitan Municipality), labeller will seperately label this phrase and only label Alinur Aktaş as **Person**.

- General names following a proper name should not be included in the NE except the location names including "Lake", "Street" and "University" etc. **Ex:** İstanbul should be labeled as **Location** in the query İstanbul ilinde hava durumu (Weather forecast in Istanbul city), on the other side, location names such as Van Gölü (Van Lake), İstiklal Caddesi (İstiklal Street) should be labeled with the following location name.

- Due to the Turkish morphology, an apostrophe is attached at the end of the proper name if it is followed by a suffix. Such words with apostrophes should be labeled as a whole. **Ex:** Yunanistan’ın (Greece’s) should be labeled instead of Yunanistan (Greece) in queries.

- Subordinates consisting more than two or more words should be labeled as a whole.

During the whole process, we employed an in-house labeling and verification tool. Figure 1 shows an example annotation screen used in the study. In the light of the given instructions, the annotator labeled the phrase Fazilet Hanım ve Kızları (a Turkish serie) as **Production_art_music** and Ege- menler Yalısı (a location in this serie) as **Location**.

### 2.3 Consolidation Step: Annotator Disagreement

The first three weeks of the annotation process was dedicated to the labeling of the queries and the final week was used to check the mismatches between
annotators and consolidate the output. Almost half of the queries (45,442) are labeled by two different annotators. These queries are categorized into three groups; i) queries that both annotators agree on, ii) queries that two annotators do not agree on, and iii) queries that one of the annotators labels some words and the other annotator does not label any of the words.

Leaving out the queries that both annotators agree on, 10,800 queries are considered in the consolidation step in which four experts (different from the annotators) checked the mismatching labels. If any of the labels is correct, it is selected as the final label. If both labels are wrong, the true label is determined by the expert. Figure 2 illustrates the consolidation screen used in order to analyze the mismatch between the annotations of a query. Regarding the rule that the longest phrase should be retrieved, the label from the first annotator is kept and the label from the second annotator is discarded.

2.4 Dataset Statistics

The collected dataset consists of 97,428 search engine queries and includes 294,100 words. Figure 3 illustrates the distribution of query lengths. The dataset mostly contains short word sequences of length between one and four. The average length of the queries is 3.018. The longest query has 35 words whereas the shortest one is a single word.

Table 1 provides the number of different named entity types used in this study and the percentage of multi-word entities for each type. The most frequent named entity type is Organization. Person, Production_art_music and Location are three other named entity types that occur too often. Measure is the rarest type whereas Date and Currency are not observed very frequently.

3 Experiments and Results

Using this new dataset, we trained a Turkish NER system and demonstrated the improved NER performance of using short search queries during training. Our Turkish NER system is trained by fine-tuning the BERTurk (Schweter, 2020) model using our dataset. BERTurk is a community driven BERT (Bidirectional Encoder Representations for Trans-

Table 3: Comparison of three class NER performances

formers) (Devlin et al., 2018) model for Turkish. Its training corpus has a size of 35GB and 44B tokens with a vocabulary size of 128K. For fine-tuning the BERTurk model for NE classification, \( \text{max} \_\text{seq} \_\text{length} \) is set to 128, \( \text{train} \_\text{batch} \_\text{size} \) and \( \text{eval} \_\text{batch} \_\text{size} \) are set to 32, \( \text{learning} \_\text{rate} \) is set to \( 2e^{-5} \) and the model is trained for 5 epochs.

In order to evaluate the performance of the NER system, the dataset is split into three: train, validation and test. For the test set, 1% of the data is selected randomly from the whole dataset by preserving the distribution of named entity types. Similarly, 1% is randomly selected as validation data and the remaining 98% is used for training. Using 1% of the whole dataset for testing purposes resulted about 1000 test queries and all seven classes are included proportionally to their distribution in the dataset.

In addition to the BERT model, we have also experimented with a pre-trained version of ELECTRA (Clark et al., 2020) model (also publicly available within the BERTurk study), which allowed us to compare the performance of the collected dataset on different deep architectures. Table 2 illustrates the performance of the NER systems (TC-BERT and TC-ELECTRA) fine-tuned using our dataset.

Publicly available Turkish NER models and other studies in the literature usually take three named entity types (Person, Organization and Location) into account. The effort towards increasing the number of named entity types is very limited for Turkish and to the best of our knowledge there is no other study that focuses on the named entity types discussed in this paper. Therefore, comparing the performances of our system with previous studies on the same test set is not immediately clear.

For a fair comparison, we removed the remaining labels from our test set by keeping three base named entity types (Person, Organization and Location). Since our model is based on seven named entity types, we filtered out the output labels that belong to other types (by masking as Other) and generated the final results. We compare our results with two recent Turkish NER studies: i) the NER model of “Turkish-Bert-NLP-Pipeline” (Yıldırım, 2019) that is known for its high performance on well-formed Turkish texts and ii) recent neural sequence tagging models discussed in (Aras et al., 2021). As depicted in Table 3, the NER system trained using our dataset of short queries outperforms the systems trained using grammarly correct Turkish sentences, both in terms of accuracy and F-measure.

4 Conclusion

This study presents a new Turkish NER dataset which is created specifically for short word sequences that comprises a large portion of the search engine queries. Our aim is to improve the NER performance of the models that are trained using grammatically correct sentences and fail to perform well on search engine queries. The dataset is created by cleaning and labeling 100K search queries and provides a rich resource for Turkish NER studies. In addition, our transformer based NER system presents useful baseline accuracies for future studies.

Our next step is to train a BERT-based language model from scratch by using search engine queries and replace the pre-trained BERT model provided by BERTurk. This will allow us to develop a NER system specific to short queries. Furthermore, creating a knowledge graph by utilizing the named entity labels will be an important step in enhancing
overall search engine performance.

Abstract

Opinion prediction is an emerging research area with diverse real-world applications, such as market research and situational awareness. We identify two lines of approaches to the problem of opinion prediction. One uses topic-based sentiment analysis with time-series modeling, while the latter uses static embedding of text. The latter approaches seek user-specific solutions by generating user fingerprints. Such approaches are useful in predicting user’s reactions to unseen content. In this work, we propose a novel dynamic fingerprinting method that leverages contextual embedding of user’s comments conditioned on relevant user’s reading history. We integrate BERT variants with a recurrent neural network to generate predictions. The results show up to 13% improvement in micro F1-score compared to previous approaches. Experimental results show novel insights that were previously unknown such as better predictions for an increase in dynamic history length, the impact of the nature of the article on performance, thereby laying the foundation for further research.

1 Introduction

Sentiment analysis plays a key role in economic, social, and political contexts. Companies can understand customer’s opinions based on reviews and/or social media conversations to make fast and accurate product decisions. They can index unstructured customer data at scale based on broad sentiments such as positive, negative, or neutral. It also enables market research - explore new markets, anticipate future trends, and seek an edge on the competition. In a political context, sentiment analysis can be useful in understanding political homophily using tweets analysis (Caetano et al., 2018).

Moreover, as social media has emerged as a new source of communication, governments can analyze people’s reactions to issues such as police-related encounters, mob protests and anticipate responses before they turn violent. In this context, predicting people’s opinion before expressing is an important next step in applying sentiment analysis to real-world applications. We are approaching this problem through sentiment prediction, especially on current news events, that can raise situational awareness, understand the future viewpoints of the citizenry on pressing social and political issues.

Recently fine-grained models generated a person’s fingerprint, based on one’s recent reading and response history, to predict response on an unknown event (Yang et al., 2020). In this work, we propose a novel architecture to create a dynamic fingerprint of a user that is contingent upon the target event. We choose to evaluate our models on the dataset used by Yang et al., 2020, which contains newspaper articles as events and users’ comments on them as opinions. Those ground truth opinions are used as a basis for sentiment prediction in this work.

Our model consists of three main steps. In the first step, relevant articles are extracted from a user’s reading history based on their similarity to target article. In the second step, the contextual embedding of these relevant articles, conditioned on the target article, is used to create a reading track. Similarly, we create a writing (response) track with the contextual embedding of extracted articles with corresponding comments by the user. Lastly, dynamic fingerprints are generated based on the temporal pattern of the reading and writing tracks. These dynamic fingerprint vectors for a particular user are then used to predict the user’s sentiment on the target event.

Our main contributions in this paper are:

1. A novel architecture of dynamic fingerprint generation based on the contextual embedding of the user’s reading history.
2. Experimental results show that our method
outperformed the previous approach over various news outlets datasets.

2 Related work

Opinion prediction based on the temporal pattern of sentiments is a relatively new research topic, but basic concepts such as sentiment analysis, question answering based on dialogue context have been explored in different communities and settings.

Si et al., 2013 proposed a technique to leverage topic-based Twitter sentiments to predict the stock market using vector autoregression and Dirichlet process mixture models. Li et al., 2019 proposed a time+user dual attention-based LSTM network to perform emotional analysis on Chinese public opinion texts on social networking platform. But they did not use contextual embedding and explore the prospect of generating a unique user fingerprint before predicting sentiment.

Conversational question answering (CQA) is an emerging research area in the machine reading comprehension task (MRC). For single-turn MRC tasks, contextualized language representation using BERT has obtained state-of-the-art scores on SQuAD datasets (Devlin et al., 2019). CQA is a multi-turn question answering task that includes passage comprehension, contextual understanding, and coreference resolution. Zhu et al. have proposed SDNet (Zhu et al., 2018) to solve this problem by concatenating previous questions and answers as one query to fuse context into traditional MRC models by leveraging BERT, attention, and RNN techniques. Similarly, Ohsugi et al., 2019 have proposed fine-tuning approach with BERT in a multi-turn context by modeling the interaction between paragraph and dialogue history independently.

However, these models cannot be applied to the present problem since they did not integrate the concepts of the sequential pattern of sentiments along with the unique fingerprint of each user, which can play a key role in predicting the future opinion of a user on different topics.

3 Proposed model and methodology

In this section, we propose two classes of FingerPrint Embedding models (FPE) - Static and Dynamic - for the task of predicting the sentiment of a user $u$ to a new article. In a narrow sense, we used the term static to refer to the approach of using recent comment history, which is independent of the nature of target article $A(t)$, and dynamic to refer to the approach of using articles relevant to target article $A(t)$ in the overall history of user’s comments, which are dependent on the nature of target article. In a broad sense, static and dynamic terms distinguish the way target article $A(t)$ is integrated with user’s reading history to generate the fingerprint.

We used the user’s commenting history on articles that they read. We assume that we know the sentiment of each comment. (This can be obtained with one of the many sentiment analysis tools.) Formally, we are given the articles, comments along with the sentiments of a user $u$, i.e., $(A_1, C_1, S_1), (A_1, C_2, S_2), ..., (A_2, C_j, S_j), ..., (A_{t-1}, C_n, S_n)$, and the goal is to predict the sentiment $S_t$ of $u$’s response to unseen article $A_t$. In general, $n > t$ because a user may post multiple comments to an article.

The overall architecture includes history selection, text embedding, fingerprint creation, and lastly sentiment prediction. We describe them below.

3.1 History selection

We have explored two methods of history selection - static history and dynamic history.

Given an article $A_t$, its static history, according to the user $u$, is the list of the most recent article-comment pairs posted by $u$. Depending on the magnitude of $s$ and number of comments made by the user, the list may include comments from one article or multiple articles. We use this method in the Static FPE model.

For the dynamic history of article $A_t$, we have ranked all articles of author’s reading history based on similarity and picked top $r$ articles, along with their comments, as shown in Figure 1. Here similarity between articles is calculated using DistilRoBERTa Semantic textual similarity model (Reimers and Gurevych, 2019).

It is a variant of sentence-BERT, a modified pre-trained BERT network that uses siamese and triplet network structures to derive semantically meaningful sentence embeddings that are then compared using the cosine-similarity metric.

Table 1 shows the article samples extracted by both methods. For the target article “Pelosi says house will condemn all hate as anti-semitism debate overshadows congress”, we can see that articles in the dynamic history, especially articles 1,3,4

Table 1: Articles extracted by different methods of history selection. We can see that dynamic history of articles are more relevant than static history.

are more related to the themes such as congress, hate etc., of target article. But static history does not show any relevant articles, except for article 4, which was also because the user has read the target article in the recent past. So we can see that dynamic history has a more pertinent set of articles than static history.

3.2 Text embedding

In this stage, we create reading and writing tracks based on the selected user’s history. Specifically, we encode articles and comments using contextual embedding by two types of encoders (BERT variants) - DistilBERT (Sanh et al., 2019) and ELECTRAN (Clark et al., 2020) models. However, the proposed models are open to any variant of BERT encoder. We have used encoders in two modes - single-sentence mode where single span of contiguous text is encoded in form a special classification token \([CLS]\); two-sentence mode where two spans of text separated by \([SEP]\) token are encoded as \([CLS]\).

In the static FPE model, as shown in Figure 2, reading track comprises of selected articles, encoded by fixed-length \([CLS]\) tokens of single-sentence mode of BERT variant models, i.e., \([CLS]_{t-1}, ..., CLS_{t-2}, CLS_{t-1}\). We have conducted experiments both on - pretrained (with frozen parameters) and trained - BERT variants. Writing track comprises of both article and comments at each time step \(k [A_k, C_k]\), encoded as \([CLS]\) token outputs of two-sentence mode of BERT variant models, similar to reading track, i.e.,
For the Static FPE model, in stage 1, for a target article \( A(t) \), \( s \) article-comment pairs from \((t-s)\) to \((t-1)\) immediate past from a particular user’s history are selected. In stage 2, the contextual embedding of \( s \) articles are generated, and corresponding [CLS] tokens from DistilBERT/ELECTRA models are extracted as reading track \( R(t-s) \) to \( R(t-1) \). Similarly, contextual embedding of articles \( A(t-s) \) to \( A(t-1) \) conditioned with corresponding comments \( C(t-s) \) to \( C(t-1) \) are generated and [CLS] tokens are extracted as writing track \( W(t-s) \) to \( W(t-1) \). In stage 3, an RNN with 2 hidden layers is trained with concatenation of both tracks against corresponding comment sentiment \( S(t) \) at each time step \( t \) and the last hidden layer output is extracted as the fingerprint of user. In the last stage, a Multi-layer perceptron (MLP) is trained on the concatenation of the fingerprint \( h^f_t \) and [CLS] against the sentiment \( S(t) \) of the user’s comment on article \( A(t) \).

\[
[CLS]_{t-s}, ..., CLS_{t-2}^W, CLS_{t-1}^W.
\]

In the dynamic FPE model, as shown in Figure 3, for the reading track - target article \( A_t \) is appended to every article of relevant history and both of them are encoded by two-sentence mode of BERT variant models as [CLS] token outputs, i.e., \([CLS]_{t-r}, ..., CLS_{t-2}^R, CLS_{t-1}^R\). The writing track is similar to that of static FPE model, i.e., \([CLS]_{t-r}^W, ..., CLS_{t-2}^W, CLS_{t-1}^W\).

Lastly, both the tracks are concatenated at each time step to create a unified fingerprint in case of static FPE model. But in dynamic FPE model, these tracks are used as separate entities to create two different fingerprints in the next stage.

### 3.3 Fingerprint creation

In this stage, unidirectional RNN is used to form contextual understanding of both reading and writing tracks.

In the static FPE model, each [CLS] token of reading track is concatenated with corresponding [CLS] token of writing track at each time step, i.e., \([CLS]_{t-r}^R, CLS_{t-s}^W, ..., CLS_{t-2}^R, CLS_{t-2}^W, CLS_{t-1}^R, CLS_{t-1}^W\). We have used Gated Recurrent Unit (GRU) (Chung et al., 2014) instead of LSTM, because the former has fewer parameters, trains faster with comparable performance to the latter. A two-layer GRU network is trained with the above concatenated output against corresponding sentiments \( S_{t-s}, ..., S_{t-2}, S_{t-1} \). The last hidden layer output is taken as the fingerprint embedding \( h^f_t \) for article \( A_t \) of user \( u \).

In the Dynamic FPE model, we create a separate fingerprint for the reading track and writing track, respectively, with 2-layer RNN and 1-layer RNN networks. Both are GRU networks. An additional layer is used for the reading track to get a more complex feature representation of the relationship between target articles and the relevant history of articles. Here, fingerprint embedding is the concatenation of the last hidden layer outputs of both networks, i.e., \([h_t^R; h_t^W]\).

### 3.4 Sentiment prediction

Lastly, a one-layer Multi-Layer Perceptron (MLP) is trained with concatenation of fingerprint embedding and [CLS] token embedding of the target article, as input against the sentiment of response. In the static FPE model, the MLP is trained on \([h^f_t; CLS^A_t]\) against output \( S_t \). Whereas in the dynamic FPE model, it is trained on \([h_t^R; h_t^W; CLS^A_t]\) against output \( S_t \).

## 4 Experiments

The main goals of our experiments are:

1. Measure the performance (in terms of micro
Figure 3: For the Dynamic FPE model, in stage 1, for a target article \( A(t) \), \( r \) relevant article-comment pairs from a particular user’s complete history are selected based on semantic textual similarity. In stage 2, the contextual embedding of each of the \( r \) articles conditioned with target article \( A(t) \) is generated and corresponding [CLS] tokens from DistilBERT/ELECTRA models are extracted as reading track. Similarly, the contextual embedding of articles \( A(t-r) \) to \( A(t-1) \) conditioned with corresponding comments \( C(t-r) \) to \( C(t-1) \) are generated, and [CLS] tokens from DistilBERT/ELECTRA models are extracted as writing track. In stage 3, the reading track is encoded with a two-layered RNN trained against the corresponding comment sentiment \( S(t-r) \) to \( S(t-1) \) at each time step and the last hidden layer output is extracted as the reading fingerprint of the user. Similarly, the writing track is also encoded with a one-layered RNN and the last hidden layer output is extracted as a writing fingerprint. In the last stage, an MLP is trained on the concatenation of the reading fingerprint \( h_f^R \), writing fingerprint \( h_f^W \) and [CLS] \( A(t) \) against sentiment \( S(t) \) of corresponding comment \( C(t) \) of user on article \( A(t) \).

F1-score) of both static and dynamic model variants in the prediction of the sentiment of a user to an unknown article

2. Analysis of model performance by studying the impact of dynamic history length and nature of articles on prediction.

4.1 Data preparation

We perform our empirical study on the datasets used for Personal opinion prediction by Yang et al., 2020. In these datasets, news articles are randomly selected from Archiveis, The Guardian, and New York Times. We do not consider users with fewer than ten comments. If after this step an article remains without any user, the article is discarded. We checked manually a random subset of articles and their comments and found that irrelevant comments are very few to ignore.

Each input example case comprises a target article/comment and its corresponding selected history of article-comment pairs. For each user, the data is split into training and test sets in the ratio of 90:10 ratio sequentially, i.e., the last 10% of comments made by user chronologically as test data and the remaining as training data. Also, the training set is split into training and validation data in the ratio of 90:10 preserving the sequential order.

Since our task is to predict the sentiment (as a score in \([-1, 1]\)) on a future comment, we considered 4 models to conceive the sentiment score. They are - Vader (Hutto and Gilbert, 2014), Flair (Akbik et al., 2019), BlobText sentiment, and BlobText subjectivity (Loria et al., 2014), to automatically label all comments. We assume that users have consistent views and stances on the same event within these articles and comments. Vader is a rule-based model for general sentiment analysis. It is constructed from a generalizable, valence-based, human-curated gold standard sentiment lexicon. When assessing the sentiment of tweets, Vader outperforms individual human raters (Hutto and Gilbert, 2014). Flair presents a unified interface for all word embeddings and supports methods for producing vector representation of entire documents. We use the Flair pre-trained classification model for sentiment labels. The model is trained on the IMDB dataset and has 90.54 micro F1-score. BlobText is a simple rule-based API for sentiment analysis. It has both sentiment model and subjectivity model, and we refer to them as Bsent and Bsubj respectively.

We used article titles and comment content as the basis for our model. We did not use article content since they are extremely long and moreover our focus is on user’s opinion on the article, not the article per se. Table 2 shows the dataset statistics.
Figure 4: Micro F1-scores of all models on test data for all outlets with baseline scores, shown as white empty circle in the figure. We can see that dynamic FPE models have better performance of 4-13% points over baseline FPE model, except for Vader sentiment, across all three outlets.

4.2 Baselines and experiment settings

We evaluated our models against the baseline Fingerprint embedding (FPE) model (Yang et al., 2020). In FPE, recent history of a target article was extracted and then Byte-Pair Embedding (BPE) (Heinzerling and Strube, 2018) and GRU were used to encode the words in articles and comments into fixed-length vectors. Subsequently, user’s fingerprint was generated using a second GRU that modeled the sequence of history, which was a direct concatenation of prior articles and comments, encoded as fixed-length vectors. Finally, the concatenation of fingerprint embedding and target article embedding was given to MLP to predict the sentiment.

On the contrary, we examined both recent and relevant history of target article. We also used BERT based contextual embedding to encode the relationship between articles and comments rather than separate encoding. Finally, we created fingerprint separately for reading and writing track and then concatenated in the final stage for predicting the sentiment.

4.3 Implementation

As discussed in Section 3, we have primarily two models - static FPE and dynamic FPE- with different variants of each by using two types of contextual encoders- DistilBERT and ELECTRA, along with frozen and trained parameters. For static FPE models, we have taken an arbitrary history length of 12 article-comment pairs, so $s = 12$ for fingerprinting. For dynamic FPE models, we have taken relevant dynamic history length of 15 article-comment pairs, $r = 15$, after comparing micro F1-scores for various lengths from 5 to 20. We discuss about the impact of dynamic history length on performance in Section 5. In all cases, a hidden layer of GRU with a dimension of 256 is created. We have trained all model variants for 10 epochs and saved the model based on the mean micro F1-score over all four sentiments on the validation dataset. Usually, the best model is achieved around 5-6 epochs.

We use Adam optimizer with weight decay (Loshchilov and Hutter, 2019) and a schedule of learning rate (lr) that decreases following the values of the cosine function between the initial lr set in the optimizer to 0, with several hard restarts, after a warmup period during which it increases linearly between 0 and the initial lr set to 0.001 in the optimizer. We implemented the model using PyTorch lightning, a wrapper for PyTorch. The code is released at GitHub.

5 Results and discussion

Table 3 describes the model notation and configuration used in the results. Figure 4 shows that except for vader sentiment, all our model variants outperform the FPE baseline. In the remaining three sentiments, dynamic-FPE-ELECTRA (frozen) model with either dynamic or static history outperformed the remaining variants and also FPE baseline. This could be because of multiple reasons, and we discuss them below.

Firstly, contextual embedding, in place of static BPE embedding in FPE, of articles and comments is a key factor behind the superior performance. Specifically, the contextual embedding of article history with target article (reading track) and with corresponding comment history (writing track) has enabled us to generate a better representation of the input text.

Secondly, the dynamic FPE model, unlike the static FPE model, creates reading and writing fingerprints through GRU networks separately before concatenating them for sentiment prediction. With an extra GRU hidden layer in the reading track compared to the writing track, we have been able to create a higher level of understanding of the temporal relationship between target article and history articles. From these fingerprints, we also found that users with the closest fingerprints in the euclidean space are found to have higher prediction accuracy than that of farther fingerprint users.

Further, the ELECTRA-based model outperforms DistilBERT-based model in most of the cases, despite having only 20% of the number of parameters of DistilBERT-based model. This reiterates the result of Clark et al., 2020 that novel pretraining by a discriminative model that predicts whether each token in the corrupted input was replaced by a generator sample or not performs better than masked language modeling pretraining method of DistilBERT, even for a small model.

Other important inferences are:

1. Performance increases with length of relevant history for dynamic FPE models in general;
2. Articles with a large proportion of comments with negative sentiment have a higher micro F1-score compared to controversial (equally positive and negative sentiment comments) and positive comments (predominant positive sentiment comments).
3. BERT variant models with frozen parameters have better performance than those with all parameters trained. This may be because the pretrained model is trained on a much larger corpus than our problem dataset and so it has better language understanding.

For complete details of these experiments, please refer to longer version of the paper.

6 Limitations and future work

According to Sutrop and Laas-Mikko, 2012, fingerprinting for predicting behavior is second-generation biometrics, which is different from first-generation biometrics that uses characteristics that are visible to the naked eye such as facial images.
hand fingerprints. In this context, user fingerprinting in our model can be loosely classified under behavior fingerprinting. We did linguistic opinion and content-based user fingerprinting as a response history embedding for a user. In this section, we briefly discuss the limitations of the dataset and model, and future research direction.

Firstly, the newspaper articles, in general, may be biased in terms of story selection, tone, and organizing of the story. The users (readers) may also have an implicit bias - attitudes that unconsciously affect individual thoughts and actions - and confirmation bias - the tendency to support information that confirms their beliefs. To address these biases, we would like to extend our model to datasets that are not related to news articles.

Moreover, representations encoded in the models often inadvertently perpetuate undesirable social biases from the data on which they are trained. NLP models, especially neural embeddings, may perpetuate these biases towards race, religion, gender and disability (Hutchinson et al., 2020; Manzini et al., 2019; Sap et al., 2019). Though the BERT variant based sentence encoders exhibit less bias than previous models (May et al., 2019), we would also like to experiment with other sentence encoders to measure the bias in our predictions in future work.

Another limitation of our approach is that we used only article titles rather than whole content. This would be more critical when the title is misleading, for instance in satirical articles. Moreover, we have not experimented with multilingual models of pretrained BERT variants.

For future research, these experiments can be extended for whole article content and use various attention mechanisms to generate better fingerprints and also generate author profiles based on their reading history. Further, BERT variants trained in other languages can also be used.

7 Conclusion

In this paper, we propose a novel dynamic fingerprinting technique based on BERT variants and RNN networks to predict a user’s sentiment to an unseen article based on reading-writing history. Two variants of our model extract relevant history in two different ways and create contextual embedding for articles read by a user conditioned with target article and also corresponding comments. Finally, we used RNN to interpret temporal relationship and create a fingerprint, which is used to predict unseen target article. Our models demonstrated state-of-the-art performance on a real-world dataset. From our experiments, we found that performance saturates after an optimum length of relevant history.

Abstract
The massive spread of false information on social media has become a global risk especially in a global pandemic situation like COVID-19. False information detection has thus become a surging research topic in recent months. In recent years, supervised machine learning models have been used to automatically identify false information in social media. However, most of these machine learning models focus only on the language they were trained on. Given the fact that social media platforms are being used in different languages, managing machine learning models for each and every language separately would be chaotic. In this research, we experiment with multilingual models to identify false information in social media by using two recently released multilingual false information detection datasets. We show that multilingual models perform on par with the monolingual models and sometimes even better than the monolingual models to detect false information in social media making them more useful in real-world scenarios.

1 Introduction
By June 2021, the coronavirus (COVID-19) pandemic has affected 219 nations around the world with 176 million total cases and 3.81 million deaths. The nature of the virus caused many governments to implement lockdown in their countries. As a result, many people started spending more time at home during the pandemic and started using social media more, providing an unexpected boost to engagement on these platforms (Hettiarachchi and Ranasinghe, 2020b).

As a drawback of these exponential growths, social media has become a conduit for spreading both rumours and deliberate misinformation, and many perpetrators are deploying sites such as Facebook, Twitter, YouTube, and WhatsApp to create a sense of panic and confusion. On the other hand, the general public can not completely ignore the information seen in social media due to the fact that the Centers for Disease Control and Prevention, the World Health Organisation (WHO), numerous journals, government and other health care organisations are regularly posting guidance across a host of platforms. Therefore, rather than completely disregarding information seeing in social media, accurate identification of false information is crucial (Nguyen et al., 2020).

Considering the high data generation in social media, manual approaches to filter false information require significant human efforts. Therefore an automated technique to tackle this problem will be invaluable to the community. In the light of this many shared task has been organised to tackle the false information detection in social media (Shaar et al., 2021; Nakov et al., 2021a) leading to implement various machine learning models which can identify false information automatically (Uyangodage et al., 2021; Tziafas et al., 2021). However, most of these approaches build language-specific models trained specifically on a particular language. Given the fact that most of the social media platforms are massively multilingual, maintaining fake news identification models for each language would not be feasible. One machine learning model that can work across many languages would be invaluable to the community.

In this research, we explore multilingual models for false information detection. We experiment with two recently created datasets that target two different aspects in false information detection which also covers 5 languages; Arabic, Bulgarian, English, Spanish and Turkish. We show that multilingual models based on pretrained transformer models perform on par with the language-specific models trained for each language on both aspects in false information detection making them more feasible in real-world applications.
2 Related Work

False Information Detection Identifying false information in social media has been a major research topic in recent years. According to literature, mainly, there are two types of methods for false information detection as Social Context-based methods and Content-based methods (Guo et al., 2020). Social Context-based methods use different properties in user profiles such as user’s credibility (Li et al., 2019) or stances (Mohammad et al., 2017) while the Content-based methods use different features in the content of posts such as certain keywords, number of URLs and the length of textual content to detect false information. However, due to ethical considerations, most of the social media platforms do not allow to release datasets with details which can be used to identify users of the posts. Therefore Social Context-based methods have not been popular in recent research as Content-based methods. Due to the nature of datasets we use for this research, we also focused on Content-based methods.

Content-based methods mainly focus on different features of post contents. For example, Castillo et al. (2011) found that highly credible tweets have more URLs and lengthy textual contents than low credible tweets. Also, many studies utilise lexical and syntactic components of the content as useful features. For instance, Qazvinian et al. (2011) found part of speech (POS) as a distinguishable feature for false information detection. Similarly, Kwon et al. (2013) found that some types of sentiments including positive words (e.g. love, nice, sweet), negating words (e.g. no, not, never), cognitive action words (e.g. cause, know) and inferring action words (e.g. maybe, perhaps) as apparent features for a periodic time-series model to identify key linguistic differences between true and fake tweets. With the recent popularity gained by embedding and deep learning-based approaches in natural language processing, there was a tendency to use deep neural networks powered by content embeddings to perform false information classification too (Ma et al., 2016). Later, with the introduction of transformers (Devlin et al., 2019; Conneau et al., 2020), there was a tendency to involve large pretrained transformer models also (Uyangodage et al., 2021; Tziafas et al., 2021; Qarqaz et al., 2021). However, all of these models were trained specifically on a single language making them less useful in real scenarios where we need to process multilingual data.

Multilingual models Multilingual models allow training a single model to perform a task on multiple languages. These types of models have been used by many tasks such as offensive language identification (Ranasinghe and Zampieri, 2020, 2021a,b) and machine translation (Nguyen and Chiang, 2017; Aharoni et al., 2019). All of these studies train one machine learning model on all the languages which the training data is available and show that the multilingual models perform on par with or sometimes even better than monolingual models. The recently released multilingual transformer models that support more than 100 languages like BERT (Devlin et al., 2019), XLM-RoBERTa (Conneau et al., 2020) have made multilingual research easier. Even though these multilingual models improve the feasibility of the research to be applied on a real-world application, to the best of our knowledge, no prior work has been done for multilingual false information identification focused by this paper.

3 Data

For this research, we used two recently released datasets on false information identification. We mainly considered two factors when selecting datasets; the dataset should be annotated in multiple languages and it should have been annotated very recently.

The first dataset (NLP4IF) which was released for NLP4IF shared task; Fighting the COVID-19 Infodemic is about predicting several binary properties of a tweet on COVID-19 such as whether it is harmful, whether it contains a verifiable claim, whether it may be of interest to the general public and whether it appears to contain false information (Shaar et al., 2021). The data has been released for three languages; English, Arabic and Bulgarian1. Seven labels were targeted by this dataset. The first label was Verifiable Factual Claim: Does the tweet contain a verifiable factual claim?. We only considered this label for our research as this is directly related to false information detection and this label had the most annotated data out of the seven labels. False information detection using this label can be considered as a binary text classification task.

1The dataset can be downloaded from https://gitlab.com/NLP4IF/nlp4if-2021
The second dataset (CLEF2021) that we considered was released for CLEF2021 CheckThat-Lab (Nakov et al., 2021a) Task 1: Check-Worthiness Estimation of the tweets (Nakov et al., 2021b). Given a tweet, the participants need to predict whether it is worth fact-checking. This task is directly related to the first label of the NLP4IF dataset. However, contrast to the binary classification in the previous task, the models in this task need to predict a continuous value between 0-1 that reflects the worthiness to perform fact-checking. The dataset has been annotated in five languages; Arabic, Bulgarian, English, Spanish and Turkish (Nakov et al., 2021b) promoting multilingual research.

4 Architecture

The main motivation for our architecture is the recent success that the transformer models had in various natural language processing tasks including text classification (Ranasinghe and Zampieri, 2020, 2021a,b), word sense disambiguation (Hettiarachchi and Ranasinghe, 2020a, 2021), language identification (Jauhiainen et al., 2021) etc. Apart from providing strong results compared to RNN based architectures (Ranasinghe et al., 2019), transformer models like BERT (Devlin et al., 2019) provide pretrained multilingual language models that support more than 100 languages which will solve the multilingual issues of these tasks (Ranasinghe and Zampieri, 2020).

Transformer models take an input of a sequence and output the representations of the sequence. There can be one or two segments in a sequence which are separated by a special token [SEP] (Devlin et al., 2019). In this approach we considered a tweet as a sequence and no [SEP] token is used. Another special token [CLS] is used as the first token of the sequence which contains a special classification embedding. For text classification tasks, transformer models take the final hidden state of the [CLS] token as the representation of the whole sequence (Sun et al., 2019). A simple softmax classifier is added to the top of the transformer model to predict the probability of a class. For text regression tasks, a fully-connected layer is added on top of the [CLS] token. The fully-connected layer will have a single output neuron which predicts the target. For both tasks, all the parameters of the transformer model as well as W are fine-tuned jointly by maximising the log-probability of the gold truth.

5 Experimental Setup

We trained a transformer model for each dataset mentioned in Section 3. Given the very unbalanced nature of the datasets, the transformer models tend to overfit and predict only the majority class. Therefore, for each label, we took the number of instances in the training set for the minority class and undersampled the majority class to have the same number of instances as the minority class.

We then divided this undersampled dataset into a training set and a validation set using the 0.8:0.2 split. We mainly fine-tuned the learning rate and the number of epochs of the classification model manually to obtain the best results for the validation set. We obtained $1e^{-5}$ as the best value for the learning rate and 3 as the best value for the number of epochs for both datasets. The other configurations of the transformer model were set to a constant value over all the experiments in order to ensure consistency between them. We used a batch size of 8, Adam optimiser and a linear learning rate warm-up over 10% of the training data. The models were trained using only training data. We performed early stopping if the evaluation loss did not improve over 10 evaluation rounds. The implementation was done using HuggingFace transformer implementation (Wolf et al., 2020). A summary of hyperparameters and their values used to obtain the reported results are mentioned in Table 1. The optimised hyperparameters are marked with $\dagger$ and their optimal values are reported.

Table 1: Hyperparameter specifications

For monolingual experiments, we trained language-specific transformer models on that particular language only. As pretrained transformer models, we used Arabert (Antoun et al., 2020) for Arabic, bert-base-cased (Devlin et al., 2019) for English, BETO: Spanish BERT for Spanish (Cañete et al., 2020) and BERTurk for Turkish. Unfortunately for Bulgarian, we could not find a suitable
pretrained transformer model. Therefore, for Bulgarian, we used the bert-multilingual-cased (Devlin et al., 2019) model.

For multilingual experiments, we first combined data instances from all the languages of each task which left us with two large multilingual false information identification datasets. Then we trained the transformer models on that combined datasets. As the multilingual pretrained transformer model, we used the bert-multilingual-cased (Devlin et al., 2019) model.

6 Results

In Table 2 we show the results we got for the test set of the NLP4IF dataset. We used the same evaluation metric as the organisers of the task; Macro F1 in order to compare our approach with the baselines and the best systems submitted.

Table 2: Results ordered by Macro F1 for Arabic, Bulgarian and English languages in NLP4IF dataset. Monolingual implies the results of the monolingual models and Multilingual implies the results of the multilingual model for each language. Additionally, we report Ngram and Random baselines, and best systems submitted for the shared task.

As can be seen in the results, for the NLP4IF dataset, multilingual models perform better than the monolingual models and the best systems in Bulgarian and English while performing on par in Arabic. Please note that these best systems (Qarqaz et al., 2021; Tziafas et al., 2021) have been trained specifically on those language pairs using language specific natural language processing pipelines, yet the multilingual models outperform them in English and Bulgarian.

The results for CLEF2021 dataset is shown in Table 3. For this dataset also we used the same evaluation metric that the organisers used - Mean Average Precision (MAP) (Nakov et al., 2021b) ².

Table 3: Results ordered by Mean Average Precision (MAP) for Arabic, Bulgarian, English, Spanish and Turkish languages in CLEF2021 dataset. Monolingual implies the results of the monolingual models and Multilingual implies the results of the multilingual model for each language. Best system denotes the results of the best system submitted to the language. Additionally, we report the Ngram baseline.

As can be seen in the results multilingual models outperformed monolingual models in Arabic, Bulgarian, Spanish and Turkish languages while performing on par with English. Similar to the results of the previous dataset, these multilingual models are very competitive with the best systems submitted to each of the languages.

7 Conclusion

In this paper, we explored multilingual models for false information identification using two recently created datasets. In our experiments, we observed that multilingual models built using powerful pretrained multilingual transformers perform on par or sometimes even better than the monolingual models. These results are consistent with

²The results are extracted from https://gitlab.com/checkthat_lab/clef2021-checkthat-lab
both datasets and across five languages. Findings in this paper would be valuable when building real-world applications for false information identification where maintaining separate machine learning models for each language would be more expensive and chaotic.

As future work, we would like to expand this research into more transformer models and more languages. We would like to experiment with how the multilingual transformer models with the cross-lingual concepts like XLM-RoBERTa would perform in multilingual false information identification. Furthermore, we would explore zero-shot and few-shot learning with multilingual models which would be beneficial to low resource language where the training data is scarce.

Abstract

Since a lexicon-based approach is more elegant scientifically, explaining the solution components and being easier to generalize to other applications, this paper provides a new approach for offensive language and hate speech detection on social media, which embodies a lexicon of implicit and explicit offensive and swearing expressions annotated with contextual information. Due to the severity of the social media abusive comments in Brazil, and the lack of research in Portuguese, Brazilian Portuguese is the language used to validate the models. Nevertheless, our method may be applied to any other language. The conducted experiments show the effectiveness of the proposed approach, outperforming the current baseline methods for the Portuguese language.

1 Introduction

In Brazil, hate speech is prohibited. Nevertheless, in government and civil society, the regulation of hate speech is not effective due to the difficulty to identify, quantify and classify abusive comments. Indeed, this is rather a difficult requirement to satisfy. According to Mesquita (2018), the Safer-net non-governmental organization, which operates in cooperation with public organizations in Brazil, as well as companies, such as Google, Facebook, and Twitter, proposed a collection of data on actions that violate human rights. The data is very worrisome: during the 2018 year’s election period, denunciations with xenophobia content had an increase of 2,369.5%; apology and public incitement to violence and crimes against life, 630.52%; neo-nazism, 548.4%; homophobia, 350.2%; racism, 218.2%; and religious intolerance, 145.13% ¹. Figure 1 shows the hate crimes evolution that occurred in the most populous Brazilian state ². The data was collected from São Paulo public security government. The pink line provides data on religious intolerance crimes, red on homophobia/transphobia, blue on race/ethnicity/color, green on region/origin, yellow on political intolerance, and light green on other crimes.

Figure 1: Hate crimes occurrence in São Paulo from 2016 to beginning of 2020.

Indeed, it is generally agreed that the high incidence of hate crimes is boosted by the popularization of online social networks. In social media, people and organizations may use the language to defamation, oppression, and terrorism. The language used intentionally in order to disrespect, insult or attack the reader is denominated in literature by abusive language, unless otherwise stated such as offensive language (Çöltekin, 2020; Pitenis et al., 2020; Razavi et al., 2010), hate speech (Schmidt and Wiegand, 2017; Waseem and Hovy, 2016) and cyberbullying (Rosa et al., 2019).

According to Warner and Hirschberg (2012), hate speech is a particular form of abusive lan-

¹https://www.bbc.com/portuguese/brasil-46146756

²https://www.ssp.sp.gov.br/
guage considering stereotypes to express an ideology of hate. In the same settings, Nockleby (2000) defines hate speech as “any communication that disparages a person or a group based on some characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, religion, or other characteristic”.

To the best of our knowledge, no previous methods exist in order to embody an offensive lexicon annotated with contextual information to automatically classify abusive language on social media. Therefore, the main contribution of this paper is providing a new method for abusive comment detection on social media. Moreover, as already mentioned, due to the severity of the hate crimes in Brazil, and the lack of research in this language, Brazilian Portuguese is the language used to evaluate the proposed method, which showed high performance, outperforming the current baseline methods for Portuguese. Despite the proposed approach has been orchestrated over Brazilian Portuguese comments, the method in this paper may be applied to any other language. Finally, this paper also presents the evaluation of algorithms used for feature selection.

The remainder of the paper is structured as follows. In Section 2, we briefly introduce the most relevant related work. Section 3 presents a overview of the data. Sections 4 and 5 describe the proposed method and the performed experiments. In Section 6, we report the evaluation results. In Section 7, we make some final remarks.

2 Related Work

Several efforts have been made to provide automated detection approaches for hate speech and offensive languages on social media (Gao and Huang, 2017; Davidson et al., 2017; Warner and Hirschberg, 2012). The basic state of the art framework consists of creating lists of words that contain sets of known hate keywords. Furthermore, corpora are manually annotated in order to construct training datasets labeled with hate speech and non-hate speech. At last, automated methods of learning, such as traditional machine learning or neural-based machine learning, are used to automatically detect hate speech in social media texts. However, most hate speech resources and models are proposed for English (Zampieri et al., 2019; Basile et al., 2019; Davidson et al., 2017; Njagi et al., 2015; Ting et al., 2013).

For Portuguese, Fortuna et al. (2019) adopted the definition of hate speech proposed by Fortuna and Nunes (2018), and proposed a new dataset composed of 5,668 tweets, as well as automated methods using a hierarchy of hate to identify social groups of discrimination. The authors have obtained 78% f1-score using a neural network (LSTM). Additionally, de Pelle and Moreira (2017) provide a new dataset composed of 1,250 comments collected from G1 Brazilian online newspaper and annotated with offensive and non-offensive tags. In addition, the authors present classification results achieved by classical machine learning algorithms (SMV and NB), reporting results over 81% f1-score.

3 Data Overview

3.1 HateBR Corpus

HateBR was proposed by Vargas et al. (2021), and consists of the first large-scale dataset for hate speech and offensive language detection for the Portuguese language. HateBR corpus annotation presents 89% of human inter-annotator agreement. The corpus is composed of 7,000 Instagram comments annotated with three different layers: (i) binary classes (offensive and non-offensive); (ii) offense-levels (highly, moderately, and slightly offensive); and (iii) nine hate group targets (xenophobia, racism, homophobia, sexism, religious intolerance, partyism, apology to dictatorship, antisemitism, and fatphobia).

The authors report that the comments were collected from six public Instagram accounts of the Brazilian political domain. Moreover, they selected three liberal-party accounts followed by three conservative-party accounts, being four women and two men. Due to the degree of complexity of the offensive language and hate speech detection tasks, mainly because it involves a highly politicized domain, the authors decided to enroll annotators at higher levels of education (Ph.D.), which are from different political orientations and colors in order to minimize bias.

Tables 1, 2, 3 show the HateBR dataset statistics.

1 According to the professor at Harvard University, “partyism” is a form of hostility and prejudice that operates across political lines (Sunstein, 2016). Moreover, Westwood et al. (2018) demonstrated that partyism influences behaviors and non-political judgments.

3.2 MOL - Multilingual Offensive Lexicon

MOL (Multilingual Offensive Lexicon)\(^4\) consists of a multilingual offensive lexicon, composed of 1,000 explicit and implicit offensive and swearing expressions of offense and swearing, which were annotated with a binary class: context-dependent and context-independent offensive. For example, the term “*vadia*” (“slut”) consists of a context-independent offensive term. On other hand, the term “*inútil*” (“useless”) is a context-dependent offensive term. Note that this last term is classified as context-dependent offensive because it also may be employed in a non-offensive context, such as “this smartphone is useless” or “the process is useless for this task”.

The MOL was extracted from HateBR corpus (Vargas et al., 2021), and each term or expression was annotated by three different annotators obtaining a high human agreement score (73% Kappa). Furthermore, as already mentioned, implicit content also was extracted using “clue terms or expressions”. For example, the expression “*voltar para a jaula*” (“go back to the cage”) consists of a “clue expression” to identify the implicit offensive term “*ladrao*” (“thief”). Finally, terms that showed explicit potential to indicate hate speech targets were also annotated, for instance, “*vadia*” (“slut”) and “*judeus dos infernos*” (“jews from hell”). Note that the occurrence of these cases may indicate sexist and antisemitism comments.

4 The Proposed Approach

We present a new approach to detect abusive comments on the web and social media. Our method embodies an offensive lexicon, which provides contextual information on hate speech and offenses. We show in detail our approach in Sections 4.1, 4.2, and 4.3.

4.1 Tasks

In this paper, we assume that abusive language detection may be divided into two main tasks: (i) offensive language detection, (ii) hate speech detection. Considering this premise, we train two different classifiers. The first classifier automatically identifies offensive comments. On the other hand, the second classifier automatically identifies comments that present hate speech content. Note that a hate speech comment is always an offensive comment, however, an offensive comment may present or not hate speech content. Figure 2 shows each of these different tasks in detail.

4.2 The Feature Set

Defining the most appropriate textual representation is a crucial task that directly influences the performance of the predictive model built by the classification algorithms. In this paper, we modeled hate speech and offensive language through

![Figure 2: Our approach to use the HateBR dataset and automatically detect offensive comments, as well as offensive comments with hate speech content.](https://github.com/francielleavargas/MOL)
different representation paradigms and features. We describe each one in what follows.

4.2.1 Lexical and Morphosyntactic Features
We selected lexical elements (each word into the document without stopwords), as well as part-of-speech-based features, using the Stanford Stanza POS tagger\(^5\) for Portuguese.

4.2.2 Lexicon-Based Features
We included features from three different lexicons: one sentiment lexicon (Sentilex-PT (Silva et al., 2012)), one emotion lexicon (WordNetAffect.BR (Pasqualotti, 2008)), and finally, one offensive contextual lexicon (MOL).

1. Sentiment Lexicon: we evaluated features based on sentiment (Silva et al., 2012) and emotion (Pasqualotti, 2008) lexicons, which present semantic polarity (e.g., positive, negative and neutral) and emotion types (e.g., anger, love, hate, disgust, suspicious and fear).

2. Contextual Lexicon: we evaluated features based on an offensive lexicon (MOL) annotated with contextual (context-dependent and context-independent) labels.

4.2.3 Word Embedding Features
We also evaluated word embedding-based features. Different from other language models, BERT (Bidirectional Encoder Representations from Transformers) is usually used to pre-train deep bidirectional representations from unlabeled texts by jointly conditioning on both left and right contexts in all internal network layers (Devlin et al., 2019). In a similar setting, we also used fastText, the Facebook pre-trained models (Joulin et al., 2016).

4.2.4 Feature Set Overview
We summarize in Table 4 the five feature representations used in this paper.

<table>
<thead>
<tr>
<th>N.</th>
<th>Features</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>POS+S</td>
<td>Bag-of-POS+Sentiment</td>
</tr>
<tr>
<td>2</td>
<td>BOW</td>
<td>Bag-Of-Words</td>
</tr>
<tr>
<td>3</td>
<td>MOL</td>
<td>Bag-Of-MOL</td>
</tr>
<tr>
<td>4</td>
<td>B+M</td>
<td>Bag-Of-Words embodying the MOL</td>
</tr>
<tr>
<td>5</td>
<td>BERT &amp; fastText</td>
<td>Multilingual pre-trained models</td>
</tr>
</tbody>
</table>

2. BOW: we created a bag-of-words representation or, in other words, we generated a text representation that describes the occurrence of dataset vocabulary for each comment. We simply calculate how many times each word of our dataset vocabulary (features) appears in each comment.

3. MOL: in this representation, a bag-of-words was generated using the terms or expressions extracted from the offensive lexicon (MOL), which were used as features. Therefore, for each comment, the occurrence of the MOL’s terms was counted. Additionally, context labels (context-independent and context-dependent) have been considered in order to compute different weights to context-independent and context-dependent features. The frequency of the terms with context-independent labels were multiplied by 2, while the frequency of the terms with context-dependent labels remained the same. Specifically for hate speech detection task, we also checked if a term presented any markers that identify hate speech content, and, if this condition was true, an additional weight was accounted. Therefore, in the MOL representation, the value of a term \(x\) in the document (comment) \(y\) for the offensive comment detection (task 1) is defined according to

\[
MOL_{x,y} = freq_{x,y} \ast weightC_x
\]  

and for the hate speech detection (task 2) is given by

\[
MOL_{x,y} = freq_{x,y} \ast weightC_x \ast weightH_x
\]

where \(freq\) is the frequency of the term in the document, \(weightH = 2\) when the term is a marker that identifies hate speech and \(weightH = 1\) otherwise, \(weightC = 1\) for

\(^5\)https://stanfordnlp.github.io/stanza/pos.html
context-dependent terms and $weight_C = 2$
when the term is context-independent.

4. B+M: we generated a bag-of-words representation, which embodies context label information from the offensive lexicon (MOL). In other words, we firstly generated a bag-of-words from all comments into the dataset. Then, we performed the match with terms into MOL, and then we assigned a weight for terms or expressions labeled with context-dependent (weaker weight) and context-independent (stronger weight). The contextual labels are provided by MOL. Therefore, in B+M representation, the value of a term $x$ into the document (comment) $y$ is defined according to

$$B + M_{x,y} = \text{freq}_{x,y} \times weight_C$$  \hspace{1cm} (3)

where $freq$ is the frequency of the term in the document, $weight_C = 2$ for context-dependent terms and $weight_C = 3$ when the term is context-independent.

5. In a different setting, the feature extraction for the BERT and fastText followed state of the art text classification with a maximum size of 500. For the fastText classifier, we set the maximum size equal to 64 and the maximum number of features equal to 10,000. We used the standard processor model and evaluated the n-gram range for unigram, bigram, and trigram.

4.3 The Learning Methods

In general, previous works on hate speech detection use neural networks or traditional machine learning techniques on specific communities (Davidson et al., 2017; Founta et al., 2019; Del Vigna et al., 2017; Njagi et al., 2015; Djuric et al., 2015). In order to evaluate the performance of neural networks and traditional machine learning techniques, we used the following learning methods: Support Vector Machine (SVM) (Scholkopf and Smola, 2001) with linear kernel; Multinomial Naive Bayes (NB) (McCallum et al., 1998; Eyheramendy et al., 2003); Multilayer Perceptron (MLP) (Haykin, 2009) with one hidden layer (with 100 neurons), and ReLU activation function; Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) with two hidden layers (with 200 and 50 neurons, respectively) and a softmax output unit for the binary classification. ReLU was used as the activation function, as well as number of epochs equal to 10, and a random batch size of 100 documents. Moreover, we also used pre-trained models of word embeddings, such as BERT (Devlin et al., 2019) and fastText (Joulin et al., 2016).

5 Experiments

We carried out a wide variety of experiments. We describe the entire process in Sections 5.1, 5.2, 5.3 and 5.4.

5.1 Data Preparing

We accomplished an approach for data preparation, as shown in Figure 3.

![Figure 3: Data preparation.](https://spacy.io/models/pt)

Firstly, we normalized our dataset using the normalization tool for Brazilian Portuguese proposed by Bertaglia and Nunes (2016). The normalization process consists of identifying noise, which is very common in User-Generated Content (UGC), such as orthographic errors, often phonetically-motivated, abbreviations and expressions often used informally by web users, proper names and acronyms wrongly or not at all capitalized, agglutinated words that should be split, and wrong use of sentence delimiters; and suggesting possible substitutions.

Moving forward, in the second step, we remove emoticons, special characters, accounts, hyperlinks, and websites. In step 3, we lemmatize our dataset using Spacy$^6$. Finally, in step 4, accentuation is removed.

5.2 Feature Selection

Feature selection (FS) allows the removal of irrelevant and redundant features. In this paper, in order to select the best feature set, we applied the following FS algorithms: (i) Correlation-based Feature Selection (CFS) (Hall, 1998), which selects characteristics that are highly correlated with

$^6$https://spacy.io/models/pt
the class and not correlated with each other using Pearson coefficient\(^7\) as criteria, and (ii) Information Gain Analysis (InfoGain) (Witten et al., 2016), which quantifies and chooses the characteristics that have the maximum information gain concerning the class. We apply both FS techniques on the NB, SVM, MLP and LSTM models. For BERT and fastText features, we do not apply FS techniques. Finally, we evaluated the performance of the FS techniques for each feature representation. More specifically, we measure the potential of the algorithms to help in the gain and loss of accuracy, precision, recall, and f1-score. Results are shown in Table 7.

5.3 Class Balancing

The most common class balancing methods are oversampling (Chawla et al., 2002) and undersampling (Witten et al., 2016). In undersampling, the number of examples of each class is maintained based on the number of examples from the minority class. Differently, in oversampling, the approach involves the construction of examples for the minority class, although these examples may not add any new information to the model. In our experiments, we adopted the undersampling on the unbalanced classes of hate speech, specially due to the fact that this approach makes overfitting unlikely. Note that, in our dataset (the HateBR), there are 727 labeled hate speech samples versus 2,227 labeled non-hate speech samples. As a result of the undersampling approach, we obtained 727 labeled samples for hate speech and 727 samples for non-hate speech.

5.4 Evaluation

Our models were trained and tested using 10-fold cross-validation (Stone, 1974). We have computed the classical machine learning evaluation measures of Precision, Recall and F1-Score. We present these evaluative measures for each class involved, as well as simple arithmetic means. The results are shown in Table 5. Moreover, we evaluated BERT and fastText pre-trained models, and show the obtained results in Table 6.

We also present the evaluation of the methods with feature selection (FS). We measure the gain and loss of precision, recall, and f1-score for each selected algorithm (CFS and InfoGain) in both tasks: offensive language detection and hate speech detection, as well as for each representations: POS+S, BOW, MOL and B+M. Table 7 shows the results. We should point out that T1 is the sum of each representation, and T2 is the sum for each FS algorithm.

Finally, Table 8 shows the comparison of the results with the current baseline methods for Portuguese.

6 Results

As shown in Table 5, the B+M proposed method in this paper obtained better results of precision, recall, and f1-score in both tasks - offensive language and hate speech detection. The worse results were obtained using the POS+S approach, which combines part-of-speech and sentiment lexicon features. We should point out the considerable impact of an offensive lexicon for abusive language detection, when compared to the impact of a sentiment lexicon. Our results showed that sentiment lexicon approach present weak performance for abusive language detection on the web and social media.

Moving forward, the conducted experiments also show that the traditional machine learning techniques presented better performance than neural-based classifiers for offensive language tasks. Nevertheless, for the hate speech detection task, the neural-based classifier overcame the traditional machine learning methods.

In general, BERT and fastText, as shown in Table 6, presented a high performance for both tasks (offensive language and hate speech detection), even though our approach (B+M) has overcome the fastText (trigrams) in 2% (f1-score) for hate speech detection, as well as presented better precision performance, and the same recall and f1-score performances for offensive language detection.

Considering the feature selection (FS) performance, as shown in Table 7, the InfoGain algorithm produced better results for precision, recall, and f1-score than CFS algorithm for offensive language detection (task 1). On other hand, for hate speech detection (task 2), CFS algorithm obtained better performance than InfoGain in recall and f1-score. Moreover, for offensive language detection (task 1), InfoGain applied on BOW and B+M representations obtained performance gain, and POS+S and MOL presented loss of perfor-

---

\(^7\)Pearson’s correlation coefficient is a linear correlation coefficient that returns a value between -1 and +1. A -1 means there is a strong negative relationship, and +1 means there is a strong positive relationship.

### 6.1 Comparing Results

Table 8 shows a comparison of results between our new proposed method and baseline methods for Portuguese. Although a direct comparison is unfair (as the authors use different datasets), it offers an idea of the general performance of the methods.

de Pelle and Moreira (2017) report a f1-score of 81% using SVM and NB algorithms. For the same algorithms, our approach presented 88% of f1-score, improving the performance. In the same settings, Fortuna et al. (2019) report a f1-score of 78% using the LSTM algorithm. In our experiments, we obtained an f1-score of 86%, also using the LSTM algorithm, consequently, our approach presented better performance.

### 7 Conclusions

In this work, we provide a new approach for the automatic detection of abusive comments on social media. Our approach embodies an offensive lexicon that provides contextual information. Due to the increase of abusive comments on social media in Brazil, as well as the lack of research in annotated datasets, we decided to use an Brazilian annotated dataset to evaluate the models. The proposed approach obtains high performances: 88% f1-score for offensive comments detection, and 85% for comments with hate speech, which overcame the current baseline methods for Portuguese.

We also evaluated the performance of feature selection (FS) methods, and conclude that InfoGain algorithm is the best algorithm for the offensive comment detection task, considering the obtained gains in recall and f1-score. For the hate speech detection task, CFS algorithm obtained better performance. Accordingly, based on the obtained results, we concluded that the proposed approach in this paper for automated detection of abusive comments is efficient and highly relevant, bearing in mind the current Brazilian social scenario, in which hateful comments are a very relevant social problem. Moreover, in the next year (2022), there will be presidential elections in Brazil, and this paper may provide a reliable automated approach for abusive comments detection in order to minimize political polarization, as well as hate crimes on social media.

Abstract

The task of automatic diagnosis encoding into standard medical classifications and ontologies is of great importance in medicine - both to support the daily tasks of physicians in the preparation and reporting of clinical documentation, and for automatic processing of clinical reports. In this paper, we investigate the application and performance of different deep learning transformers for automatic encoding in ICD-10 of clinical texts in Bulgarian. The comparative analysis attempts to find which approach is more efficient to be used for fine-tuning of pre-trained BERT family transformer to deal with a specific domain terminology on a rare language such as Bulgarian. On the one hand, we use SlavicBERT and MultiligualBERT models, which are pre-trained for a common vocabulary in Bulgarian but lack medical terminology. On the other hand, we compare them to BioBERT, ClinicalBERT, SapBERT, BlueBERT models, which are pre-trained for medical terminology in English, but lack training for language models in Bulgarian, and vocabulary in Cyrillic. In our research study, all BERT models are fine-tuned with additional medical texts in Bulgarian and then applied to the classification task for encoding medical diagnoses in Bulgarian into ICD-10 codes. A big corpus of diagnoses in Bulgarian annotated with ICD-10 codes is used for the classification task. Such an analysis gives a good idea of which of the models would be suitable for tasks of a similar type and domain. The experiments and evaluation results show that both approaches have comparable accuracy.

1 Introduction

The task for automatic encoding of Electronic Health Records (EHR) with standard medical classifications is a hot-topic. The international classification of diseases, 10th revision (ICD-10)\textsuperscript{1} is one of the most commonly used standard medical classifications due to the availability of translations in several languages. It is a hierarchical classification that encodes each diagnosis into a standard code which is used for statistical analysis and insurance reimbursement. The current solutions for this task are based on a restricted subset of ICD-10 codes or address some specific task trained on a small manually annotated corpus.

Recently some deep learning models like BERT (Devlin et al., 2018) pre-trained transformers were applied for different Natural Language Processing (NLP) and clinical NLP tasks. The first type of transformers is language models that cover common vocabulary on several languages: SlavicBERT (Arkhipov et al., 2019) and MultiligualBERT (Pires et al., 2019). The second type is transformers that cover specific terminology in English. In this particular case, the base language model is pre-trained with medical terminology by using scientific articles abstracts from PubMed\textsuperscript{2} or full-text articles from PMC\textsuperscript{3}: BioBERT (Lee et al., 2020), ClinicalBERT (Alsentzer et al., 2019), SapBERT (Liu et al., 2021), BlueBERT (Peng et al., 2019), MT-BERT (Peng et al., 2020), PubMedBERT (Gu et al., 2020). The later transformers prove that rel-

\textsuperscript{1}https://icd.who.int/browse10/2019/en
\textsuperscript{2}https://pubmed.ncbi.nlm.nih.gov/
\textsuperscript{3}https://www.ncbi.nlm.nih.gov/pmc/
atively high accuracy can be achieved in training for automatic ICD-10 classification task for the English language (Moons et al., 2020). We hypothesise that comparable accuracy can be achieved also for languages other than English using either type of pre-trained BERT transformers.

2 Related Work

The task for automatic ICD-10 encoding of textual descriptions of diagnosis was addressed in several research challenges like i2b2 NLP Challenges, CLEF eHealth, etc. The major problem is that ICD-10 classification contains more than 11K codes and requires a significant number of labeled training data. In general, there are only available labeled datasets for a limited number of ICD-10 codes, which is one of the reasons why this task is not yet solved to the full range of ICD-10 codes. Lavergne et al presented in (Lavergne et al., 2016) a dataset for for ICD-10 coding of death certificates that contains 377,677 labeled statements with 3,457 unique ICD-10 codes. Usually, the labeled datasets are highly unbalanced that has a huge impact on the annotation method performance. This problem was addressed in (Parlak and Uysal, 2018), where the authors apply techniques for imbalance effects reduction, like splitting feature spaces and compressing label dimension. The ICD-10 classification task was investigated for several languages. The best performance for languages other than English was achieved with SVM models (Bagheri et al., 2020) F1 54.9% for Dutch; the longest common subsequence problem (Chen et al., 2017) for Chinese with F1-score of 81.1%; a hierarchical approach (Ning et al., 2016) for Chinese with F1 score of 91.08%; information retrieval techniques for Turkish (CEYLAN et al., 2012) with the best score of 76.5%. Another approach is to view the problem as a multi-label classification task and use neural networks like CNN, LSTM/BiLSTM, and HA-GRU (Wang et al., 2020), or applying BERT which has shown good results on this task in German (Amin et al., 2019). Hybrid approaches, that combine different models show a slight improvement in the results (Amin et al., 2019).

For the Bulgarian language was done some preliminary experiments using SVM and small training corpora (Boytcheva, 2011), where the model achieved F-score 84%. We need to mention that the reported results in this work are based on significantly smaller training and test datasets with limited number of ICD-10 classes. In this paper we use big annotated corpora and include almost all ICD-10 codes used by medical practitioners in Bulgaria. In (Velichkov et al., 2020) we show some successful application of the BERT pretrained transformers for ICD-10 encoding. Inspired by the promising results we will investigate both language models: MultilingualBERT and SlavicBERT and will compare them with the state-of-the-art models for medical domain in English: BioBERT, ClinicalBERT, BlueBERT and SapBERT.

3 Data

3.1 Language Model Pre-training Dataset

For the Pre-training Dataset we have used a combination of medical articles and medical journals scraped from the internet. Medical articles were crawled from MedInfo4. We’ve also used a dataset of crawled medical articles that is already publicly available in GitHub5. Medical journals were crawled from MedUnion6, JournalsMuVarna7, MedicinaNauka8, CmlMuSofia9, Bulsem10, Basa11, MedSport12 and Vma13. The crawled medical articles and journals were cleaned from single and double quotes, as well as any special characters and new lines.

From MedInfo we have crawled 1,740 medical articles. Each article describes different topics in terms of medical diseases, as well as possible treatments for the different diseases.

Each medical journal is in a PDF format and was split by page during crawling.

From MedUnion we have crawled 612 pages of medical journals. Each journal describes modern medicine and different aspects of it.

From JournalsMuVarna we have crawled 1,230 pages of medical journals. Each journal describes different topics like Social medicine, Health policy, Healthcare management, History of medicine and healthcare, and others.

10 http://www.bulsem.bg/bg/about-jem
11 https://www.basa.bg/
12 https://www.med-sport.net/index.html
13 https://www.vma.bg/
From MedicinaNauka we have crawled 281 pages of medical journals. Each journal consists of Bulgarian science and medicine topics and advises on how to tackle different medical issues that can occur.

From CmlMuSofia we have crawled 160 pages of medical journals. Each journal provides information about original scientific developments such as articles and reviews. Healthcare Management, Medical Ethics, and History of Medicine are also regularly covered in each journal.

From Bulsem we have crawled 1,924 pages of medical journals. Each journal has original articles from all fields of medicine and dentistry by Bulgarian and foreign authors.

From Basa we have crawled 1,353 pages of medical journals. Each journal consists of reviews, original articles, clinical cases, and case reports.

From MedSport we have crawled 1,793 pages of medical journals. Each journal covers problems of sports orthopedics, rehabilitation, physiology as well as the medical aspects of the training and competition process.

From Vma we have crawled 4,848 pages of medical journals. Each journal consists of scientific developments, publications from scientific medical forums, cases from the practice, and reports about new scientific events.

The ICD-10 classification contains several levels encoded with a different number of signs. The root level is encoded with the letters from the English alphabet, and subsequent levels append a number to the parent one. In this article we examine 3-sign and 4-sign codes, for example, the 3-sign A00 is the code for "Cholera", and 4-sign A00.0 is encoding a specific type of cholera - "Cholera due to Vibrio cholerae 01, biovar cholerae".

In the current article, we use the corpus published by Boytcheva et al (Boytcheva et al., 2020) as a basis and we perform additional preprocessing. It consists of two datasets: one with 189,756 3-sign samples and the other with 383,042 4-sign samples. The unique codes (classes) for each dataset are 2,035 and 10,971, respectively. It is important to emphasize that the dataset with 4-sign codes also includes 3-sign codes. The descriptions are in Bulgarian, Latin, and transliterated from Latin to Cyrillic. The second dataset (containing 4-sign and 3-sign codes) is used to process and conduct experiments with different BERT family models. ICD-10 codes are numerous, with some having only a few samples in the dataset. In other words, the dataset is highly imbalanced. For this reason, additional processing has been done, which aims to achieve three things:

1. Add artificially created samples. This is done by applying the following data augmentation techniques: word exchange; exchange of random letters in one word; delete any letter of a word; change any letter in a word to one close to it on the keyboard.

2. Codes that have less than 5 samples should be reduced to a higher level in the code hierarchy. This is possible because ICD-10 codes have a strictly specific hierarchy. For example, a 4-sign code like A00.0 has 4 levels - each of its symbols. The highest level is the letter. The next three levels are the numbers. About 4,939 classes in the dataset have less than 5 samples.

---

14https://github.com/BorisVelichkov/ICD10-Medical-Data
Those with a 4-sign code are reduced to their corresponding 3-sign code (remove the 4-sign specific class from the classification). 405 classes with 3-signs are under-represented and thus we cannot apply this approach for them.

3. To unite the classes that are not related to a particular disease but have a special purpose for capturing external factors influencing health. These are the codes V01-Y98 (External causes of morbidity and mortality) and Z00-Z99 (Factors influencing health status and contact with health services). They are reduced to the upper levels V and Z, respectively, following ICD-10 grouping logic.

The converted dataset (Full) is divided into three parts: train (Train), validation (Dev), and test (Test) datasets. An additional column for alternative codes has been added to the validation and test datasets, as a diagnosis can be assigned to more than one code. For each dataset, the number of samples, the number of unique codes, the number of samples with alternative codes, and the number of unique tokens are shown in Table 1. It is good to note that in the validation set there are 1,708 unique tokens that are not present in the training set, as well as 1,701 tokens in the test set that are not present in the training set. The intersection between these tokens is approximately one-third - 586 common unique tokens. Descriptive statistics such as the minimum number, the maximum number, the mean, and the median of the alternative codes are shown in Table 2. The numbers vary between 1 and 24, with most being closer to only one alternative code. An equivalent table with descriptive characteristics for the number of tokens is Table 3. There, the number of tokens varies between 1 and 34, but the average is between 4 and 5.

4 Deep Learning Methods for text-based classification

BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2018) is a deep learning language model pre-trained on a large corpus of data using bidirectional transformers that provides context-aware token and sentence representations. There are multiple BERT models for different languages and domains and BERT has shown very good results on a variety of different tasks. Transfer learning can be applied by using the published models and fine-tuning them with a smaller dataset on the target task.

We evaluate multiple BERT models by applying additional pre-training for Bulgarian medical texts using the masked language task and then fine-tuning them on the multi-class classification for ICD-10 codes.

For the masked language task, we mask the standard 15% of tokens and train the model to predict the correct token following the architecture from the original paper (Devlin et al., 2018). The goal of training is to minimize the perplexity of the model. We use the language model pre-training dataset to improve BERT’s understanding of Bulgarian medical text. We split the language model pre-training dataset in a proportion of 80:20 - 80% for training and 20% for testing.

WordPiece is used for tokenization and the original vocabulary from each model is used. As subword tokens are used, all words can be represented with tokens in the vocabulary. To train domain/language-specific extension to the vocabulary, a large corpus of training data would be required which is unavailable for Bulgarian.
the encoder and is trained to predict the correct ICD-10 class using a softmax activation. We return the top 5 classes with the highest probability as a prediction from the classifier as each diagnosis can belong to more than one class. We report accuracy, macro-F1, and mean reciprocal rank (MRR) metrics for the classification task.

The Multilingual BERT model uses BERT-base as a starting point and is additionally fine-tuned on the masked language task using Wikipedia articles in 104 languages incl. Bulgarian

BioBERT is based on BERT-base and fine-tuned on PubMed abstracts and PMC full-text articles

BlueBERT is a model based on BERT that is pre-trained on PubMed abstracts and (MIMIC-III) clinical notes

ClinicalBERT is initialized from BioBERT and trained on MIMIC-III, which contains around 2 million notes

SapBERT is a PubMedBERT that was further fine-tuned with synonym pairs from the knowledge base of UMLS, a collection of biomedical ontologies

SlavicBERT is a model, derived from MultilingualBERT, trained on Wikipedia articles in Bulgarian, Czech and Polish and news in Russian

5 Experiments and Results

Table 4: BERT fine-tuned models and their perplexity.

<table>

</tr>
</tbody>
</table>

In the current article, experiments were performed with six different types of BERT models.

Each was additionally fine-tuned on medical articles in Bulgarian and then attached to the classification task to associate the diagnosis with the corresponding ICD-10 code. ClinicalBERT is fine-tuned for 20 epochs with a final perplexity of 1.7606 (the 12th epoch was 1.7788). SlavicBERT is fine-tuned for 16 epochs and has a perplexity of 5.6693 (the 12th epoch was 5.7312). All other models are trained in 12 epochs. All perplexities can be seen in the Table 4. In the classification task, all models are trained in 10 epochs. The change in loss can be seen in Fig. 2. Detailed results including Accuracy, Macro F1 and MRR are shown in Table 5. It is noted that the highest MRR and Macro-F1 is using MultilingualBERT (95% and 91%, respectively), followed by ClinicalBERT with 1% below (94%) MRR and 87% Macro-F1. ClinicalBERT has the highest accuracy - 92%.

As we can see all the models are doing quite well. What makes the ClinicalBERT one of the best is that this model is pre-trained on top of many clinical notes, which contain a large amount of medical concepts. Many of them are in Latin and are the same in their use in different languages. Also these notes are most likely quite close to medical diagnoses. It is also the model that has been fine-tuned for most epochs (20 epochs versus 16 for the...

SlavicBERT and 12 for the rest). This may be the reason why ClinicalBERT leads MultilingualBERT in the accuracy (with 5% better). MultilingualBERT, on the other hand, is trained in over 100 languages, which may allow it to do very well in different languages and to be relatively easy to be fine-tuned on new data. Similarly, it can be said that another advantage is that the diagnoses combine text in Bulgarian, Latin and transliterated from Latin to Cyrillic. In addition, we can say that in other studies for the same task in Bulgarian, MultilingualBERT is the model that gives the best results. Here it has best macro F1 and MRR.

In order to be able to illustrate in a more understandable way the task we will show three examples of real diagnoses from discharge letters of patients and how two of the classifiers (MultilingualBERT and BioBERT) predicted codes of these diagnoses in the Table 6. As we can see the two classifiers return the true code at first position for the first diagnose. Also for this sample BioBERT has more close predictions in the top 5. The second and the third diagnoses are a little bit more complex because they have 4-sign code which in these cases is same for both - "C91.1". As can be seen, in addition to the same code, the two diagnoses are very similar in text. For both diagnoses, BioBERT returns the 3-sign code first and the exact 4-sign code second. The same thing is seen with MultilingualBERT, but only for the first of the two diagnoses. For the second, the results are worse and the classifier can only guess the 3-sign code of the diagnosis. An interesting observation is that it is also in fifth place in the top 5 predicted codes.

In contrast with the results presented in (Velichkov et al., 2020) the SlavicBERT model in our experiments shows comparable results with the other models, and moreover it is the second ranked model on the basis of accuracy. Another difference in our results is that ClinicalBERT outperforms BioBERT in all three evaluation metrics - accuracy, macro F1 and MRR. In both cases the reason is longer training (more epochs) for the fine-tuning of the models.

6 Conclusion

In the current article, a comparative analysis of six different BERT models is made, each of which is trained on a large amount of data and additionally fine-tuned on a big corpus of medical texts in Bulgarian. It can be said that the selected models are a good representative sample for the task on which they are applied, as among them there are models trained on over the top 100 languages, trained on Slavic languages, trained on medical and bio literature. The results obtained are quite high and show that all tested models are promising. As future improvements, it would be good for all models to be fine-tuned further, both with more texts and with more epochs. It would be good to equalize the number of epochs of fine-tuning for all models. Also other good improvements would be comparing the models before and after fine-tuning and applying cross-validation to more accurately evaluate the models.

Abstract

Giving feedback to students is not just about marking their answers as correct or incorrect, but also finding mistakes in their thought process that led them to that incorrect answer. In this paper, we introduce a machine learning technique for mistake captioning, a task that attempts to identify mistakes and provide feedback meant to help learners correct these mistakes. We do this by training a sequence-to-sequence network to generate this feedback based on domain experts. To evaluate this system, we explore how it can be used on a Linguistics assignment studying Grimm’s Law. We show that our approach generates feedback that outperforms a baseline on a set of automated NLP metrics. In addition, we perform a series of case studies in which we examine successful and unsuccessful system outputs.

1 Introduction

Giving feedback is one of the most critical parts of education and training. It allows the instructor to correct errors in students’ understanding and guide them to the correct solution. In automated learning systems, such as intelligent tutoring systems (ITSs) the feedback and hints are focused on getting the student to complete the assignment, but this may not take into account their mastery of that skill. While better feedback can be made by considering student intent, we find that current models are lacking in this regard. They are typically focused on learning objective mastery and may not necessarily give the whole picture when determining why students answered something the way they did.

But there is a natural solution to this, in that skilled educators are capable of intuitively modeling a student’s thought process and determining mistakes in it. This skill is often developed over time. The difficulty of this task for educators depends on the field of study, with some more free form fields like writing and programming being particularly difficult. By indirectly modeling a student’s intent by instead modeling how the instructor gives feedback, we can use this model to generate novel feedback sentences.

We propose a system that when given a mistake that has been identified in the task of deriving sound changes from Proto-Indo-European to Proto-Germanic, will automatically generate an explanation that identifies the mistake and the reasoning to why this sound change should not apply in this case. We call this method Mistake Captioning as it takes inspiration from image captioning methods and post-hoc AI rationale generation methods such as Ehsan et al. (2019) Automated Rationale Generation.

We apply a suite of automated machine translation and image captioning metrics to test our system. We also take a closer look at 3 cases from a more complete retraining of the network to better understand how the network is performing and how well the metrics perform regarding our task. We find that this method is a good start, but more data and work need to be done to be able to integrate this into a serious learning environment.

2 Background and Related Work

In the space of ITSs a problem is how to get a student to the correct solution. One of the ways to achieve this is by having an expert to author the correct solution and the path to take to get there (Marwan et al., 2020; Unnam et al., 2019; Ariely et al., 2020). These all require the use of an expert to either structure the assignment such that feedback can be extracted or to label assignments to create a system that can learn the expert knowledge. In some domains this is not necessary as the students can provide the data for the path to the solution themselves. This data-driven approach
uses data from multiple students to create all possible paths that lead to a solution, as shown by Stamper et al. (2008) in their work on Hint Factory. This was later extended to create paths that optimize for productivity metrics by Maniktala and Barnes (2020). In vast solution spaces generating all possible paths to the solution is not feasible, and in Rivers and Koedinger (2017) work this is done by abstracting states so that a single state can represent a large space of states.

Our method does not attempt to establish a correct answer like these previous methods as they do not tackle an underlying problem as to why students make mistakes. We structure our problem not as a method of guiding the student to the correct path, but by trying to correct the thought process that led them to their current answer. This is similar to the methods used in image captioning (You et al., 2016) where they train a model to recognize what is in an image by relating human authored captions to images. This model is then used to generate captions on similar features in new pictures. This is also like the work done in post-hoc AI rationale generation like that of Ehsan et al. (2019). In this work they relate a set of human actions to human rationales of those actions for the use of explaining AI behavior. In our system, we make use of human actions in the form of mistakes and relate them to human explanations of the mistake.

2.1 The Proto-Indo-European Language and Grimm’s Law

Our application area for this paper is on an assignment concerning Grimm’s Law, which is a series of sound changes that occurred in the evolution of Proto-Indo-European (PIE) into Proto-Germanic (PGmc). PIE is a reconstructed language that attempts to recreate the common ancestor of Indo-European language family. While no direct evidence remains of PIE, the similarities between the languages in this family indicate that they come from a common ancestor. Despite these similarities, there are still differences in the languages that can be attributed to shifts in pronunciation as time went on and communities speaking this language became isolated from others. PGmc. is also a reconstructed language, serving as the source of all Germanic languages. Sound changes can be traced from PIE to PGmc.

We focus our task on a set of sound laws that describe how stop consonants change from PIE to PGmc collectively known as Grimm’s Law (Campbell, 2013) and also include instances where Grimm’s Law does not occur. Grimm’s Law consists of three different changes that all contribute towards a single shift known as a chain. These changes are as follows:

1. PIE voiceless stops change to voiceless fricatives.
2. PIE voiced stops change to voiceless stops.
3. PIE voiced aspirated stops change to voiced stops or fricatives.

Together they are chained such that affected sounds in PIE are shifted one step to their form in PGmc. This limited set of shifts is what is represented in our data and is the reason for some of the limitations.

3 Methods

3.1 Data

The data used in this paper is centered around the linguistics PIE rule, Grimm’s Law (Campbell, 2013). Since the task is to generate a reasoning for a mistake made by students, we have opted to organize the data as a fill-in-the-blank task, as one would show up as an assignment. Since we are focusing on captioning the mistake, the changes from PIE to PGmc must contain a mistake and an explanation for that mistake. To create these erroneous responses, we had a linguistics expert generate a number of entries fulfilling these categories: a PIE word; a PGmc form of that word with blanked areas demarked by underscores; a faulty PGmc form containing only a single mistake each, so that the explanations can be more focused on that specific mistake. When multiple mistakes are identified for each PIE word, they are separate entries with separate explanations. Likewise, if there are multiple blanks to fill in for a word, then each blank will have a separate set of entries for its possible mistakes. The explanations were written with a simplified style as to not introduce too much detail into the explanations that
PIE | Blanked PGmc | Faulty PGmc | Explanation
--- | --- | --- | ---
pis'kós | is az | fishaz | k ultimately does become h, but not when immediately following stops & fricatives
pis'kós | is az | biskaz | p can shift to b, but only when the middle of the word preceding an accented vowel
pis'kós | is az | fisgaz | k can shift to g, but only when preceding an accented vowel in the middle of a word
pis'kós | is az | fisxaz | k normally changes to x, but not when preceded by a stop or fricative

Table 1: The data entries for the mistaken sound changes in the PIE word for “fish”

resulted in each explanation being a single sentence following a general format. This sentence is in the rough form of “the mistake that was made, reason why it is not applicable in this case”. For example, in Table 1 the explanation for why fishaz is wrong has k ultimately does become h as the mistake that was made and but not when immediately following stops & fricatives as the reason why it is not applicable in this case.

This data was gathered by a single Linguistics Expert, with minor input from the authors as to style and structure to better suit this data for machine learning. Our linguistics expert is an associate professor of linguistics that frequently teaches classes on PIE. There were no attempts to control for consistency in tone, tense, or voice style, so such variations do occur in the data. Because the sentences follow a general format, there are some exact explanation matches in the data. Since this was the application of a small set of rules over a larger set of words, finding common letter changes and explanations could not be avoided. We collected 163 entries of PIE words, fill-in-the-blanks, faulty PGmc words, and their corresponding explanations. These came from 55 unique PIE words and contained 53 unique explanations to cover all cases found in the data. The most common explanation occurred 15 times, while others only occurred once in the entire dataset. Even those that occurred once often shared similar phrasing with other explanations since they were drawn from a common set of rules and a common set of consonants.

The data was further structured for training as seen in Table 2. To preserve the question that was being hypothetically asked to solve and the answer, we combined the PIE form and the faulty PGmc form, separated by a space, as our model input. For our model output we used the explanations without adding anything, but we did remove and change some characters. We removed all instances of ending punctuation like periods and exclamation points and spaced out commas to count them as separate tokens. The white space was also normalized and any leading or trailing white space was removed. While not shown in the table, the input was tokenized character by character to help preserve the differences between the faulty PGmc, while the output was done word by word.

3.1.1 Data Noise

Our data is very limited in scope due to the effort it requires to generate it. If we were to train our model only using the data as it is, we would likely run into issues with overfitting and overtraining. To alleviate this, we have injected noise into the data to be able to train longer. For our training output, creating noise is a straightforward process. In every training iteration, the output has 30% of its words masked out. This value was chosen to keep most of the explanation intact while still having a significant amount noised as overfitting is a serious concern. This means that at no training iteration has the model ever seen a complete output sentence, but with enough training iterations the unmasked portions should have overlapped enough to reveal the complete sentence.

The input was a more complicated process. Since the input is smaller than the output, we made the attempt to preserve some of the important parts, namely the actual changes from PIE to PGmc. Since these are fill-in-the-blank tasks, we have access to the parts that contain no mistakes and using this part of the dataset we identified the portions
of the Germanic words that are considered safe to mask out in the form of maskable indices. These are shown in the 3rd column of Table 2, though these may not visually line up to the index of the words since letters that are accented are encoded as multiple characters. Since this only affected the PGmc part of the already smaller input, instead of masking 30% of the characters we only mask a single character at a time and limit it to only 30% of the time. This hopefully allows us to make a more robust set of training examples without disrupting the underlying meaning too much.

### Table 2: The processed data entries for the word “fish”.

</tbody>
</table>

3.2 Model

For our model we use a sequence-to-sequence network. Sequence to sequence networks utilize two recurrent neural networks: an encoder and a decoder. The encoder encodes the sequential data into a fixed length context vector that is meant to represent the important elements of the input. This context vector is then used by the decoder to generate a natural language output. In our case, this output is an explanation, but this can be used for other tasks. Sequence to sequence networks have been used for translation (Sutskever et al., 2014) and post-hoc rationale generation (Ehsan et al., 2019) tasks, and while our task is not a traditional translation or rationale generation task it can be modeled as one. The network learns to take the input sequence of our PIE and faulty PGmc words as a character sequence and translate them into a word sequence for our explanations. By connecting the input to the explanation, we are learning human-like reasoning for why the mistakes happened. We use Gated Recurrent Units (GRUs) to take advantage of their faster training time and better use with smaller data (Chung et al., 2014). We also make use of an attention mechanism (Graves, 2013) on the decoder to learn to focus on the important parts of the output explanation.

The model was trained on 75,000 iterations using the same 163 question and explanation pairs, but as mentioned previously in each iteration some characters and words were masked to prevent the model from seeing them. During each training iteration a random sample from the data is run through the network after having noise applied.

4 Experiments

We conducted two experiments to evaluate our method: A quantitative approach using a set of automated metrics to judge the candidate explanations, and a qualitative case study to demonstrate what types of outputs were generated. For both the qualitative and quantitative evaluation we used 5 different automated metrics: BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE (Lin, 2004), CIDEr (Vedantam et al., 2015), and BERTScore (Zhang et al., 2019).

For our quantitative evaluation, we used k-fold cross-validation to control for the variance in our data. We compare our approach against a majority baseline. Since several of the explanations in the data were repeated, we decided that a better baseline would be the majority baseline and used the most repeated explanation in our data. This explanation was used 15 times in the data, and for the majority baseline we set the generated output to all be this exact sentence. This explanation can be seen in Table 4 in the baseline incorrect, candidate sentence. While the majority baseline has a low
accuracy, about 9.2%, it was chosen to show that the method is viable before continuing to a human evaluation.

For our qualitative analysis, we opted to look at outputs for a retrained model that was trained on all but 8 random examples of the data. Since our dataset is small, we decided that training on all but a small number of examples would give better insights on what the network was learning. We examined how the model performed in generating explanations for each of the 8 examples that were held out during training. From these 8, we used their automated metric performance in conjunction with their correctness to divide them into three categories: correct, partially incorrect, and incorrect. We then explore why this occurred and reason about the implications of these results in practice.

During training, we use the following hyperparameter values for our model. We used a teacher forcing ratio of 0.5, and a learning rate of 0.01. For the hidden layers (consisting of the attention and GRU layers), a fixed size of 256 was used. All outputs were limited to a maximum length of 30 but this limit was not reached. To test the model, we implemented beam search to select the best candidate explanation instead of the default greedy search. In addition to improving the accuracy of the model this allowed us to look at multiple final outputs, each scored by the model. This is useful in manually judging if the alternatives to the top output were more correct. We limited the beam width to 5.

5 Results

We found that our method consistently outperformed the baseline in all metrics as can be seen in Table 3. This provides evidence that our model is working to learn when to apply and how to recreate humanlike feedback in response to mistakes. We also found that the leave-8 retraining performed better than the 5-fold models. This trend can be visually seen in Figure 1.

Applying a 2-sided t-test we find that the difference between the baseline and the 5-fold is statistically significant ($p < 0.0001$) in all cases. When comparing the baseline to 8 case studies this also holds true ($p < 0.001$). There is also no statistically significant difference between the case studies and the 5-fold.

6 Discussion

In this section, we discuss the results in more detail, going over the results of the automated metrics and case studies.

6.1 Automated Metrics

While the automated metrics do show that our method outperforms our baseline, they are not perfect. One finding that came out of this evaluation is that automated metrics can be misleading when evaluating performance. This is because automated metrics for evaluating language generation systems often measure how well generated sentences overlap with reference sentences. The change of a single word alters the semantic meaning of an explanation, however, which can fool the metrics into scoring it higher than it is. Likewise, a generated explanation can be nearly correct but contain little similarity in structure to the original. This is ultimately a limitation of the data since we only have a single reference explanation for each faulty PGmc example. In the data there exist explanations that explain a concept similar to other explanations but are differently structured. If the model lifts the structure of one explanation to the correct change and reasoning of a change, there is no guarantee that this will match the reference explanation and will be scored more poorly. This does not mean that these metrics are not useful, though, just that the limited scope of our data makes it less suited to these metrics. There is a general trend between how well the explanation performs compared to how correct it is, as we will see in the case studies. In general, this seems to suggest that how

well these metrics will perform will change if we get more data, both on the number of PIE words and the number of possible explanations for each mistake.

6.2 Case Studies

To take a better look at the generated explanations we have a separate leave-8-out training. In these 8 that we left out and tested on we found three categories: correct, partially incorrect, and completely incorrect. Correct explanations include the correct mistaken change and the correct reason it was not applicable, while partially incorrect only include one of the two. Incorrect explanations contain neither. Of the 8, 4 of these where correct, 3 were partially incorrect, and only one was completely incorrect. We have selected 3 examples to match these 3 categories to look more closely at.

6.2.1 Completely Incorrect

There was only a single example of the completely incorrect case, which is shown in Incorrect case in Table 4. This explanation does not identify the sound change giving \( k \) instead of \( t \) for the sound change. For the reasoning it seems like it is on the correct track by mentioning \textit{preceded by stop or fricative} but reverses whether the change occurs because of this. In fact, this is a case of the candidate explanation having no relation to the reference explanation, nor is close to any reference explanation for that PIE word, nor the PIE and PGmc input. The candidate explanation refers to a \( k \) which does not appear in input but, as will be expanded on later, this may be a case of encoding. Due to the way that the input is interpreted on a character-by-character basis the model may have recognized the presence of the \( k \) and conflated it with a \( k \). It also used the explanation that is most repeated in the dataset, which suggests that it picked the most popular explanation as opposed to correctly learning this change.

6.2.2 Partially Incorrect

For the partially incorrect case we find that the model could identify something correct but not everything. Sometimes this was only identifying the correct sound change or the correct reasoning, but in the case that we are focusing it generated a completely new explanation that was one word from being correct. This candidate explanation changed the word \textit{must to only} which completely changes the meaning of the explanation. In our explanation generation we saved the top 5 sentences, and the correct explanation does appear as the second. This may be another encoding issue since the phrase \( k \textit{only} \) appears several times in our dataset. We used beam search to attempt to avoid this problem, but in this case, it does not seem to have been enough. The complete phrase that was generated does not appear as a reference explanation in any of the examples, so it is unknown as to why it chose this one. It is likely that having more reference explanations would help as it would force the model to learn more important features.

In another case of partially incorrect, we found that the exact reference explanation that never appeared in that training data, which means that the model could not have possibly generated a completely matching explanation.

6.2.3 Correct

The correct category is marked by when the model was correctly able to generate an explanation for the mistake that was made, matching both the change and reasoning. This is also the largest category, comprising 4 of the 8 examples. These score highly on all the metrics. This category has sound changes that are well represented in the training data, with no reference explanation appearing less than 5 times. In the case shown in Table 4, the

reference explanation appeared 8 times which is relatively high, but not unique to this category. The completely incorrect case had its reference sentence appear 12 times in the data, meaning that this is likely not the most prominent factor in whether a generated explanation will be correct or incorrect.

In all these cases we find that the automated metrics to judge these explanations are generally higher when the answer is more correct, and generally lower when it is more incorrect. This holds in cases when there is only partial correctness. As mentioned before this is likely due to our limited data and may break if we have more reference sentences. We hope to expand the data to cover other changes in linguistics, though the method should be able to be transferring to other domains too.

7 Future Work

Due to the way that our method works in identifying a single mistake at a time, we can use the fill-in-the-blank task to generate explanations on multiple mistakes. This is done by first comparing the answer given to the correct answer and finding the difference between the two and isolating each individual mistake. Each of these individual mistakes can be then applied to the original correct answer to create separate faulty answers which can subsequently be run through our system. Using this method, we can also change the fill-in-the-blank task to a simple response, where the student is tasked to correctly make all the changes to the PIE word to produce a PGmc word.

Either through separate models for separate rules (and enough annotations on the input) or by training a single more complex model, it may be possible to create a system that can caption all mistakes for a given task. This could work in conjunction with automatically grading the assignments to quickly provide feedback on the mistakes.

8 Conclusion

In this paper we show a method of the novel task of creating automated captions of mistakes. These captions serve as explanations for what the thought process behind the mistake was, and why it is not applicable in this case. We apply two methods to test our model, comparing against a baseline with a suite of automated metrics, and manually identifying and analyzing the sentences in a series of case studies. Our experiments show that our method has promise in creating these automated captions but that there are significant challenges that need to be overcome.

We set out tasks in the domain of Linguistics pedagogy, and in this we can make improvements with representation of the input data and with gathering more and more varied data. We also hope to expand this to include a wider set of rules covering a larger set of sound changes, and eventually evaluate the method using a human study. We hope that this method of mistake captioning can be applied to other fields of study.

Abstract

Post processing is the most conventional approach for correcting errors that are caused by Optical Character Recognition (OCR) systems. Two steps are usually taken to correct OCR errors: detection and corrections. For the first task, supervised machine learning methods have shown state-of-the-art performances. Previously proposed approaches have focused most prominently on combining lexical, contextual and statistical features for detecting errors. In this study, we report a novel system to error detection which is based merely on the n-gram counts of a candidate token. In addition to being simple and computationally less expensive, our proposed system beats previous systems reported in the ICDAR2019 competition on OCR-error detection with notable margins. We achieved state-of-the-art F1-scores for eight out of the ten involved European languages. The maximum improvement is for Spanish which improved from 0.69 to 0.90, and the minimum for Polish from 0.82 to 0.84.

1 Introduction

Post processing is the most conventional approach for correcting errors that are caused by Optical Character Recognition (OCR) systems. Traditionally, the task is divided into two subtasks: (1) Error detection to classify words as either erroneous or valid, and (2) Error correction to find suitable candidates to correct the erroneous words (Kolak and Resnik, 2005; Kissos and Dershowitz, 2016; Mei et al., 2016). A large body of work has proven the success of statistical and supervised machine learning methods for both subtasks (Afli et al., 2016; Schulz and Kuhn, 2017; Nguyen et al., 2018; Amrhein and Clematide, 2018; Nguyen et al., 2019).

Machine learning methods largely rely on feature engineering for their performances, particularly in supervised settings. Feature engineering involves exploring various features and feature combinations that best characterise the data. However, for post-OCR error detection, finding a suitable set of features is challenging because of the diversity of OCR errors (Amrhein and Clematide, 2018). This has been demonstrated in previous work and more recently in the ICDAR competitions (Chiron et al., 2017; Rigaud et al., 2019) where various features have been explored with varying success rates (more details in Section 2).

To address this challenge we propose a novel approach to the error detection task. Instead of examining more features we focus merely on a single feature, namely the n-gram counts of the candidate token. Our approach is inspired by dictionary lookup approaches, which are known for their simplicity and efficiency but are restricted to the dictionary size. Since building large-scale dictionaries is a challenging task in itself, we propose to generate n-grams of a given candidate token, and then use their counts as the only feature to train machine learning models (more details in Section 3). We evaluate our method on the ICDAR2019 dataset (Chiron et al., 2017) and compare the results to a number of approaches reported in the competition (Section 4). Our system achieves state-of-the-art results for eight out of the ten involved languages by beating the previous results with fair margins and comparable scores for the remaining two languages. Our approach is very simple and is computationally less expensive as it does not require any other feature computation apart from the n-gram counts.2

2The data and models are available under CC BY
2 Related Work

Our work takes inspiration from dictionary based approaches and uses supervised machine learning techniques to train a post-OCR error detection model. We therefore focus on reviewing the works related to dictionary and statistical supervised machine learning based approaches.

Simple dictionary based approaches have performed reasonably well for various natural language processing tasks (e.g. Hull and Grefenstette (1996); Sindhu and Sagar (2017)). It is therefore not surprising the approach has been applied to detecting OCR errors before (Schulz and Kuhn, 2017; Nguyen et al., 2018). Taking this approach, dictionaries and large word lists are usually compiled from corpora and other sources. Each token in the data is then compared with the word in the dictionary to determine whether it is an error word or not. This approach has been explored by the CSITJ team who was among the six successful teams participating in the ICDAR 2019 competition (Rigaud et al., 2019). The team compiled a dictionary of over 370 thousand English and French words and checked each word in the dataset against it.

Dictionary lookup methods for post-OCR are challenging because they usually suffer from out-of-vocabulary problem. Another limitation is in detecting real-word errors, i.e. the word appears in the dictionary but is wrong in its context. Therefore alternative methods to OCR error detection have been proposed (see a comprehensive survey of existing methods by Nguyen et al. (2021)).

The remaining teams in ICDAR 2019 applied techniques from: (i) Context-based character correction using BERT (CCC) – the winning system; (ii) Character level attention approach using the open source system OpenNMT (CLAM); (iii) Weighted finite-state transducers based on noisy channel model (REA1&2); and (iv) Character level seq2seq multi-layer LSTM (UVA).

Other approaches to post-OCR error detection combined character-, word-n-grams and context based features to train a machine learning model (Mei et al., 2016; Khirbat, 2017; Nguyen et al., 2019; Dannéls and Persson, 2020). Mei et al. (2016) trained a regression model on 6 features containing n-gram and context information. Khirbat (2017) trained a support vector machine (SVM) model with 3 features: presence of alphanumeric characters, bi-gram frequency of the word and context information that is if the word appears with its context in other places. Nguyen et al. (2019) trained a Gradient Tree Boosting classifier on a set of 13 character and word features on two datasets of English historical handwritten documents (monograph and periodical) taken from the ICDAR competition (Chiron et al., 2017). The features they experimented with include character and word n-gram frequencies, part-of-speech, and the frequency of the OCR token. Dannéls and Persson (2020) trained an SVM model on 6 statistical and word based features including the number of non-alphanumeric characters, number of vowels, word length, tri-gram character frequencies, number of uppercase characters and the amount of numbers occurring in the word.

As many authors point out the choice of the features is essential for the performance of the machine learning model. The advantage of these methods is that they are trained to detect both real-word and non-word errors. The drawback is they require laborious feature engineering.

Laborious feature engineering is a bottleneck not only for machine learning but also for other statistical approaches that rely on pre-defined features extracted from data, such as noisy channel approaches (Evershed and Fitch, 2014; Kissos and Dershowitz, 2016; Drobac et al., 2017).

3 Method

3.1 Datasets and Preprocessing

We used the datasets from the ICDAR2019 competition on post OCR error detection and correction. The total size of the original data is 22 million characters and it contains varying numbers of characters for ten European languages (Bulgarian, Czech, German, English, Spanish, Finnish, French, Dutch, Polish, Slovenian) together with the corresponding ground truth data. The dataset comes with the OCRed and ground truth aligned at the character level. For our experiments, we needed to align it at the token (word) level. We did that by tokenizing the ground truth at space and for each token taking the same number of characters from the OCRed version. After we removed the special alignment symbols (‘@’ and ‘#’) inserted by organizers for alignment. The resulting OCRed and ground truth tokens were compared to set the labels ‘0’ if the

4.0 licence at https://github.com/spraakbanken/NovelOCRErrorCorrection.
token was erroneous or ‘1’ if the token was valid. These labels are the dependent variables that are to be learned and predicted by the machine learning models. Table 1 shows example tokens, ground truth, and the labels from English, Danish, and Finnish datasets. Table 2 shows the number of training and test sets produced for each language after removing the duplicates and instances with ‘NA’ values and the class percentage i.e. what percentage of the total is the class ‘0’ and ‘1’ in the training and test sets.

### 3.2 Machine Learning Models and Encoding

Machine learning classifiers are known to have pros and cons depending on the task at hand. Dannélls and Virk (2020) compared between 5 state-of-the-art machine learning classifiers including Logistic Regression, Decision Tree, Bernoulli Naive Bayes, Naive Bayes and SVM. They found that SVM is the best choice for post-OCR detection. Others have also shown the performance of SVM is equivalent to the performance of artificial neural networks (Arora et al., 2010; Hamid and Sjarif, 2017; Amrhein and Clematide, 2018). In response to these previous experiments, in this study we have chosen to experiment with SVM models.

We take advantage of the implementation of the machine learning algorithms in the `sklearn` module (Pedregosa et al., 2011). Because the module requires the data to be in numeric form we used one-hot encoding for data transformations (see Section 4.1). While the details of the encoding method are beyond the scope of this paper, the major idea behind one-hot encoding is to add an extra dimension in the feature vector for each unique feature value. This produces an N dimensional feature vector (the learned encoding), where N is the total number of unique values of all features. In our case we have words as the training data. Suppose \([w_1, w_2, w_3, \ldots, w_n] \) is the set of unique words, and \([0, 1, 1, \ldots, 0] \) is the set of corresponding labels representing whether the word is erroneous or not. The learned one-hot encoding will be a \((n+2)\) dimensional vector, where \(n\) is the unique number of words in the training data and there are 2 unique label values. Each word is then encoded by setting the corresponding word and label dimensions of the vector to 1 while the remaining dimensions are set to 0.

### 3.3 Generating the Machine Learning Features

As mentioned previously, we took inspiration from dictionary look up based approaches, but in this study we have applied it in a novel way. Instead of building a dictionary separately from different external resources, we let our SVM model build it from the training data. This was achieved by learning one-hot encoding from the training data (i.e. words), encoding the training data and then using the resulting vectors as the only feature to train the SVM model. In other words, we turn the model into a dictionary lookup kind of system as the model memorizes vectors of each training instance. During prediction the trained model simply relies on the observed word, i.e. whether its encoded feature vector has been seen in the training data and predicts accordingly.

This type of approach has a major restriction that it is not scalable and is bound to feature values seen in the training data. In our case this means if a word has not been seen in the training data the system will simply fail to predict whether it is erroneous or not. Another downfall is that depending on the size of training data it may take days to train such models. To overcome these limitations we experimented further with the n-gram approach. Instead of using the complete word, for each candidate token, we generated character uni-grams, bi-grams, and tri-grams from it. These n-grams together with their counts within the token were used as feature values to train and test the model. To take an example, suppose our candidate word is ‘passenger’. The computed uni-, bi-, and tri-gram counts will be as follows:

- **uni-gram** \{'a':1, 'e':2, 'g':1, 'n':1, 'p':1, 'r':1, 's':2\}
- **bi-gram** \{'p':1, 'as':1, 'en':1, 'er':1, 'ge':1, 'ng':1, 'pa':1, 'r':1, 'se':1, 'ss':1\}
- **tri-gram** \{'pa':1, 'ass':1, 'eng':1, 'er':1, 'ger':1, 'nge':1, 'pas':1, 'sen':1, 'sse':1\}

It is worth mentioning that the scope of n-gram counts is limited to the word itself, rather than the entire training data i.e. these counts represent the occurrence of a particular uni-, bi-, or tri-gram within the word rather than the total count of the n-gram in the training data. Previous authors have attempted to exploit n-gram frequencies (e.g. Mei et al. (2016); Khirbat (2017)) computed over the

4 Experiments and Results

4.1 Experimental Settings

We experimented in four different settings, named ‘Word’, ‘Unigram’, ‘Bigram’ and ‘Trigram’. Each refers to a setting in which a particular feature described in Section 3.3 is used i.e. ‘Word’ represents the setting where complete words are used as the only feature, while ‘Unigram’, ‘Bigram’ and ‘Trigram’ to the setting where generated uni-, bi- and tri-gram counts are used as features respectively.

In each of the settings, we kept the same division of training and test datasets as in the ICDAR 2019 competition to make the results directly comparable.

As for the machine learning models, we used sklearn’s ‘DictVectorizer’, ‘OneHotEncoder’, and ‘CountVectorizer’ for data transformations and ‘SVC’ classifier with default parameters for training and testing. The only optimization was done by setting the class_weight to ‘balanced’ to overcome the issue of imbalanced class distribution in the training data for some of the languages (more detail about it in the following results section).

4.2 Results and Discussion

The results of the experiments are presented in Table 4 for all four settings i.e. ‘Word’, ‘Unigram’, ‘Bigram’, and ‘Trigram’. For comparisons, the results from the ICDAR2019 post-OCR error detection task are given in Table 3. The scores are highlighted in bold if they are better than the ICDAR2019 results for the corresponding language in each individual setting, while the best score across all four settings is underlined. If a score is both bold and underlined, it means it is the state of the art score.
As can be seen, with ‘Word’, our system beats the ICDAR2019 F1 scores for five languages (BG, EN, ES, NL, PL), while ICDAR2019 scores are better for three language (CZ, DE, FI, SL). Due to the time constrains we could not complete the experiments for the remaining two languages (FR, FR).

With ‘Unigram’, our system beats the ICDAR2019 F1 scores for six languages (BG, EN, ES, FR, NL, PL) with the default class distribution (more details about class distribution to follow). With the balanced class distribution, we were able to beat scores of two more languages (CZ, SL) making it eight in total. For the remaining two languages (DE, FI), ICDAR2019 results are better. Also not that we get noticeable improvements in F1 scores with ‘Unigram’ as compared to ‘Words’ for all of the languages except NL and PL.

With ‘Bigram’, our system beats the ICDAR2019 results for seven languages (BG, CZ, EN, ES, FR, NL, PL) with default class distribution. Again, due to time constraints, we were unable to complete the experiments with the balanced class weight in the ‘Bigram’ setting, but similarly to the other results in the ‘Unigram’ setting, we should expect an improvement once the experiments have been completed. The languages for which our approach does not beat the ICDAR2019 scores are Finnish and Danish. There is a marginal difference for Finnish (0.83 vs 0.84), while a notable difference for Danish (0.81 vs 0.95). Also note, we achieved further improvements compared to the ‘Unigram’ F1 scores.

With ‘Trigram’ the results start deteriorating for most of the languages, and improve for a couple of them (FR and NL) achieving state-of-the art for NL.

In summary, we were able to beat ICDAR2019 results for eight out of ten languages in different settings reaching state-of-the art F1 scores (underlined and bold) for those languages. The improvements vary from +0.2 to +2.1 for Bulgarian (0.77 to 0.86), Czech (0.70 to 0.78), English (0.67 to 0.83), Spanish (0.69 to 0.90), French (0.67 to 0.83), Dutch (0.71 to 0.87), Polish (0.82 to 0.84), and Slovenian (0.69 to 0.74).

As can be noticed in all four settings, we get
comparatively low F1 scores for CZ, DE, and SL. The reason for this is the low recall resulting from imbalanced class distribution in the training data of these languages. The class distribution for the class label 0/1 is 0.19/0.81, 0.29/0.71, 0.16/0.84 and 0.20/0.80 respectively for CZ, DE, SL, and FI as also shown in the Table 2. The sklearn’s SVC classifier provides an option to balance the class weight by setting its class_weight parameter to ‘balanced’. With this optimization the results improved for CZ, FI, SL as shown in Table 4 in the ‘Unigram’ settings while declined for the rest of the languages.

5 Conclusion and Future Work

Training supervised machine learning models with large number of features is a computationally expensive task. This has been demonstrated in previous work where handcrafted features were considered at the expense of high computational costs. In this study we have taken a different approach and have proposed to use n-gram counts as the only feature to train SVM models. N-gram counts have previously been used for post-OCR detection, but not in the sense that we have proposed in this study. Instead of computing the n-gram counts over the entire training data we have proposed to compute them within a given token and use them as the only feature to train and test our models.

To find the best ‘n’ for the n-grams, we experimented with uni-grams, bi-grams, and tri-grams. We tested the approach on the ICDAR 2019 dataset. As the experiment results show, with uni-grams our model outperforms the best system reported in the ICDAR2019 competition for six out of the 10 European languages included in the competition with default class distribution, and two more languages with balanced class distribution. With bi-grams, our model outperforms the previous system for 7 languages with comparable results for the remaining three languages. With tri-grams the results start deteriorating for most of the languages meaning that bi-grams are the best choice. Overall, with this approach we were able to beat 8 out of the 10 languages achieving state-of-the-art results for those languages.

The proposed approach is interesting because it eliminates the need for feature engineering; a task which is laborious and computationally expensive. The results show simple n-gram counts, which are fairly easy to compute, are enough for the task at hand. The approach is also gainful because it does not require large amounts of data. Given the relatively small datasets we experimented with we were able to show our method is performing better for the majority of languages compared to deep learning systems such as the ones explored by the CCC and UVA teams.

As previously said, we have used an SVM classifier with default parameters. In the future, we plan to apply parameter optimization, e.g. scaling, class distribution, grid-search, etc. to try and improve the results further. For example to detect real word errors when the word with an error is still a good word but inappropriate in the context. Another possible way to improve the results is to use the back-off approach in the n-gram setting. Taking a back-off approach we will use a bi-gram if a tri-gram is not in the vocabulary in a tri-gram setting, and likewise a uni-gram if a bi-gram is not in the vocabulary.

With these reported state-of-the-art results on post-OCR error detection, it will be interesting to experiment how these results will contribute to the improvement of the overall task of post-OCR error correction. We leave this to be another possible direction to explore further.

Abstract

FrameNet is a lexical semantic resource based on the linguistic theory of frame semantics. A number of framenet development strategies have been reported previously and all of them involve exploration of corpora and a fair amount of manual work. Despite previous efforts, there does not exist a well-thought-out automatic/semi-automatic methodology for frame construction. In this paper we propose a data-driven methodology for identification and semi-automatic construction of frames. As a proof of concept, we report on our initial attempts to build a wider-scale framenet for the legal domain (LawFN) using the proposed methodology. The constructed frames are stored in a lexical database and together with the annotated example sentences they have been made available through a web interface.

1 Introduction

Frame semantics is a theory of meaning in natural languages proposed by Charles Fillmore (Fillmore, 1977, 1982). The theory stipulates that meanings of words can be best understood with reference to the situations they invoke in the minds of the speakers. The concrete manifestation of frame semantics is the computational lexical resource FrameNet, first constructed within the English Berkeley FrameNet (BNF) project (Baker et al., 1998). The resource has inspired work on framenets for many other languages and domains, including Chinese (You et al., 2007), French (Candito et al., 2014), German (Burzachetti et al., 2009), Hebrew (Hayoun and Elhadad, 2016), Korean (Kim et al., 2016), Italian (Lenci et al., 2010), Japanese (Saito et al., 2008), Portuguese (Toro, 2013), Spanish (Díaz, 2009) and Swedish (Borin et al., 2010a; Dannélls et al., Forthc.a).

FrameNet is built around the notion of frames. A frame in this context is a schematic representation of events, objects, situations, institutions, etc. The primary components of a frame are the frame definition along with the frame elements and the lexical units documented with corpus evidence (Ruppenhofer et al., 2016).

There are at least three major framenet development strategies that have been reported in the literature (Candito et al., 2014) namely: (1) lexicographic frame-by-frame (2) corpus driven lemma-by-lemma (3) the full-text strategy. Of these three, the most commonly applied strategy is frame-by-frame, where the frame is defined along with its frame-elements first. Example sentences are then chosen from a corpus for a disambiguated annotation of lexical units and frame-elements. In the lemma-by-lemma strategy, a set of lemmas (lexical units) are chosen first and then all their occurrences are annotated in a given corpus together with the annotation of frame-elements. In the full-text strategy, all content words in a given text are annotated. The latter two strategies pre-suppose that frames already exist, although new frames can also be developed as new senses of lexical units are encountered in the text.

All three strategies involve exploration of corpora and a fair amount of manual work for construction of semantic frames, and for searching suitable example sentences to be annotated. Various framenet development projects have reported the use of (or developed) tools to assist in the corpus exploration and frames construction parts (e.g. the Swedish FrameNet++ project; Borin et al., 2010b;
lines for frame construction (Burchardt et al., 2009; Ruppenhofer et al., 2016). However, there is no well-thought-out automatic/semi-automatic procedure for frame development from scratch.

In this study, we propose a data-driven method for the identification and semi-automatic construction of domain-specific semantic frames. The identification involves recognizing the domain-specific events, entities, relations, procedures, etc. for which the semantic frames can be constructed. The development part involves discovering various semantic roles of a given frame, spotting and linking lexical units to the target frame, and annotating example sentences.

2 Data and Pre-processing

As a proof of concept of our methodology, we prepared a small data-set by collecting a set of documents from the legal domain and applied OCR processing to produce a machine readable version. The data was then enriched with metadata and linguistic annotations. It was then stored and made accessible through a corpus infrastructure tool for easy excess and exploration.

The data used in this study was downloaded from web repository of the united nations high commissioner for refugees. A subset of 900 pdf documents resulting from the hits for the search string “well-founded fear of being persecuted” were downloaded and then OCRed using ABBYY FineReader software. Each document was processed for the following document, token, and structure level attributes.

- **Text-Level Attributes:** Article title, author, publisher, topic, and country.
- **Token-Level Attributes:** word tokenization, lemmatization and part of speech (POS) tags.
- **Structure-Level:** Sentence segmentation and dependency parses.

Document level attributes were preserved while downloading the documents, and for various token and structure level annotations we used Sparv (Borin et al., 2016), which is an annotation pipeline developed and maintained at Språkbanken Text.

It can be used to automatically annotate textual data with various token, text, and structure level attributes using in-house and third party annotation tools. We used Stanford’s NLP toolkit (Manning et al., 2014) for token and structure level annotations. After annotating the data, it was made available through Korp (Borin et al., 2012), a state-of-the-art corpus infrastructure tool developed and maintained by Språkbanken Text. It provides various basic and advanced level features to better search, explore, and visualize a corpus. Figure 1 shows a screenshot of the search results together with various annotations when searched for a simple string ‘article’. The left-hand pane shows the sentences containing the search string, and the right-hand pane shows various text level (title, author, topic, etc.) and token level (lemma, pos-tag, etc.) tags for the selected token (the word ‘title’ highlighted with black background). The bottom right corner also shows the dependency parse tree of the sentence.

The extended search tab provides options to search for any of the individual attributes (e.g. author, title, pos-tag etc.) or a combination of them combined by and/or logical operators. The advanced tab allows the user to formulate a search query using the CQP query language (Christ, 1994). The data is password protected due to IPR issues and is intended to be used for internal research purposes at this stage. However, in the future we have plans to release it with suitable licensing options.

3 Frame Development Methodology

A step-wise description of the frame development methodology is given below. This is followed by construction of an example frame using the described methodology. The developed frame is a part of the legal domain framenet (more details about the legal domain framenet in Section 4).

1. As a first step, the word segmented data reported in Section 2 is sorted in the descending order of term frequencies after removing the function words. The purpose is to identify the

---

1[www.refworld.org](http://www.refworld.org)

2This search string was chosen in connection to another part of the project with its own objectives of analyzing the ill-treatment of refugees.

3[https://www.abbyy.com/](https://www.abbyy.com/)

4Språkbanken Text is a research unit and also forms part of Nationella språkbanken (the National Language Bank), a national e-infrastructure supporting research based on language data in Sweden.

5Here, we use “term” in a basically non-technical sense, to
most frequently used terms and cover them first while designing the frames.

2. Each item in the obtained list is inspected manually to decide if it is a domain-specific term or not with the help of a domain expert if required. In a better setting, the word list can be filtered out beforehand with the help of any already existing domain-specific terminology list or a lexical database such as WordNet (Fellbaum, 1998) to speed up the process and reduce the manual work, but we leave this aspect to be explored in the future.

3. Once a term has been determined to be a domain-specific term, the next step is to check if the term fits as a lexical unit of an already existing frame or not. If it does, it is simply added as a lexical unit of the existing frame. If not, it means a new frame needs to be designed. A suitable name for the frame is chosen, and the following procedure is followed to identify various frame-elements of the frame. Let the term be T.

(a) All sentences containing the term T are extracted from the data and their dependency parses are retrieved from the parsed data reported in Section 2.

(b) From the dependency parses, the head and dependent text segments are grouped together for each of the dependency relations.

(c) The text segments in each group are then manually inspected and a decision is made to whether we need a frame element or not.6 If yes, a suitable frame-element title is chosen, and the element is made part of the frame. This step is repeated for each dependency relation.

Let’s now walk through the construction of an example frame Article using the above described methodology. In our data collection, the term ‘article’ occurred 29 times, and it is easy to recognize that this term has a legal domain sense in addition to four others as per WordNet. Considering that no frames have been designed previously, we need to construct a frame for which the word ‘article’ will be a lexical unit. This is step 2 of our methodology. We chose the name Article for the frame, and move towards construction of its structure i.e. step 3. Table 1 shows text segments generated using step 3 for the syntactic relations ‘dobj’ (i.e. direct object)7 and ‘nmod’ (nominal modifier). For space reasons, only a few entries for a selected set of relations are shown.

A manual inspection of the text segments under the ‘Dependent’ for the ‘dobj’ relation reveals that the word ‘article’ whenever used in the legal domain is often followed

---

6This is basically a linguistic decision which requires both experience of framenet development and training in grammatical and lexical-semantic analysis for the language in question ([legal] English in our case). See Ruppenhofer et al. (2016) for a more detailed discussion of the considerations and reasoning involved.

7The constituents in question are not direct objects; rather, the relation should be labeled ‘flat’ or possibly ‘appos’ under the UD scheme. This does not matter to our example, but it will of course become important when we will be looking to
by a figure or figures that refers to the article number of the constitution/agreement. This means we need a frame-element to capture and represent this usage. It can perhaps be argued that it is so obvious that the term ‘article’ will be followed by an article number so why we need to follow the described procedure. It may appear obvious in this case, but it can not be generalized across frames and frame-elements (imagine the construction of the frame *Injunction* which refers to a judicial order restraining a person from beginning or continuing an action). Our experience suggests that this usage based methodology is very helpful in identifying the frames and frame-elements.

Similarly, a manual inspection of the text segments under the ‘Dependent’ for ‘nmod’ relation revealed that there is often a mention of a law/protocol/constitution to which the article belongs e.g ‘of the Turkish constitution’. This means we need a frame-element to capture that information, hence, the frame-element *Constitution*. The same procedure was followed to design the frame-elements *Interpretation*, and *Date* while inspecting the ‘acl:relcl’ (i.e. relative clause modifier) and ‘nmod:tmob’ (i.e. temporal modifier) relations respectively.

For the actual frame construction and storage, we used *Karp*, which is another lexical infrastructure tool developed and maintained at Språkbanken. Figure 2 shows a screenshot of the tool and the structure of the *Article* frame. It also shows a set of annotated examples and the lexical units which can trigger this frame.

4 A Legal Domain FrameNet and its Applications

4.1 LawFN

General-language lexical resources such as BFN are both too broad and too narrow for successful deployment in domain-specific natural language processing (NLP) applications. On the one hand, they contain more than one sense for many headwords, most of which are not relevant in the domain of interest (but which lower the accuracy of the analysis). On the other, they often lack some important domain-specific usages. For this reason, several domain-specific frame-nets have been compiled, covering e.g. medicine, football/soccer and tourism (Borin et al., 2007; Schmidt, 2009; Torrent et al., 2014).

There have been some initiatives reported in literature on building frame-nets for the legal domain (e.g. Venturi, 2011; Bertoldi and Chishman, 2012). However, to the best of our knowledge, these efforts have been quite limited in scope, and no full-scale resource of the kind proposed here has been presented. In this study, we report on our initial attempts to build a wider-scale FrameNet for the legal domain that we call LawFN.

4.2 Applications of LawFN

The major motivation behind initiating the development of LawFN is its potential applications in the area of Legal Tech, which refers to the use of technology and software for providing various legal services and support to the legal industry. In recent years, Legal Tech has gained popularity, and the use of technology is increasing in many legal-domain activities such as case management, contract management, document automation and analysis (Gruzauskas and Ragavan, 2020), etc. Some of these tasks require semantic analysis of the text within legal domain documents.

When we apply currently available semantic analysis technology to extract information about laws automatically from text we do not retrieve the desired analysis. For example when we analyze the sentence: “Justice Kirby similarly stated in the same judgement that the convention does not require or imply the elimination by the state of all risks of harm; rather it posits a reasonable level of protection, not a perfect one.”, with the general framework for semantic role labeling (Punyakanok et al., 2008), we get the analysis as shown in Example 1.

(1)  

As Example 1 shows, the identified LU is ‘state’, and the frame elements are *Announcer*, *Discourse* [stated] *Location* [that the convention does not require or imply the elimination by the state of all risks of harm; rather it posits a reasonable level of protection, not a perfect one.] *Utterance*.

</tr>
</tbody>
</table>

## 4.3 Frame Types in LawFN

For a better organization, we divide frames in the LawFN into two types: Entity frames and Event frames. Entity frames are simpler in their structure and they are meant to represent various legal domain entities e.g. judge, court, tribunal, etc. Event frames are a bit more complex in their structure and are meant to represent various legal domain events or processes such as prosecution, judgement, defense, etc. In another sense, entity frames act as slot fillers for various semantic roles of an event frame. Consider Figure 3 showing an annotated sentence in which a filler frame (i.e. Judge) files in a semantic role of an event frame (i.e. Judgement).

In the annotated sentence, the frame Judge is triggered by the lexical unit ‘justice’ and NAME is the only frame element which is realized in this sentence (the annotation in red color). This frame then becomes frame-element JUDGE for the semantic frame Judgement triggered by the lexical unit ‘judgement’. The Judgement frame is the only other realized frame-element (annotation in green).

### 4.4 Current Status of LawFN

Using the proposed frame-development methodology, we have developed a total of 10 frames, containing 36 frame-elements, 24 lexical units, and 22 annotated example sentences. A list of constructed frames together with their frame-elements, lexical units, and annotated example sentences are provided in Appendix A.

## 5 Conclusions and Future Work

Our contribution is twofold. First, we have reported a semi-automatic frame-development methodology, which can help speed up the frame development process. Second, we have reported initial attempts in building a framenet for the legal domain and
In the future, we have plans to continue constructing more frames. Our dataset is quite limited in scope and size, which we plan to extend in the near future. With the bigger data set, we will be able to explore more syntactic patterns. This means capturing more possible use cases, and hence being in a position to better design the frames. Also, we have plans to annotate data with the developed frames, and build a frame-semantic parser exploiting machine learning. The developed parser then can be used for automatic semantic analysis of legal domain documents, which then can be used to extract particular types of information from those documents. As an example, suppose one is interested to extract all judgements made by a particular judge under a particular law/protocol/agreement from a corpus of court decisions. Parsing the corpus for Judgement, Law, and Article frames can help extract that information automatically. Evaluation of the extracted information for accuracy is another direction that we plan to explore in the future.

Abstract

Linguistic typology is an area of linguistics concerned with analysis of and comparison between natural languages of the world based on their certain linguistic features. For that purpose, historically, the area has relied on manual extraction of linguistic feature values from textual descriptions of languages. This makes it a laborious and time expensive task and is also bound by human brain capacity. In this study, we present a deep learning system for the task of automatic extraction of linguistic features from textual descriptions of natural languages. First, textual descriptions are manually annotated with special structures called semantic frames. Those annotations are learned by a recurrent neural network, which is then used to annotate un-annotated text. Finally, the annotations are converted to linguistic feature values using a separate rule based module. Word embeddings, learned from general purpose text, are used as a major source of knowledge by the recurrent neural network. We compare the proposed deep learning system to a previously reported machine learning based system for the same task, and the deep learning system wins in terms of F1 scores with a fair margin. Such a system is expected to be a useful contribution for the automatic curation of typological databases, which otherwise are manually developed.

1 Introduction and Background

Linguistic typology is an area of linguistics concerned with analysis of and comparison between natural languages of the world in terms of their structural and functional attributes. Among others, major objectives of the area are exploring the range of possibilities for expressing different linguistic categories, trying to understand the extent to which the presence of different features depend on one another in larger patterns, and to study how the global distribution of language traits has come about through an interplay of tendencies inherent to languages and historical contingencies (Bickel, 2015). For achieving such aims, historically, the area has relied heavily on scholars having to read textual documents (commonly known as descriptive grammars) describing languages, manually extracting values of a pre-defined set of features, and then comparing languages based on the extracted feature values. To make the whole exercise systematic and structured, traditionally, the features are expressed in the form of questions e.g. ‘What is the order of adjectives and noun in language X?’, and scholar’s job is then to find answers to such questions by reading descriptive documents about language X. The answers are often formulated to be simple strings e.g. ‘NA’, ’AN’, or ’Both’ representing the fact that nouns precede adjectives, nouns follow adjectives, or ’both nouns may follow or precede adjectives’ respectively in the case of above give question. For easy storage and retrieval, the questions and their answers are recorded in special kind of databases known as typological databases. There exist many such databases and a fuller list is available at languagegoldmine.com/. These databases are later used to compare and analyze languages to achieve the above mentioned objectives of the area. In addition, information in such databases has proven to be useful for a number of natural language processing (NLP) related tasks. A survey on the usefulness of typological information in NLP can be found in (O’Horan et al., 2016).

As can be imagined, the manual development of typological databases is an expensive enterprise both in terms of time and efforts, and also their qual-

Sep 1–3, 2021.
https://doi.org/10.26615/978-954-452-072-4_167
ity and coverage is bound by human brain capacities. Extensive digitization efforts (e.g., (Michel et al., 2011)) and the advancement of computational methodologies, including NLP, offer many possibilities for easing the task of developing linguistic typological databases. A maximally automated approach would allow for the generation of such databases at a hitherto unparalleled scale, increasing both the number of features and languages that can be analyzed and compared taking the area to new heights. However, this requires developing methodologies and systems for automatic extraction of typological linguistic information from descriptive documents. This exactly is a major objective of the study reported in this paper.

Previously, a few approaches and systems have been reported for the automatic extraction of typological information, but a practical system still remains to be be developed. Pattern matching and machine learning based classification are the two main computational paradigms that have been exploited so far (see Section 3). Pattern matching has its own limitations as it is impossible to design patterns which can cover every possible scenario. Similarly, machine learning classification algorithms are heavily dependent on feature engineering, which have its own limitations and features are often expensive to compute. To address some of these issues, we report a deep learning based system in this study (Section 4). First, textual descriptions are manually annotated (Section 4.1) with special structures called semantic frames, which are based on the theory of frame-semantics (Section 2). Those annotations are learned by a recurrent neural network using word embeddings learned from general purpose text as the major source of knowledge (Section 4.2). The trained model is used to annotate the un-annotated data, and the annotations are then converted to linguistic feature values using a separate rule based module (Section 8). Our frame annotation system beats previously reported systems on a test set with a fair margin in terms of F1-scores.

2 Frame-Semantics, FrameNet, and Frame-Semantic Parsing

Frame semantics is a theory of meanings in natural languages (Fillmore, 1982). It stipulates that meanings of words can be best understood with reference to the situations they invoke in the minds of the speakers. The concrete manifestation of frame semantics is a computational lexical resource called a framenet. The first such resource was the English Berkeley FrameNet (BNF) (Baker et al., 1998) which has inspired work on framenets for many other languages. The “lexical entry” in a framenet is called a (semantic) frame, which is a script-like description of a prototypical event, object, relation, or scenario. A frame consists of triggers – the lexical units (words) which evoke a specific situation – and additional components called frame-elements that fills in various semantic slots of the frame. Below is an example sentence manually labeled with the COMMERCE_SELLING semantic frame and its frame-elements i.e. seller, buyer, and price. The frame is triggered by the word ‘sold’.

The process of automatically performing the above type of annotation/analysis is called semantic parsing. The first such frame semantic parser was proposed by Gildea and Jurafsky (2002), which has been followed by a number of other systems/approaches (e.g., (Das et al., 2014; Roth and Lapata, 2016)).

3 Related Work

Previously, a few experimental techniques and associated systems have been reported for automatic extraction of typological information. In (Borin et al., 2018; Virk et al., 2017), the authors have reported on simple pattern matching and syntactic parsing based systems. The systems have modest accuracy and recall and are very restricted with respect to the number of features they can target.

To overcome some of those limitations, in (Virk et al., 2019) the authors exploited frame-semantics and machine learning approaches to build a system that can extract information about a few experimental features. The systems is based on the work reported in (Malm et al., 2018) where the authors proposed to use frame-semantics to represent the typological linguistic information. They also developed a domain specific framenet (LingFN) containing semantic frames for the linguistic domain representing various linguistic terms and phenomena (e.g. verb, noun, agreement, inflection, etc.). The developed LingFN was used by Virk et al. (2019) to annotate textual descriptions of languages with linguistic domain frames (more details in Section 4.1) and develop an automatic typological information extraction system using machine learning.
In (Søren and Rama, 2019), the authors reported a two step strategy to detect the parts of the text that possibly contains value of a given feature, and then extracting the feature value from it. For the first step their approach relies on keyword spotting and pattern matching, while on machine learning classification for the second step.

In (Hammarström, 2020), the author reported a simple keyword based approach for extracting values of one typological feature about tones for many languages from thousands of documents with an overall accuracy of 89.1%.

4 Proposed System

Figure 1 shows the complete architecture of the system that we propose. As shown, it has a clear division between three components: data annotation, deep learning, and typological information formulation. In the following subsection, the first two components will be explained, while the explanation of the third component is deliberately deferred until Section 8 for a better flow.

4.1 Data

A small corpus consisting of descriptive grammars of the natural languages spoken in South Asia was reported in (Borin et al., 2018), and a set of documents from that corpus annotated with LingFN frames was reported in (Virk et al., 2019). Annotation of a descriptive grammars with LingFN frames involve identification of verbal units and selection of appropriate linguistic semantic frames and their frame elements. As a part of the study reported in this paper, the annotated corpus was extended resulting in a total of 70 annotated documents (a document corresponds to 3 to 7 pages of text). Figure 2 shows an annotated sentence. As can be seen, the sentence is annotated with two linguistic domain frames i.e. VERB triggered by the word ‘verb’ having ‘data’ and ‘data_translation’ frame elements and the frame ‘AFFIXATION’ triggered by the word ‘suffixed’ and having ‘degree’ and ‘anthromorphic_entity’ frame elements. We refer the reader to (Virk et al., 2019) for more details on annotations and the annotation process. The data used in this study consists of a total of 70 documents comprising around 3,986 sentences, 7,170 semantic frames, and 4,669 frame-elements.

4.2 Deep Learning Part

In the system developed here, manually labeled data (reported in previous subsection) is used to train a deep learning model which is then used to label un-annotated data. The architecture of model is similar to the one proposed by Swayamdipta et al. (2017) using the RNNs. Figure 3 shows a simplified version of the architecture together with various inputs (features). To make the description self explanatory, we briefly explain here both the inputs and the architecture with respect to an example input sentence: ‘Nouns agree with the adjectives’. The word ‘agree’ triggers the frame AGREEMENT (shown in red), while ‘Nouns’ and ‘the adjectives’ represent two text segments (in purple). These text segments fill in the roles of two frame-elements, i.e. ‘Segment_1’ and ‘Segment_2’, to be learned and later predicted by the deep learning model. The model uses two bilingual LSTM networks (biLSTM) and one LSTM for various computations as described below.

- Each word at position $q$ in the input sentence is converted to a vector:

$$v_q = [d_q; e_q; o_q; γ_q]$$

(1)

where $d_q$ is the learned embedding\(^1\) of the word type, $e_q$ is a pre-trained embedding of the word type, $o_q$ is the learned embedding of the part-of-speech tag of the word, and $γ_q$ is the distance of the word from the beginning of the target (the word triggering a frame).

- These word representations are given as input to a bidirectional LSTM (biLSTM), each of whose hidden state then becomes a contextualized representation of the following form.

$$h_q^{ok} = [biLSTM^{tok}(v_1, v_2, ..., v_n)]$$

(2)

- These token representations are then used to compute contextualized representation of various spans of the sentence as shown below:

$$h_{(i,j)}^{span} = [biLSTM^{span}(h_1^{ok}, v_2^{ok}, ..., h_j^{ok})]$$

(3)

\(^1\)In this study, we use Stanford’s GloVe (Global Vectors for Word Representation) word embeddings (Pennington et al., 2014) as proposed by Swayamdipta et al. (2017). GloVe embeddings were created from data from Wikipedia and newswires.
The token hidden states given above (Eq 2) together with an LSTM are used to compute a contextualized target representation as shown below:

$$v_t = \left[ \text{LSTM}_{\text{target}}(h_{t_{\text{start}}-1}, \ldots, h_{t_{\text{start}}+1}) \right]$$  \hspace{1cm} (4)

The target representation, together with the learned frame embedding $$v_f$$ and the lexical unit embedding $$v_l$$, are used to represent segments as:

$$v_{f,l,t} = [v_f; v_l; v_t]$$  \hspace{1cm} (5)

And, for every segment, a segment score is computed as:

$$v_s = [h_{i,j}^{\text{span}}; v_l; \mu]$$  \hspace{1cm} (6)

Where $$v_s$$ is a learned embedding of a segment at position $$(i, j)$$ and $$\mu$$ represents two other features: the length of the span, and the span’s position with respect to the target.

This is then passed through a rectified linear unit to get a segment score as:

$$\phi(s, x) = w_2 \cdot \text{ReLU} \{ w_1 [v_s; v_{f,l,t}] \}$$  \hspace{1cm} (7)

The segment score then becomes part of a criterion, which the model is trained to maximize on the training data. Once trained, the model is used to predict labels for various spans of the input sentence. The experiments to label sentences using the learned models are reported in the next section. For more technical details on the deep learning model and its input, we refer the reader to (Swayamdipta et al., 2017).

5 Experiments

The data was divided into two major sets labeled as ‘Full’ and ‘Filtered’. The former is the data set where the annotation of all frames and frame-elements were preserved, while in the later the annotation of two problematic frame elements (i.e. ‘data’ and ‘data_translation’\(^2\)) were removed from the training data. The reason for removing

\(^2\)In LingFN, many frames have data and data_translation frame-elements, which are used to represent examples of various morphology or grammatical linguistic categories of the language described in the document. As an example consider the following annotation in which both data and data_translation frame-elements have been used to annotate an example numeral (i.e. ghri) and its translation (i.e. ‘one’): The numeral \([ghri]\_data, \text{[one]}\_data_translation\) is used as an indefinite article.
these two frame-elements is that they contain non-English words for which the embeddings are missing in the learned embedding space consequently impacting the model’s performance adversely. To show their impact, we conducted experiments with and without those frame-element annotations. With those two data sets, the experiments were conducted with the following three settings:

- **Word Embeddings**
- **Character Embeddings**
- **Mimic Embeddings**

In the first setting, word-embeddings were used to compute the token level representations (i.e. Eq 1), and consequently all other computations involving token representations. In the second setting, word-embeddings were replaced with character embedding, while in the third setting they were replaced with mimic embeddings. The motivation behind these three settings follows.

Since the word embedding space was learned from a general-purpose text, it understandably does not contain many of the the domain specific words in the data used in this study (i.e. the descriptive grammars). In addition, there are the non-English words, i.e the transliterated forms of the words of a specific language given as examples in the descriptive documents. In the annotated data, such words often appear as a part of the ‘data’ frame-element. For all those cases, a default word embedding was used by the system while learning and predicting the frame annotations. This means that the knowledge that words can bring to the system while learning was not available to the system resulting in a decreased system performance (as obvious from the results discussed in Section 6). As a solution to this out-of-vocabulary words issue, we experimented with the other two settings.

In the second setting, word embeddings were replaced with character embeddings while computing Eq 1, resulting in different token and span level representations (Eq 2 and 3). This was based on the intuition that even if a complete word has not been seen in the training set, the characters it contains have, hence, utilizing the character-level knowledge. This is particularly pertinent in the case of ‘data’ frame element. As is apparent from the results in given in Section 6, this technique improved the result considerably. A primary computational concern with this solution from the outset was the need to train character embeddings, which is computationally a highly expensive task. For that we relied on automatic conversion of a set of pre-trained word embeddings into character embeddings\(^3\). In this technique, for each word in a set of word embeddings, each character is given a vector inferred from the parent word. Then, for each word in the embeddings, when the character is seen again this vector is adjusted to reflect its average in the entire set. This technique is a useful workaround to get a meaningful set of character embeddings.

---

\(^3\)https://minimaxir.com/2017/04/char-embeddings/
In the third setting, word embeddings of the unknown words were inferred from the existing word-embedding space and used while computing input (Eq 1). The embedding inferring technique has been proposed by Pinter et al. (2017) in which a character-based bidirectional LSTM was used to infer vectors for a list of unknown words and to add them to the existing word-embeddings. They call their method the ‘mimick’, and it predicts an embedding for a word that should fit into the same space based on the sequence of character embeddings for the characters in the given word.

Originally, the authors used their technique in the context of OCR error correction and spelling variations issue, but in our case we have used it for the out-of-vocabulary issue. It appeared to be equally useful in our case as is obvious from the results given in the next section.

6 Results

Table 1 shows the results of three experimental settings discussed in the previous section. To show the impact of the ‘data’ and ‘data_translation’ frame-elements, results have been shown with and without them (i.e. ‘Full’ and ‘Filtered’ in the table). As can be seen, the system achieved a considerably low F-score when tested on the full data, which improved when the data and data_translation frame-elements were removed. The word to character level embedding replacement obtained an improvement from 46.9 to 51.3 on the full data, while from 55.0 to 58.8 without data and data_translation frames. This suggests that the character-level embeddings are a better choice in a domain specific setting even if there are no non-English transliterated words. As for the mimic technique, it deteriorates from 46.9 to 46.3 when applied on the full data, but improves from 55.0 to 57.0 when tested without the problematic data and data_translation frame elements. This suggests:

- The technique of inferring word embeddings and using them for the out-of-vocabulary issue is equally useful as it was for the OCR error and spelling variation issue.
- It is not advantageous to infer and use the embeddings of totally unrelated words i.e. the non-English transliterated words, such as words in the data frame element.

In summary, we achieved the best results with character-level embedding when applied to the full data, and with the mimic technique when data and data_translation were excluded.

7 Comparison to a Previous System

Table 2 shows comparison between the deep learning based vs a machine learning based system reported in (Virk et al., 2019) for the frame annotation task. The comparison is done on a separate smaller data set as the (Virk et al., 2019) system could not be run on the full data set due to memory issues arising from data size. As can be seen, both on the full and filtered data set versions, the proposed system beats the older system with a fair margin in term of F-scores. This proves the worth of such a system for domain specific frame semantic parsing which is to be used for typological information extraction as described in the next section.

8 Typological Information Formulation Module

In the proposed system, once a sentence has been automatically annotated with semantic frames and their frame-elements (the output from the second part of the system architecture), the annotations can be converted to a typological feature value as an answer to a typological question. Currently, we rely on a rule-based module for the conversion from annotations to feature values as explained in (Virk et al., 2019). This involves writing small modules as shown in Algorithm 1 given in Appendix A for converting annotations to feature values.

As can be seen the algorithm simply loops through the set of frames (line 2) and frame elements, and depending on their contents (line 3, 7, 8, 10, and 12), it assigns appropriate features value for the adjective-noun-order feature (line 9, 11, and 13) discussed in the introduction section. Similar modules can be used for other typological features.

Appendix B shows a set of order related feature and their values automatically extracted from descriptive grammar of ‘Ulwa’ language (Barlow, 2018) using the developed semantic parser, and the rule-based feature formulation module given in Appendix A. Note all features were extracted using only SEQUENCE semantic frame from LingFN.

4A semantic frame in LingFN which encodes ordering related information similar to the example given in the introduction section.

Table 2: Comparison to a previously reported system

9 Conclusions and Future Work

Our main contributions are two-fold. First, we have reported a deep learning based system for the automatic extraction of typological information from descriptive grammars of natural languages. As mentioned previously, the manual extraction of such information is very costly both in terms of cost and human efforts. Any assistance in this regard is much appreciated as typological linguistic information is not only useful for investigating the linguistic diversity of the universe, but is also being used for many other NLP related tasks. A survey of usefulness of typological information in various NLP tasks can be found in (O’Horan et al., 2016).

Unlike, previously reported systems for the same task, the system proposed in this study uses word-embeddings as the only knowledge source and does not require any feature engineering to identify suitable feature set for the machine learning part.

Second, we have shown how word-embeddings learned from general purpose text can be used in a domain specific setting, and how character embeddings can also be used as a work around for out-of-vocabulary terms. Further, inferring word embeddings is another way to deal with out of vocabulary words as long as the words are not cross-lingual (English and non-English in our case). In the future, we would like to improve the system by experimenting with n-gram embedding instead of character embeddings. In another direction, word-embeddings could be learned from domain-specific data-sets as opposed to general purpose word-embeddings used in this study, which could avoid the issue of out-of-vocabulary words issue.

Evaluation of the extracted typological information is another task that we have plans to carry out in the near future. One can select a suitable set of features from one of the existing typological databases, and use their values as a gold-standard to evaluate the performance of the system proposed in this study.

Abstract

Business Process Management (BPM) is the discipline which is responsible for management of discovering, analyzing, redesigning, monitoring, and controlling business processes. One of the most crucial tasks of BPM is discovering and modelling business processes from text documents. In this paper, we present our system that resolves an end-to-end problem consisting of 1) recognizing conditional sentences from technical documents, 2) finding boundaries to extract conditional and resultant clauses from each conditional sentence, and 3) categorizing resultant clause as Action or Consequence which later helps to generate new steps in our business process model automatically. We created a new dataset and three models to solve this problem. Our best model achieved very promising results of 83.82, 87.84, and 85.75 for Precision, Recall, and F1, respectively, for extracting Condition, Action, and Consequence clauses using Exact Match metric.

1 Introduction

Business processes which serve as basis for many (if not all) companies are usually stored as unstructured data, especially as text documents (Blumberg and Atre, 2003). They can reflect all organization tasks and activities in order to provide services. Therefore, these documents could be converted into process models which allows to discover, analyze, redesign, monitor and control these business processes (M. Dumas, 2018). The discipline which is responsible for management of this life cycle is known as Business Process Management (BPM).

Today, this well known practice is very interdisciplinary and combines: organizational theory, management, and even computer science. One of the sub-areas of computer science is Natural Language Processing (NLP) and due to large number of freely available NLP tools such as taggers, parsers, and the lexical database WordNet, NLP is applied in a multitude of domains and BMP is no exception. The application of NLP techniques could be used to extract useful information from textual documents to infer a process model, and also to extract information from the process model to facilitate visual process analysis (Leopold, 2013).

Process modelling is a very complex and time-consuming task. In this work we mainly focused on the analysis of extracted information from text documents in order to have more accurate process models. Given a list of extracted sentences from technical documents, the contributions of our work consists of the following: 1) classifying if a sentence is a conditional sentence, 2) identifying and extracting the conditional and resultant clauses from a conditional sentence, and 3) categorizing the extracted resultant. Section 2 introduces business context and application for our tasks. Section 3 explains how we defined the tasks and created the new dataset TechCond towards solving the tasks. Section 4 presents our methods and models for the tasks. Section 5 shows experiments, evaluation results, and the error analysis that identifies the limitations of our models.

2 Business Context, Application, and Related Works

Process Discovery Traditional process models based on interviews often provide only a limited or biased picture of the actual process. Such highly abstract result can be interpreted in many ways. Therefore, during the past decade process mining and visualization tools (i.e., Celonis, UIPath) were developed to improve process visibility by generating highly adaptable, highly maintainable and validated business process models. However, these tools focus only on analysis of results from structured data - process sequences from actual user
Desktops, or systems logs. It is well known that Desktop Procedures (DTPs) and Standard Operation Procedures (SOP) are very common process documentation techniques (Phalp and Cox, 2007). Therefore, in order to see a broader picture of the process the information from textual source should be analyzed and included into process model. One of the tools which includes multiple sources is Process Discovery Accelerator (PDA).

**Application**  PDA is a business process mining and discovery tool currently available only for automation consultants of our company. It runs as a web application in production on the Services Essentials for Automation platform of our company. PDA has three main components: 1) Standard operation procedure file analysis; 2) Click stream file analysis, sequential structured data which represents actual users activities; and 3) system logs file analysis which is also structured data from applications (system, e-mail, chat). Process Discovery Accelerator is able to discover processes using separate source components or all available at once, this procedure is called process harmonization. The final view of this procedure is single, correlated or uncorrelated processes from all available sources. The example of a single (only SOP) simple process graph result in PDA UI is shown in Figure 1. It illustrates how process flow looks like when conditional and resultant clauses are split into separate steps.

The analysis of Standard operation procedures is very challenging not only because it is based on unstructured data but also because it is very non-homogeneous, domain specific and biased since it is highly dependent on a process description creator (Baier and Mendling, 2013). These SOP files usually contain complex step descriptions, i.e., “if something, then do this” (Table 1) which sometimes could act as gateways or decision points. In order to have a more accurate process model we need to detect specific clause (conditions and actions) from already extracted process steps.

The main objective of PDA is to find automation opportunities by analyzing available data from Standard operation procedures, Click stream, and log files. Without accurate analysis of SOP files it is difficult to measure differences between different sources. Our proposed solution for conditional splitting is crucial for the SOP analysis, since it allows to see actual decision points and how complex a process is by detecting actions and/or consequences.

**Related Works**  The study (Wenzina R., 2013) proposed heuristic, rule-based method to identify condition-action sentences. By using a set of linguistic patterns authors were able to split up sentences semantically into their clauses showing the condition and the consequence with recall of 75% and precision of 88%. Note: these numbers are for specific patterns - for all activities recall is 56%. Another rule-based work was presented by (Hematialam H., 2017). This work is based on combinations of part of speech tags used as features. Authors applied more statistical approach to automatically extract features, however, the recall value is very similar to (Wenzina R., 2013). Both works were tested using sentences from medical SOP’s.

Another good example of NLP and Business Process Management combination is the work from (Qian et al., 2019). Authors used latest NLP techniques (transformers) to classify textual information from word-level to sentence-level. Although this work is most similar to our work it focuses more on automatic process graph extraction, which aims to extract multi-granularity information without manually defined procedural knowledge.

### 3 Task Definition and New Dataset

In this section, we first analyzed the sampled data from our client, then we defined the task Conditional Sentence Splitting, and created a new dataset TechCond to solve it.

#### 3.1 Preliminary Data Analysis

We received a dataset of 4,098 sampled sentences provided by our client from SOP documents that is based on few industries: financial services (banking) and retail. This dataset was manually annotated by client in four categories (at sentence level) with unbalanced label distribution:

- **No Condition (NC) (86.5%)**: sentence that has no conditional logic, no condition is found.
- **Condition Action (CA) (9%)**: sentence that has condition, and resultant is an Action.
- **Condition Consequence (CC) (3%)**: sentence that has condition, resultant is a Consequence.

[1]https://www.foodandbeveragetrainer.com/sop/

1495
Figure 1: Standard operation procedure example of welcoming guest in restaurant from food and beverage training in Process Discovery Accelerator tool UI. The process step in diamond shape indicates condition clause and dashed arrow shows resultant. Solid lines connects different process steps.

Figure 2: Syntactic structures of CA sentences.

- Only Condition (OC) (1.5%): sentence that has only condition, no resultant found.

We extracted 352 CA sentences from this client’s dataset then analyzed syntactic structures of CA sentences and different types of Action resultants (Figures 2 and 3). Based on this preliminary analysis, we then created the new dataset TechCond (Section 3.3) which has better label distribution and more fine-grained annotation. We also constructed our rule-based model (Section 4) based on the analysis of syntactic structures and Action resultant types of CA sentences.

Figure 3: Action resultant types of CA sentences.

3.2 Task Definition

We defined the end-to-end task Conditional Sentence Splitting in which the input is a given sentence, and the output is the extracted clauses classified into Condition and other resultant categories such as Action or Consequence. Since this is a large and complex task, it can be split into the following three subtasks.

Subtask 1: Conditional Sentence Classification

This task recognizes whether a given sentence is in conditional form. Conditional sentence is a sentence that expresses one or more thing(s) contingent on something else. The most basic form of a conditional sentence is

\[ \text{If } P, Q \]  

(1)
where $P$ is the conditional clause, and $Q$ is the resultant. Recognizing conditional sentences is not a trivial task because there are various ways of expressing the meaning in conditional sentences. A basic approach to identify conditional sentences is to search for a conditional clause within a sentence that has keywords like *If* or *Unless* as condition indicators. However, conditional sentences do not always appear in standard conditional form in equation (1) with these indicators. Table 1 shows examples of conditional sentences that appear in different ways.

Subtask 2: Sentence Boundary Finding and Splitting This task finds the boundary of conditional and resultant clauses in a conditional sentence. A basic approach is to locate the comma that separates between conditional and resultant clauses. For example: *If it rains, children stay inside.* The comma in this example is a strong indicator showing that the first part of the sentence that has condition indicator *If* is a conditional clause, and the second part is a resultant. However, as conditional sentences can appear in numerous ways (Table 1), this makes conditional sentence splitting a complex task.

Subtask 3: Resultant Categorization After splitting a conditional sentence into conditional and resultant clauses, the next step is to categorize if the resultant is an Action or a Consequence clause. In our application, we are interested in Action clause as it helps us to create a new action branch for our process model. For example:

- **Refer to the author if you are in any doubt about the currency of this document.** The resultant "Refer to the author" is an Action clause which means the action will be taken should the condition be satisfied.

- **If the entered password is matched with the one stored in system, the user is authenticated.** The resultant "the user is authenticated" is a Consequence clause which shows the result should the condition be satisfied. Thus, no action is captured and no action branch is created for our process model.

Some common types of Action resultant are:

- Imperative type is phrase that has an imperative verb to give a command or an order.
- Obligation type is phrase that expresses something necessary to follow or execute. It usually has modals of obligation such as *must, have to, have got to, need to, etc.*
- Others are phrases that are neither in imperative nor in obligation form but actual meaning expresses the same.

3.3 TechCond Dataset
We created the new TechCond dataset with conditional sentences to predict sentences with conditions and different types of resultants. We extracted sentences from real text documents collected from public technical manuals and regulation documents from different websites. Technical documents included manuals and troubleshooting guides for different software products and applications available online as documents that could be downloaded. These documents were processed by the English Slot Grammar (ESG) parser (McCord et al., 2012) to identify sentences and their linguistic features. We filter out sentences having conditional words and a subordinating conjunction in their constituency parse. We tried to reduce the bias towards a specific type of conditional sentences by considering a diverse set of conditional words: *'after', 'as a consequence of', 'as a result of', 'assuming', 'if', 'if only', 'if not', 'only if', 'unless', 'until', 'when', 'because', 'as soon as', 'as long as', 'but for', 'even if', 'once', 'on the condition', 'provided', 'providing*. After we filtered out sentences potentially describing a condition, a total of 1,936 sentences with conditional statements were extracted for annotation to be part of the TechCond dataset.

Annotation Methodology We selected the Doccano \(^2\) annotation tool to annotate sequences in the sentences according to our task. Guidelines for the annotation job included possible types of sentences and clauses to annotate. The labels included in the annotation were the following:

- **Condition (CD):** Clause describing a condition. A conditional clause can come before or after the main clause.
- **Action (AC):** Clause describing an actionable result that is related to a condition. The condition can be described before or after the Action clause in the same sentence.

---

\(^2\)https://doccano.herokuapp.com/
Conditional Sentences Actual Meanings
1 If it rains, children should stay home. If it rains, children should stay home.
2 Unless it rains, children can go out. If it does not rain, children can go out.
3 1. Otherwise, they can go out. If it does not rain, children can go out.
4 Come now and I’ll give you the book. If you come now, I’ll give you the book.
5 Do you like it? You can have it now. If you like it, you can have it now.
6 For rainy days, children stay home. If it rains, children stay home.
7 Anyone who skips class will be disciplined. If anyone skips class, they will be disciplined.

</table>

Table 2: Frequency of labels by data split.

- Consequence (CS): Clause describing a non-actionable activity i.e., it does not describe an action that a system or user needs/should take.
- Only-Condition (OC): Sentence describing only a condition without additional clauses for actions or activities.
- No Condition (NC): Sentence with no conditional logic.
- Unconditional-Action: Clause describing only an action without an associated condition.

Annotators were guided to use labels at the sentence or clause level. *Sentence-level* labels included No-Condition (NC) and Only-Condition (OC) labels, and can only be assigned to a whole sentence. *Clause-level* labels included Condition (CD), Action (AC), and Consequence (CS) labels can be assigned only to a clause in a sentence having at least two clauses.

Before the annotation task, annotators were guided to analyze patterns of conditional sentences that could be found during the annotation task. For instance, sentences with short phrases such as *if possible* or *if any*, were not considered conditional phrases. Three annotators completed the annotation job for 1,936 sentences. Since a sentence having a condition can have a resultant of type consequence or action, there could be sentences with two or more types of labeled sequences. Table 2 shows the different data splits of the TechCond dataset with the final number of annotated sequences per label.

4 Model Descriptions

We present three models using both rule-based and deep learning approaches to recognize and split conditional sentences into conditional clause and other resultant categories. The rule-based model implements a pipeline that solves the end-to-end task by solving each subtask. In contrast, we considered this large task as a sequential labeling task for deep learning approach.

**Rule-Based Model**

Syntactic and semantic manually written rules are the basis for many systems that analyze technical documents, for example (Panapikolaou, 2012; Zhang and El-Gohary, 2012). In a nutshell, these approaches adopt a general architecture, which extracts the constituents of the sentence, their type and their dependency relationships using constituency or dependency parsers. Among the extracted entities, there could be conditional constituents which are further analyzed. However, we have found out that for our corpus of technical documents the systems trained on standard corpora, (Marcus et al., 1993; Taylor et al., 2003) do not perform well. A source of error might be the text itself, as the technical corpora is not necessarily written by native English speakers, but most importantly, conditional clauses have many peculiarities, both at syntactic and semantic level, which could be exploited more efficiently than a general approach does.

To achieve a high quality of parsing of the conditional sentences, we developed a system of rules that proceeds sequentially to determine (i) the conditional triggers - using lexical and semantic rules (ii) boundaries of conditional clause - using syntactic and semantic rules, (iii) the border of adjacent
constituents - using syntactic rules and (iv) the relationship between constituents and the corresponding conditional - using semantic rules.

The conditional triggers are lexical items, like *if*, *when*, but also the comma itself, “,”, “,”, or *that*, when it introduces a relative clause. The rules in (i) analyze the context and decide whether a trigger does indeed introduce a conditional. Then, the one predicate condition is used by the rules in (ii), that is, we determine exactly one verbal phrase whose boundaries are actually the boundaries of the conditional clause itself. We used semantic features, like *imperative*, or *nominalization* to decide whether a verbal group carries conditional relevance. Some of these features are extracted directly from ESG output (McCord et al., 2012), and some other are extracted by our rules via a deep analysis of copula, semantic transparent verbs and other verbal constructions that do not necessarily contain exactly one verb. The boundaries ambiguities are resolved by rules in (iii), which decide whether a noun phrase is a part of a conditional or it belongs to the following clause. The rules in (iv) check for imperative, or imperative like constructions, because a clause expressing an action that logically follows a conditional must be understood as “to do” obligation. That is, these rules rank the candidates according to their imperative valency and their position with respect to the determined conditional clause.

This model achieved an accuracy of about 70% (Table 3).

**BERT-based Model** One sequence model for conditional splitting was based on the *BERT*BASE language model (Devlin et al., 2019). This model takes a maximum 512 input word piece token sequence $X = [x_1; x_2; \ldots; x_T]$ and uses a $L = 12$ layer transformer network, with 12 attention heads and 768 embedding dimensions, to output a sequence of contextualized token representations. We used the representation of the first sub-token as the input to the token-level classifier over the conditional label set. We fine-tuned the model using 5 epochs, learning-rate 0.1, and 256 maximum sequence length.

**XLM-R-based Model** XLM-RoBERTa (XLM-R) is a SOTA multilingual masked language model trained on 2.5 TB of newly created clean CommonCrawl data in 100 languages (Conneau et al., 2019). It obtains strong gains over previous multilingual models like mBERT and XLM on classification, sequence labeling and question answering. We used the XLM − R model with standard settings: max sequence 256, learning rate 7e-5, warmup_proportion 0.1, epoch 5, batch size 8.

## 5 Experiments

To evaluate the performance of the models, we used the test set from the TechCond dataset (Section 3.3) following the data split shown in Table 2. Since our dataset was annotated at phrase/chunk level, we transformed our annotated data into Inside-Outside-Beggining (IOB) tagging format for the sequential labeling task. For example:

- **Phrase level annotation:** { "id": 908, "text": "Include the date if the opt-out period expires.”, "meta": , "annotation_approver": "admin", "labels": [0, 16, "Action"], [17, 47, "Condition"]}

- **IOB annotation scheme:** {Include B-Action, the I-Action, date I-Action, if B-Condition, the I-Condition, opt-out I-Condition, period I-Condition, expires I-Condition, . O}

Since we are only interested in having sentences split into three main categories Condition, Action, and Consequence, we focused the evaluation of the models for these labels. Table 3 shows the performance of our models for the end-to-end conditional sentence splitting on the test set of 200 sentences. The XLM-R-based model outperforms other two counterparts by large margins.
Error Analysis Figure 4 shows sentences having complex structures that our models failed to recognize and extract correct Condition, Action, and Consequence clauses. Although the rule-based model has a comprehensive set of rules for high accuracy, the coverage is limited for sentences having complex syntactic structures. It struggles to capture non-standard conditional structures, such as relative clause where no Condition clause was found (Example 1); or it captured wrong resultant (Example 2) due to structure complexity. In contrast, deep learning models performed well on (Examples 1 & 2) but failed to capture correct resultant (Example 3) due to the coordination of verbs in the Condition clause; or failed to capture full resultant (Example 4) due to a very long sentence sequence. Our models also have difficulty to process sentences with multiple conditions or multiple resultants. For example:

- **If you had dynamic SQL** (or if you re-bound static SQL), your applications might be breached.

- **If using PayPal for payment then click on the PayPal tab and then click Pay Now.**

Example 3 shows another limitation that is to differentiate between Unconditional-Action clause "Verify in MSR link the order quantity" and the actual Action clause.

6 Conclusions and Future Work Recognizing and splitting conditional sentences for automation of business process management is a complex and important task for many industries. We presented a non-trivial real-world system that can recognize and split technical instructions (at sentence level) into Condition, Action, Consequence clauses for business process modeling and automatic update. We defined an end-to-end task consisting of three subtasks that fits our business context and needs. We also created a new dataset and three models, using both rule-based and deep learning approaches, to solve this task. For future work, we plan to improve the task performance by 1) expanding the dataset and improving annotation to capture more examples of complex structures, and 2) trying better learning approaches or more linguistics attributes to help our models learn better.

Abstract

One of the mechanisms through which disinformation is spreading online, in particular through social media, is by employing propaganda techniques. These include specific rhetorical and psychological strategies, ranging from leveraging on emotions to exploiting logical fallacies. In this paper, our goal is to push forward research on propaganda detection based on text analysis, given the crucial role these methods may play to address this main societal issue. More precisely, we propose a supervised approach to classify textual snippets both as propaganda messages and according to the precise applied propaganda technique, as well as a detailed linguistic analysis of the features characterising propaganda information in text (e.g., semantic, sentiment and argumentation features). Extensive experiments conducted on two available propagandist resources (i.e., NLP4IF’19 and SemEval’20-Task 11 datasets) show that the proposed approach, leveraging different language models and the investigated linguistic features, achieves very promising results on propaganda classification, both at sentence- and at fragment-level.

1 Introduction

Propaganda represents an effective, even though often misleading, communication strategy to promote a cause or a viewpoint, for instance in the political context (Lasswell, 1938; Koppang, 2009; Dillard and Pfau, 2009; Longpre et al., 2019). Different communication means can be used to disseminate propaganda, i.e., textual documents, images, videos and oral speeches. The ability to effectively identify and manifestly label such kind of misleading and potentially harmful content is of primarily importance to restrain the spread of such information to avoid detrimental consequences for the society.

In this paper, we tackle this challenging issue (Da San Martino et al., 2020b) by proposing a textual propaganda detection model. More precisely, we address the following research questions: (i) how to automatically identify propaganda in textual documents and further classify them into fine-grained categories?, and (ii) what are the linguistic distinctive features of propaganda text snippets? The contribution of this paper consists not only in proposing a new effective neural architecture to automatically identify and classify propaganda in text, but we also present a detailed linguistic analysis of the features characterising propaganda messages.

Our work focuses on the propaganda detection and classification task, casting it both as a binary and as a multi-class classification task, and we address it both at sentence-level and at fragment-level. We investigate different architectures of recent language models (i.e., BERT, RoBERTa), combining them with a rich set of linguistic features ranging from sentiment and emotion to argumentation features, to rhetorical stylistic ones. The extensive experiments we conducted on two standard benchmarks (i.e., the NLP4IF’19 and SemEval’20-Task 11 datasets) show that the proposed architectures achieve satisfying results, outperforming state-of-the-art systems on most of the propaganda detection and classification subtasks. An error analysis discusses the main sources of misclassification. Furthermore, we analysed how the most relevant features for propaganda detection impact the fine-grained classification of the different techniques employed in propagandist text, revealing the importance of semantic and argumentation features.

2 Related Work

In the last years, there has been an increasing interest in investigating methods for textual propaganda detection and classification. Among them, (Barrón-
Cedeño et al., 2019) present a system to organize news events according to the level of propagandist content in the articles, and introduces a new corpus (QProp) annotated with the propaganda vs. trustworthy classes, providing information about the source of the news articles. (Da San Martino et al., 2019) present the benchmark of the shared task NLP4IF'19 on fine-grained propaganda detection. As a follow up, in 2020 SemEval proposed a shared task (T11) (Da San Martino et al., 2020a) reducing the number of propaganda categories with respect to NLP4IF'19, and proposing a more restrictive evaluation scheme. To evaluate the proposed approach, we rely on these two standard benchmarks, i.e., the NLP4IF'19 and SemEval'20 datasets.

The most recent approaches for propaganda detection are based on language models that mostly involve transformer-based architectures. The approach that performed best on the NLP4IF'19 sentence-level classification task relies on the BERT architecture with hyperparameters tuning without activation function (Mapes et al., 2019). (Yoosuf and Yang, 2019) focused first on the pre-processing steps to provide more information regarding the language model along with existing propaganda techniques, then they employ the BERT architecture casting the task as a sequence labeling problem. The systems that took part in the SemEval 2020 Challenge - Task 11 represent the most recent approaches to identify propaganda techniques based on given propagandist spans. The most interesting and successful approach (Jurkiewicz et al., 2020) proposes first to extend the training data from a free text corpus as a silver dataset, and second, an ensemble model that exploits both the gold and silver datasets during the training steps to achieve the highest scores. Notice that most of the most performing recent models heavily rely on transformer-based architectures.

In this paper, we also rely on language model architectures for the detection and classification of propaganda messages, empowering them with a rich set of features we identified as pivotal in propagandist text from the computational social science literature. In particular, (Morris, 2012) discusses how emotional markers and affect at word- or phrase-level are employed in propaganda text, whilst (Ahmad et al., 2019) show that the most effective technique to extract sentiment for the propaganda detection task is to rely on lexicon-based tailored dictionaries. Recent studies (Li et al., 2017) show how to detect degrees of strength from calmness to exaggeration in press releases. Finally, (Troiano et al., 2018) focus on feature extraction of text exaggeration and show that main factors include imageability, unexpectedness, and the polarity of a sentence.

3 Propaganda Detection as a Classification Task

(Da San Martino et al., 2019) define the Fine-Grained Propaganda Detection task as two sub-tasks, with different granularities: i) Sentence-Level Classification task (SLC), which asks to predict whether a sentence contains at least one propaganda technique, and ii) Fragment-Level Classification task (FLC), which asks to identify both the spans and the type of propaganda technique.

In the following example, “In a glaring sign of just how stupid and petty things have become in Washington these days, Manchin was invited on Fox News Tuesday morning to discuss how he was one of the only Democrats in the chamber for the State of the Union speech not looking as though Trump killed his grandma.” the span “stupid and petty” carries some propagandist bias, and is labeled as “Loaded Language”, “not looking as though Trump killed his grandma” is considered as “Exaggeration and Minimisation”, and “killed his grandma” is “Loaded Language”. According to the SLC task, the whole sentence should be classified as a propaganda message given that it contains at least one token (e.g., “stupid and petty”) considered as such.

As previously introduced, current systems address these tasks relying on word embedding models (e.g., BERT-embedding) and standard features (e.g., PoS, name-entity, n-grams), as representations to feed various RNN architectures (Morio et al., 2020; Chernyavskiy et al., 2020). Recently, the language model BERT (Devlin et al., 2019) has been widely utilized to optimize the performances of classification tasks, but there is still room for improvement, in particular when applied to propaganda detection (Da San Martino et al., 2020a, 2019). In this work, we experiment with multiple architectures and language models to classify propagandist messages on both sentence and fragment-level. Prior to that, we conduct a detailed investigation of linguistic and argumentation features to capture propaganda strategies.
4 Feature Analysis

Propaganda strategies generally involve specific targets to be stimulated by the message. To better study such techniques from a computational point of view, we investigate a set of features that we assume to play a role in propaganda.

4.1 Persuasion

Speech style. To analyze the writing style of the messages, we apply the dictionary-based mapping tool “General Inquirer (v. 1.02)” (Gilman, 1968). It relies on a list of lexicons from 26 domains (e.g., politician speeches, consumer protests) annotated according to 182 rating categories and dimensions (e.g., valence categories and words indicating overstatement and understatement)\(^2\). We apply such a tool on our data and we sum the ratings of each token to obtain a global score for a sentence.

Lexical complexity. Given that pre-trained language models have shown to capture lexical and semantic complexities of words, we rely on BERT (base-uncased) (Devlin et al., 2019) to extract lexical complexity features. We extract a vector of 768 dimensions per each token, then we average w.r.t. all tokens in a sentence, to obtain one vector of 768 dimensions to represent a sentence.

Concreteness. Propaganda messages tend to employ words with concrete meaning, that has more impact in conveying the intention of the message than using abstract words (Eliasberg, 1957). We rely on the concreteness lexicon (Brysbaert et al., 2013) and we sum the standardized score of each token in a sentence to obtain the global score.

Subjectivity. We rely on the subjectivity lexicon from (Wilson et al., 2005). We sum up the scores over all tokens in a sentence found in the lexicon as our extracted feature. Each word labeled as “weaksubj” is set to 0.5, and “strongsubj” to 1.

4.2 Sentiment

Sentiment labels. We use SentiWordNet 3.0 (Baccianella et al., 2010) to obtain word-level sentiment labels (positive, negative, or neutral). We sum the sentiment scores of each word in a sentence, producing a vector with 3 dimensions (i.e., pos, neg, neu) for each sentence.

Emotion labels. We extract 8 emotions (i.e., afraid, amused, angry, annoyed, don’t care, happy, inspired, sad) from DepecheMood++ lexicon (Araque et al., 2019). For each word that evokes emotions in a sentence, we produce our features by summing up each set of emotions evoked by each token, then find the average by emotions. Hence, we produce 8 emotion scores for a sentence.

VAD labels. In the three-dimensional model of affect, valence ranges from unhappiness to happiness and expresses the pleasant or unpleasant feeling about something, arousal expresses the level of affective activation, ranging from sleep to excitement, and dominance reflects the level of control of the emotional state, from submissive to dominant. We use Warriner lexicon (Warriner et al., 2013) to match each word in a sentence to its VAD standardized word scores and sum up as our features.

Connotation. Propaganda can convey sentiment beyond its original meaning. Connotation lexicon (Feng et al., 2013) provides positive, negative and neutral labels of each word. We count the frequencies of the three labels evoked in each sentence.

Politeness. Politeness evokes sentiment in readers. We use a lexicon of positive and negative words from (Danescu-Niculescu-Mizil et al., 2013), then we count the frequencies of both positive and negative words found in each sentence.

4.3 Message Simplicity

To keep the message simple and picturable is one of main purposes of propaganda. We list the features we considered to extract the simplicity of message.

Exaggeration. We use imageability lexicon (Tsvetkov et al., 2014) based on picturable vocabulary which mentally leads to an exaggerating state of mind. We consider the scores of abstraction and concreteness at each word token. We then sum up the scores for all the labels found in a sentence.

Length. “The less words used, the better to understand” can be a concept to easily interpret the propagandist message. We apply two strategies: \(^i\) we count the average char-length, actual char-length, word length, punctuation frequency, capital-case frequency per sentence (Ferreira Cruz et al., 2019); \(^ii\) we apply length encoding at character-level, plus one additional dimension for non-alphabetical char count.

Pronouns. Loaded language, name calling and labelling are the most used techniques in propaganda text (Da San Martino et al., 2019), and they all make use of pronouns. We create a lexicon of 123 pronouns in English\(^3\) and perform one-hot encoding.
encoding of common used pronouns in English.

4.4 Argumentation
We assume that argumentation plays an important role in propaganda. To extract argumentative features representing our data, we train a supervised classifier for the task of argumentative sentence classification on the persuasive essays dataset (Stab and Gurevych, 2014). First, we cast it as a binary classification task, merging premises, claims and major claims into the argumentative label, as opposed to the non-argumentative label. Then, for the argumentation component task, we rearrange the data to binary labels where the major claims and claims labels are merged, and they are opposed to premises. To address these tasks, we build and fine-tune a BERT classifier. We use a learning rate of 1e-5 with 80/20 split of the dataset. We run our classifier 3 times at different random states. The results for the argumentative sentence classification are (macro-average) F1 0.84, precision 0.86, recall 0.82, while for the component classification they are F1 0.77, precision 0.80, recall 0.75.

To extract argumentative features from the annotations provided by our classifiers, we use BERT-based features. After fine-tuning, we freeze the hidden states of these fine-tuned BERT models. To extract the argumentative and components features from each classifier, we take the [CLS] token of each sentence from the fine-tuned BERT model.

4.5 Ablation Study
To investigate the impact of the proposed features (Section 4) for propaganda detection, we perform ablation tests by testing a supervised classifier relying on BERT + logistic regression. To the purpose, we use the NLP4IF’19 training and test sets (Da San Martino et al., 2019).

Table 1 reports on the performances obtained while integrating groups of features to the proposed model. A logistic regression model is used as a baseline. Best results are obtained when adding all the proposed features, but the argumentation ones. Argumentation features alone perform almost identical as semantic features, therefore - unexpectedly - no added value can be demonstrated.

5 Sentence-level Classification
In the following, we describe the experiments we carried out to address the propaganda detection task at sentence level, investigating different architectures and leveraging both recent language models and the features that proved to play a role in propaganda messages. For the evaluation, we used the two available datasets for propaganda detection: i) the NLP4IF’19 data set (Da San Martino et al., 2019) (293 articles for training and 101 for testing); and ii) the data from SemEval’20 T11 (Da San Martino et al., 2020a) (371 articles for training and 75 in the development set).

5.1 Prediction Models
In the following, we first describe the baseline and the SOTA models we tested in our experiments, and then we present the three architectures we propose (underlined) integrating the propagandist features previously investigated (Section 4).

BERT. Our baseline model relies on a pre-trained bidirectional transformer language model to encode context specific sentence tokens (Devlin et al., 2019) (no fine tuning, default hyperparameters).

Fine-tuned BERT. We fine-tune the BERT model with a learning rate of 5e-5, and AdamW optimizer. We set the gradients to zero at every training batch. Then we use softmax activation to gate the output with the threshold of 0.5.

Fine-tuned T5. To fine-tune the text-to-text transformer (Raffel et al., 2020), we use T5ForConditionalGeneration approach (equally to question-answering task) where the input is a sentence (as a question), and the output is an answer (as a label). We use a learning rate of 3e-4, with max sequence length of 512.

Linear-Neuron Attention BERT. We replicate...
the winning approach of the NLP4IF’19 shared-task (Mapes et al., 2019). It relies on BERT architecture with some modifications of hyperparameters (sentence length of 50 tokens, a learning rate of 1e-5, along with 12 attention heads and 12 transformer blocks). It uses the linear neuron without an activation function, and a threshold of 0.3 for the final prediction.

Multi-granularity BERT. This model (Da San Martino et al., 2019) relies on BERT transformer with multi-granularity network on top that has multi-classifiers for different granularity levels of text (e.g., document, paragraph, sentence, word, subword, and character-level). We replicate this model with BertAdam optimizer and ReLU activation function.

Multi-granularity + Featured BERT. We integrate the proposed features (Section 4) into (Da San Martino et al., 2019), taking only the last layer of sentence-level granularity. We feed the proposed features to a BERT classifier to obtain logits which then aggregate with the last layer of sentence-level granularity to produce predictions.

BERT + Featured BiLSTM. We build a pre-trained BERT transformer architecture, and Bi-directional Long Short-Term Memory (BiLSTM) architecture on top of the BERT model to handle the transformer architecture with our propaganda features. Firstly, the BERT model is used with learning rate of 0.001, with AdamW optimizer. We use the output of BERT that represents the [CLS] token of each sentence to combine with propaganda features as our input to the second model, the BiLSTM. For the BiLSTM model, after we feed our inputs of both [CLS] tokens combined with propaganda features, we train our BiLSTM model with hidden size of 256. Our BiLSTM hidden states consist of the last hidden states, and the last cell state for the BiLSTM layers. We then apply relu gate function, with a linear dense, then use a dropout function of 0.1. At the last layer, we use another linear dense layer to output final logits, then we apply a sigmoid activation function as final outputs.

BERT + Featured Logistic Regression. We use pre-trained BERT transformer architecture to output [CLS] token, then use this output to stack with another prediction model, i.e., logistic regression. We build a linear classifier and feed it with propaganda features as a dense layer. We then combine these logits with [CLS] tokens as the input to logistic regression on top of BERT.

5.2 Results and Error Analysis

Table 2 reports on the results obtained for the SLC task (propaganda vs no propaganda). We run each experiment 5 times and report the macro-average of all metrics. Our proposed models achieve the highest F1-score of 0.72 using BERT + Featured Logistic Regression model (persuasion, sentiment, and message simplicity features), and the highest precision-score 0.80 using BERT + Featured BiLSTM model on NLP4IF’19 dataset, outperforming the state-of-the-art models. For SemEval’20-T11, we do not have the scores from the challenge (the binary task was not proposed), but we compare the obtained results with the replicated architectures of SOTA models. Our proposed architecture obtained the best F1-score using BERT+Featured Logistic Regression. Using semantic features alone perform slightly better than combining them with argumentation features.

Table 3 reports on some misclassified examples of our best model on NLP4IF’19 dataset. Some short sentences containing strong intention keywords (e.g., “hate”, “slave”) have been missclass-
Table 3: Examples of misclassified sentences by the BERT + featured logistic regression model (NLP4IF’19)

<table>

<tr>
<td>You are a slave to white America.</td>
<td>Hitler was a very great man.</td>
</tr>
</tbody>
</table>

Table 3: Examples of misclassified sentences by the BERT + featured logistic regression model (NLP4IF’19)

sified as false positives. As for false negatives, the underlined fragments are labeled propaganda in gold standard, but have not been recognized as such by the classifier (mainly informative statements).

6 Fragment-level Classification

In this section, we address the task of fragment-level classification, meaning that both the spans and the type of propaganda technique should be identified in the sentences. Again, to test the proposed methods, we use both NLP4IF’19 and SemEval’20 T11 datasets. However, in the two challenges, the FLC task was evaluated according to different strategies, explained in the following.

6.1 Task 1: FLC on NLP4IF’19 Dataset

In the NLP4IF’19 dataset, 18 propaganda techniques are annotated. Prediction is expected to be at token-level. Multiple tokens can belong to the same span, and annotated with one propaganda type. Tokens that do not carry any propaganda bias are annotated as “no propaganda”. To perform tokenization we run the tokenizer provided with the pretrained model of each transformer.

6.1.1 Prediction Models

**Fine-tuned BERT (baseline).** Pretrained bert-base-uncased model and BERT architecture (Devlin et al., 2019) with default hyperparameters. Our implementation is based on huggingface transformers. Settings: learning rate of 5e-5, padded length of 128, and batch_size of 16. We use CrossEntropyLoss as a loss function, and softmax activation function to gate output neurons.

**Fine-tuned RoBERTa (baseline).** We use roberta-base model with the same hyperparameters of loss and activation functions as the fine-tuned BERT model mentioned above.

**State-of-the-art Model.** The winning team applied BERT architecture for token classification (Yoosuf and Yang, 2019) on 20 labels (i.e., 18 propaganda classes, plus “background” as non-propaganda, and “auxiliary” for fractions of previous tokens). They use a BERT language model, then apply softmax function, followed by a linear multi-label classification layer to output their predictions.

**Transformer + CRF.** We use a pre-trained model base-uncased with a learning rate of 3e-5 for BERT transformer, and a pre-trained model roberta-base with a learning rate of 2e-5 for RoBERTa transformers (hyperparameters: dropout of 0.1 with the max_length of 128, batch_size of 16 with AdamW optimizer and CrossEntropy loss function). We use CRF layer as the final layer.

6.1.2 Results and Error Analysis

Table 4 reports on the obtained performances. Evaluation is reported as the average of micro-F1 scores of 5 run-times (we use the evaluation scripts provided by (Da San Martino et al., 2019)).

The proposed architecture based on transformers with CRF output layer at different learning gradients (epochs) outperforms SOTA model on several propaganda techniques at different learning gradient ranging from 5 to 15 epochs. We also tested other architectures such as Transformer+CRF with less learning gradients (3 epochs), Transformer architecture with semantic and/or argumentation features + CRF layer by adding extracted features from sentence-level (Section 4) to each token of its sentence to a linear layer before a loss function, with no major improvements.

In Table 4, we compare the performances of the proposed models w.r.t. the SOTA (Yoosuf and Yang, 2019), on the most frequent classes. Table 5 reports examples of misclassification related to that technique. We observe that our proposed model does not capture well the articles (i.e., it, as, an, the), but rather focuses on capturing intentional word tokens (i.e., white, unbelievably, rude, wonderful, treasonous). As for future work to improve results on this specific category, we will investigate the work of (Habernal et al., 2018) according to which a dedicated strategy is needed.

6.2 Task 2: FLC on SemEval’20 T11 Dataset

In SemEval’20 T11 dataset, 14 propaganda techniques are annotated. We focus here on the task called Technique-Classification task (TC). We cast it as a sentence-span classification problem, where...
we combine logits of tokenized elements from the sentence and the span, to learn the prediction. Moreover, we add the semantic and argumentation features to enhance the performance.

As pre-processing, both the tokenized sentence and the span are used to feed the transformer (Huggingface tokenizers) as follows: \(i\) we input a sentence to the tokenizer where max_length is set to 128 with padding; \(ii\) we input the span provided by the propaganda span-template published by the workshop, and we set max_length value of 20 with padding. If a sentence does not contain propaganda spans, it is labeled as a “none-propaganda”.

### 6.2.1 Prediction Models

**Baseline.** For all the tested architectures (BERT and RoBERTa), we use the same type of transformer model to produce logits \(L\) regarding the sentence-level and span-level individually. For BERT model, we use pre-trained model bert-base-uncased, learning rate of 5e-5, and \(\alpha\) of 0.1. For RoBERTa, we take roberta-base pre-trained model with learning rate of 2e-5 with \(\alpha\) of 0.5. All transformer models apply Adam optimizer, dropout 0.1, and CrossEntropy as a loss function per sentence \(\text{loss}_{\text{sentence}}\) and span \(\text{loss}_{\text{span}}\).

We arrange these alignment of \(L\) to calculate the average loss as joint loss \(\text{loss}_{\text{joint}}\) from each loss element. Here we introduce a \(\text{loss}_{\text{joint}}\) function before back-propagation:

\[
\text{loss}_{\text{joint}} = \alpha \times \frac{\text{loss}_{\text{sentence}} + \text{loss}_{\text{span}}}{N_{\text{loss}}}
\]

where \(N_{\text{loss}}\) stands for a number of loss elements that are taken into the model.

**State-of-the-art Model.** The winning team (Jurkiewicz et al., 2020) applies RoBERTa (roberta-large) with pre-trained model. The training set is increased with silver annotation based on gold annotation, and then another RoBERTa model is stacked on top to output the predictions.

**Proposed Architecture.** We propose another set of elements to feed the transformer by introducing the semantic and argumentation features into BiLSTM layer to produce \(L\) of proposed features, then we apply CrossEntropy as a loss function of our BiLSTM as \(\text{loss}_{\text{proposed features}}\) then perform an addition with other loss in the \(\text{loss}_{\text{joint}}\) function as follows:

\[
\text{loss}_{\text{joint}} = \alpha \times \frac{\text{loss}_{\text{sentence}} + \text{loss}_{\text{span}} + \text{loss}_{\text{proposed features}}}{N_{\text{loss}}}
\]

Hyper-parameters: 256 hidden_size, 1 hidden_layer, drop_out of 0.1 with ReLU function at the last layer before the joint loss function.

### 6.2.2 Results and Error Analysis

As mentioned before, the gold labels of the test set of SemEval’20 T11 are not available, but it is possible to submit a system run to the challenge website and to obtain the evaluation score. The evaluation system only accepts the exact list...
of span-templates of the test set (partial overlapping spans or missing spans are not accepted). Table 6 reports on the obtained results (through such evaluation system) on 5 runs as micro-F1. Scores in bold are the ones for which significant improvement can be observed w.r.t. SOTA model. RoBERTa with argumentation features can outperform results on “Thought-terminating_Cliches”. Moreover, by using all semantic and argumentation features together, we can obtain some improvements over “Bandwagon, Reductio_ad_hilterum” and “Casual-Oversimplification”. Table 7 shows some examples of misclassified instances. In general, we noticed that using different training epochs help detecting different propaganda techniques. In particular, it is observed that some techniques tend to be learnt best at low training epochs (i.e., “Bandwagon, Reductio_ad_hilterum”, “Thought-terminating_Cliches”), some at high training epochs (i.e., “Casual-Oversimplification”).

### 7 Concluding Remarks

In this paper, we proposed a new neural architecture combined with state-of-the-art language models and a rich set of linguistic features for the detection of propaganda messages in text, and their further classification along with standard propaganda techniques. Despite the boost in accuracy we achieved on two standard benchmarks for propaganda detection and classification (≈ 10% of F1 scores on sentence-level classification and on specific propaganda techniques on fragment-level classification), this task remains challenging, in particular regarding the fine-grained classification of the different propaganda classes. The state-of-the-art results on this subtask require further improvement to actually embed these solutions in real-world systems.

Future work goes in this direction, with the aim to improve the performance both of the disinformation detection task and of the classification of propaganda techniques. Moreover, we are currently investigating the propaganda classes we discussed in this paper in the context of political debates, with the aim of building a fallacy detection system that relies on the identification of propagandist messages in political speeches.

Abstract
The current natural language processing is strongly focused on raising accuracy. The progress comes at a cost of super-heavy models with hundreds of millions or even billions of parameters. However, simple syntactic tasks such as part-of-speech (POS) tagging, dependency parsing or named entity recognition (NER) do not require the largest models to achieve acceptable results. In line with this assumption we try to minimize the size of the model that jointly performs all three tasks. We introduce ComboNER: a lightweight tool, orders of magnitude smaller than state-of-the-art transformers. It is based on pre-trained subword embeddings and recurrent neural network architecture. ComboNER operates on Polish language data. The model has outputs for POS tagging, dependency parsing and NER. Our paper contains some insights from fine-tuning of the model and reports its overall results.

1 Introduction
The paradigm for automated language processing was originally based on building dedicated tools for every task. We illustrate it on the example of the Polish language, but it is very likely the case also for other languages. The dedicated tools include morphological taggers and disambiguators (a Polish language approximation of POS tagging), dedicated dependency parsers and named entity recognizers. For convenience, the tools sometimes were made available as web services and possibly composed into chains. One such example is Multiservice (Ogrodniczuk and Lenart, 2012), a linguistic Web service for Polish, combining several mature offline linguistic tools in a common online platform. Multiservice offers a number of pre-defined chains. For example, the dependency parser requires morphological tagging and disambiguation as the initial step. The two tools are put together in appropriate order in one chain.

Among universal tools (not dedicated to the Polish language) it is worth to mention:

• UDPipe, a pipeline (tool) for tokenization, tagging, lemmatization and dependency parsing (Straka et al., 2016).

• NLP-Cube which in addition to the capabilities mentioned for UDPipe offers sentence segmentation and lemmatization. The reported results cover many languages but not Polish (Boros et al., 2018).

• Stanza, a tool for tokenization, multi-word token (MWT) expansion, lemmatization, part-of-speech (POS) and morphological features tagging, dependency parsing, and named entity recognition. Named entity recognition models are separate and Polish is not available (Qi et al., 2020).

Recently, with the advances of neural networks in natural language processing, new tools were proposed that simplify the chains by doing several tasks at once. One example is Combo (Rybak and Wróblewska, 2018), a bi-directional recurrent neural network (RNN) using word2vec embeddings with multiple outputs for morphological and dependency analysis. The model was submitted to the CoNLL 2018 Universal Dependency shared task.

The Combo tool, while doing certain things right, has its own issues. The biggest problem is the fact that it requires word-level word2vec embeddings for every token that it encounters. Unfortunately, the number of unique tokens in the Polish language is rather large. For example, in the National Corpus of Polish and Wikipedia, the number of unique case-sensitive tokens exceeds 2 millions. This is by far too many to fit into GPU memory. This
leads to a situation where only word2vec vectors that are used in input texts are loaded into GPU memory (Embedding layer) and an additional preprocessing step of data-driven word vector selection and loading. Depending on linguistic productivity, this operation has to be repeated once in a while when processing large amounts of text. To solve this problem, one can apply techniques of vocabulary selection such as those described in (Chen et al., 2019). Hopefully, another simple solution exists for this issue: subword level embeddings (Sennrich et al., 2016). This idea, successfully applied in machine translation, became popular in multiple other scenarios and architectures, including transformer neural networks such as BERT (Devlin et al., 2019). It allows to represent an unknown word (not present in the dictionary) as a sequence of shorter tokens or subwords. Using subword-level tokenization and embeddings the problem of vocabulary selection is non-existent.

The goal of ComboNER is to (1) avoid the above issues of the initial Combo (Rybak and Wróblewska, 2018) by introducing subword tokenization and (2) add named entity recognition as another output. The overall design goal is to reduce the size of the model where possible.

2 Datasets

This section describes the datasets used to train the ComboNER model. It is only an overview with basic information about data sizes, please refer the cited papers for more details such as label descriptions and annotation principles.

2.1 POS and Dependency

We trained the POS and dependency outputs of the ComboNER model using the Polish language subset of the Universal Dependencies (UD) treebank (Nivre et al., 2020). It contains 17723 sentences in the train set and 2215 sentences in the test and dev sets. Sentences are annotated for part-of-speech, morphological information and dependencies (heads and labels).

2.2 Named Entity

To train the named entity output of ComboNER, we used the relevant subset of the National Corpus of Polish (Przepiorkowski et al., 2012). For label descriptions and annotation principles for named entities refer to the chapter 9.

Overall, the dataset contains 39534 texts and 85816 sentences. Since ComboNER requires exactly one sentence as its input (a limit imposed by the dependency structure defined for a single sentence only), we splitted the named entity data into single sentences using the Polish language model of the spacy.io. We then randomly divided the data into train and test part. This resulted in 81470 sentences (95%) in the train set and 4346 (5%) in the test set.

3 Hyperparameter Tuning

To tune the parameters we used only POS accuracy and one measure from the dependency parsing: UAS score (unlabeled attachment score). This was in order to simplify the analysis and check the balance between types of outputs. Therefore, the hyperparameter tuning was carried out only on the Universal Dependencies dataset.

Hyper-parameter tuning was done using the HParams API in TensorFlow and grid-search approach.

Tuning was subjected to the following hyperparameters:

- Length of the subword embedding vector (emb_dim). Values tested: 25, 100, 200.
- The number of subwords for which we have vectors, i.e. the size of the vocabulary (vocab): 10,000 (10k), 100,000 (100k).
- The size of the Bi-LSTM cell output assuming a single layer model (rnn). Tested values: 100, 200.

ComboNER uses pre-trained Polish language subword embedding vectors from the BPEmb library (Heinzerling and Strube, 2018). Therefore, vocabulary and vector sizes are determined by availability in BPEmb.

For initial parameter selection only the results of the first training epoch were taken into account.

The Table 1 shows tuning results of the selected output as the accuracy of the POS tagger and dependency parser - where the UAS measure was selected. It also shows the mean of both measures in the AVG column.

1https://github.com/ipipan/spacy-pl
2We did not use a validation split because hyperparameter selection was focused on UD part of the data.
3https://www.tensorflow.org/tensorboard/hyperparameter_tuning_with_hparams
The largest embeddings (emb_dim equal to 200) work best in combination with size-corresponding Bi-LSTM cells (rnn equal to 200). This observation concerns both the accuracy of POS tagging and the UAS measure of the dependency parser.

Interestingly, the number of subwords, i.e. vocabulary size (vocab), turned out to be a non-obvious measure. The POS tagger performed better with a large number of subwords (100k vocab), while a dependency parser preferred a smaller number (10k vocab). This effect was present regardless of RNN cell size.

We also tested the configuration of the model with two Bi-LSTM layers. We tested two values of LSTM cell sizes for the first layer (100, 200) and two (25, 50) for the second layer. When measuring performance for the first training epoch, a model with a two-layer Bi-LSTM performs generally worse than a single-layer model with similar settings. As a result, the addition of a second Bi-LSTM layer does not seem to be advisable.

For the named entity recognition, two variants of the model architecture were tried. In the Multiservice (Ogrodniczuk and Lenart, 2012) and in many older generation NLP tools, named entity recognition model uses POS tags as an input feature and is therefore located after POS tagging. This observation leads to testing two design choices for the named entity recognition part of ComboNER. The first one is two independent outputs for NER and POS / dependency: the outputs share only the word embedding layer. The second assumes dependence: named entity branch takes as an input not only embeddings but also hidden states from the LSTM in POS / dependency branch. This setting allows named entity recognition to take into account information from layers trained on syntactic data, in manner somewhat similar to using POS features in older NLP models.

The results in terms of F1 scores of both variants are presented in Table 2. They clearly indicate that syntactic information helps in named entity recognition as the overall gain computed as an average for all entity categories is 12.8%.

4 ComboNER Architecture

Figure 1 illustrates the design of ComboNER. Data processing starts with subword tokenization and embedding layer. Here, pre-trained subword
embedding vectors are used (along with the tokenizer), namely monolingual Polish language BPEmb (Heinzerling and Strube, 2018) trained on Wikipedia. This part is common to all outputs. Then, computation is split into two branches: one for POS and dependency, the other for named entities. Each of the two branches begins with a bi-directional LSTM layer. Named entity branch takes as input not only embeddings but also hidden states from the LSTM in POS / dependency branch. Architecture of this type was selected on the basis of experiments described in Table 2. Intuitively, part-of-speech information is often useful for named entity recognition; in certain natural language processing pipelines such as Multiservice (Ogrodniczuk and Lenart, 2012) named entity recognition (NER) uses part-of-speech (POS) features and therefore is executed downstream (after) POS.

Activations inside the network are tanh and softmax is used in the final layers. For details of implementation see (Rybak and Wróblewska, 2018); in particular, dependency parser outputs with the dot product solution follow closely the initial model.

5 Final Model

5.1 Model Parameters

For the final model, we selected following hyper-parameters:

- 100 output units in the POS and dependency LSTM,
- 50 output units in the named entity LSTM,
- dropout rate of 0.2,
- learning rate of 3e-4,
- 100 output units of the Dense layer for POS output,
- 100 output units of the Dense layer for dependency output,
- vocabulary size of 50,000 (50k),
- embedding size of 100.

The selection of embedding size 100 and 50k vocabulary is a compromise between the quality of POS and dependency outputs.

The number of parameters of the ComboNER is 5.3 millions. The size of the embedding layer alone is 5 millions (embedding size times vocabulary) and we make it trainable for both training tasks as it improves the overall results marginally. The remaining parts of the model are rather modest with named entity part contributing over 100k parameters. The disk size of the model slightly exceeds 200 MB.

The model handles sentences up to 67 subword tokens long as this was the maximum sentence length encountered in the UD dataset. It assumes that the input consists of a single sentence. No
special tokens are needed to indicate beginning or end of sentence.

5.2 Evaluations

We trained the model 45 epochs on the Polish language UD dataset (POS and dependency part) and 20 epochs on the subset NKJP (the National Corpus of Polish, named entity labels) as described in Section 2. The execution time of a single training epoch was 3 minutes on the UD treebank (POS and dependency) and about 10 minutes on the named entity data on a Tesla V100-SXM2-16GB GPU card.

Table 3 contains the POS results of the final fully trained output of ComboNER. The overall accuracy (not reported in the Table) is 0.933. The performance is satisfactory for most parts-of-speech. The worst performing one is PROPN (proper names), due to high lexical variation and relatively low frequency in the UD corpus.

In the case of dependency parser outputs, the two relevant measures are unlabelled attachment score (UAS) and labelled attachment score (LAS). The values measured are 0.71 for UAS and 0.858 for LAS score.

Table 4 contains the results of named entity evaluation. Two categories, present in the data, did not provide reasonable results: GeogName and Time. This is due to low counts, as these categories were the least frequent in the dataset. In the case of categories: Date, OrgName, PersName and PlaceName ComboNER performed with reasonable precision and recall.

6 Conclusions

This paper describes ComboNER: a new version of the Combo tool (Rybak and Wróblewska, 2018), developed with following assumptions in mind: (1) use subwords to avoid out-of-vocabulary issues (words in model’s input not present in memory / the embedding layer), (2) add named entity recognition output, (3) lightweight in terms of memory footprint, as of today’s standards. The tool was implemented in TensorFlow 2.

ComboNER follows many design choices of the original Combo (Rybak and Wróblewska, 2018), but introduces some new solutions.

Training multi-output models on multiple datasets is a challenging task. Technically, it was solved by freezing appropriate part (layers) of the model while training another part, using a dedicated TensorFlow data loader class for each corpus.

The paper contains the results of hyperparameter optimization, which dictate the final hyperparameter choice for the ComboNER model. There are several interesting findings. First, the number of subwords (vocabulary size): the POS tagger performed better with a large number of subwords (100k vocab), while dependency parser preferred a smaller number (10k vocab). Second, named entity layers greatly benefit from accessing layers pre-trained for POS and dependency. This architecture improves the F1 score of named entity recognition by 12.8% on average compared to the variant with fully independent training of both tasks.

The results of PolEval competition in 2018 are an interesting reference for comparisons regarding dependency parser and named entity recognition quality (Ogrodniczuk and Kobyliński, 2018)\(^4\). It appears that LAS score achieved by the ComboNER is competitive and easily on-par with participating systems. Unfortunately, the solutions for named entity recognition outperform the output of ComboNER in a significant manner. One explanation of this fact is context: effective named entity recognition requires context wider than just the input sentence. Most of the corpora and tools assume the supra-sentence level. Important clues for identifying named entities are often a part of preceding sentences.

In order to evaluate the POS tagger, one can compare the results of the PolEval competition in 2017(Kobyliński and Ogrodniczuk, 2017)\(^5\). In this context, the accuracy of 0.933 is very competitive and on-par with the best of the participating systems.

To recap, this paper describes a relatively straightforward yet important modifications over previous work (Rybak and Wróblewska, 2018). Our goals were to develop a small system and avoid large scale transformer, at the same time solving out-of-vocabulary problems posed by word-level embeddings. In the future it may be advisable to compare with small transformer models like DistilBERT (Sanh et al., 2020) (40% less parameters than the BERT base model).

Investigating Annotator Bias in Abusive Language Datasets

Abstract

Nowadays, social media platforms use classification models to cope with hate speech and abusive language. The problem of these models is their vulnerability to bias. A prevalent form of bias in hate speech and abusive language datasets is annotator bias caused by the annotators subjective perception and the complexity of the annotation task. In our paper, we develop a set of methods to measure annotator bias in abusive language datasets and to identify different perspectives on abusive language. We apply these methods to four different abusive language datasets. Our proposed approach supports annotation processes of such datasets and future research addressing different perspectives on the perception of abusive language.

1 Introduction

A challenge that social media platforms are facing in recent years is the large amount of hate speech and other forms of abusive language (Duggan, 2017). Manual monitoring, however, is no longer possible due to the vast volume of user-generated content. Therefore, machine learning models are trained and used by social media platforms, such as Facebook, to automatically detect such content (Kantor, 2020). According to Rose (2021), these models are a key component of Facebook’s fight against hate speech.

A problem with such machine learning models is that they are vulnerable to bias (Vidgen and Derczynski, 2021; Dixon et al., 2018). Biased models can strongly impair the fairness of a system, which can lead to discrimination (Dixon et al., 2018).

Bias in abusive language detection is already a topic that researchers have started to investigate (Vidgen and Derczynski, 2021; Wich et al., 2021). The type of bias we will focus on in this study is annotator bias. This form of bias is a result of annotators who perceive abusive language differently from each other and have different levels of experience and knowledge (Ross et al., 2016; Waseem, 2016; Geva et al., 2019; Wich et al., 2020).

We aim to investigate two aspects of annotator bias. (1) Assuming that there is only one perspective (one truth) on whether a text is abusive or not, we develop an approach to measure and visualize annotator bias. This approach optimizes the annotation process (e.g., outlier detection, adapting appropriate annotation guidelines). (2) Acknowledging multiple valid views on a text (e.g., a group has a more liberal attitude towards abusive texts, while another is stricter), we aim to identify annotator groups to model different, yet valid perspectives. The questions resulting from these research objectives are the following:

- **RQ1**: How can we measure and visualize annotator bias in abusive language datasets?

- **RQ2**: How can we identify and visualize different annotator perspectives on abusive language?

Our contributions are the following:

1. To characterize annotators, we gauge how liberal or strict they annotate in comparison to other annotators. To model annotator bias, we calculate a pessimistic and optimistic score for each annotator that can be visualized in different ways (e.g., scatter plot, cluster map).

2. To identify annotator groups with different perspectives on abusive language, we utilize a classifier-based method with the proposed approach, which is applied to one dataset.
2 Related Work

Hate speech and abusive language detection have gained a lot of attention in recent years. A range of different datasets (Vidgen and Derczynski, 2021) and shared tasks (Basile et al., 2019; Zampieri et al., 2019, 2020) were published to foster research in this area. Most of the datasets are commonly labeled by crowdworkers or those in academia with varying expertise (Vidgen and Derczynski, 2021). However, human annotations tend to be subjective and thus inconsistent (Aroyo and Welty, 2015), at least if not moderated very strictly. Especially for abusive language, Salminen et al. (2018) show that individuals interpret hate speech differently. One common method to improve the label quality is presenting each sample to multiple annotators and aggregate their results (Sheng et al., 2008). Dawid and Skene (1979) were the first to propose an approach that incorporates annotator quality into label aggregation. Their expectation-maximization (EM) algorithm uses the bias matrices to estimate the latent truth. In the matrices the annotator quality is encoded. Their seminal work led to further improvements and methods (Whitehill et al., 2009; Raykar and Yu, 2012; Hovy et al., 2013). For NLP tasks, Snow et al. (2008) used a customized Dawid-Skene algorithm to correct for individual biases of crowdworkers and improve model accuracy. However, they did not quantify and inspect the bias of the annotators.

In abusive language detection, annotator bias research has focused on how the annotators background influences their annotations. Waseem (2016) found models trained on crowd annotations are outperformed by models trained on expert annotations. Ross et al. (2016) emphasized the importance of detailed guidelines to achieve reliable annotations. Binns et al. (2017) showed that classifiers trained on annotations differ in their performance on test data annotated by men or women. Al Kuwatly et al. (2020) picked up this approach, enhanced it, included other demographics, and found significant differences for annotator’s age group and educational background. Sap et al. (2019) observed that posts in African American dialect are more likely to be labeled offensive. Similarly, Larimore et al. (2021) found that white and non-white workers annotate racially sensitive topics differently. Apart from studying the demographic background, researchers also attempt to find groups of annotators with common annotation behavior. Wich et al. (2020) use graph methods to cluster annotators in groups with higher inter-annotator agreement within groups than across groups. Akhtar et al. (2020) defined a polarization measure to split annotators in two groups that maximize opposing annotations. To the best of our knowledge, no one has quantified annotator bias at the annotator level. Furthermore, the hypothesis of multiple perspectives on abusive language is rarely investigated.

3 Datasets

We use four different abusive English language datasets to demonstrate our proposed approach. It was challenging to find appropriate datasets because our experiment requires unaggregated annotation data. Most of the abusive language datasets contain only the agreed upon labels in the documentation and not the individual votes of the annotators.

Table 1 lists the four datasets with additional in-
Figure 1: Box plots of the annotators’ inter-rater reliability scores.

formation. The first three datasets (Vidgen, Guest, and Kurrek) are similar because they are annotated by small groups of annotators (between 6 and 26). Furthermore, each document of the three datasets was annotated by two annotators. In case of disagreement, an expert reviewed the votes and decided on the gold label. In contrast, the Wulczyn dataset was annotated by many crowdworkers—a typical crowdsourcing setup: a group of workers who annotated a small number of documents. Each document was annotated by up to 10 annotators. In case of ambiguous annotations, an expert review did not take place. The gold label was determined based on majority vote. For our experiment, we convert all datasets to a binary task (abusive/neutral) to compare the results.

Figure 1 shows the distributions of the annotators’ inter-rater reliability scores in form of Krippendorff’s alpha. The colored dots represent the overall inter-rater reliability score of each dataset. We see that the overall Krippendorff’s alphas are all in the same range. The Wulczyn dataset was annotated by many crowdworkers—a typical crowdsourcing setup: a group of workers who annotated a small number of documents. Each document was annotated by up to 10 annotators. In case of ambiguous annotations, an expert review did not take place. The gold label was determined based on majority vote. For our experiment, we convert all datasets to a binary task (abusive/neutral) to compare the results.

4 Methodology

Our analysis of the annotator bias in the selected abusive language datasets consists of two parts. In the first part, we characterize the annotation behavior based on the deviations of the annotator votes compared with the gold standard of the dataset. In the second part, we visualize the perspectives of different annotator groups on abusive language with the aid of classification models.

4.1 Characterizing Annotator Bias

We define annotator bias as the deviations between the annotator votes and the gold labels of the dataset. The gold labels are either the final labels of the dataset or majority of the single votes. To measure the annotator bias, we use the concept of the confusion matrix. Figure 2 shows a matrix for a binary classification task of abusive documents (neutral/abusive). The rows represent the classes of the gold labels; the columns represent the classes observed by the annotator. The bias matrix quantifies the deviations between the labels observed by the annotator and the gold labels. Each annotator has one bias matrix.

We use cells II and III, which represent false negatives (type II error) and false positives (type I error) in the classical confusion matrix, to characterize the annotators’ behavior, and we assign each annotator a pessimistic and optimistic score. Cell II reflects the number of documents that are neutral according to the gold standard but that are annotated as abusive by the annotator, signaling that the annotator is pessimistic in these cases. Cell III is the opposite, and shows the number of documents that are labeled as abusive according to the gold standard but perceived as neutral by the annotator, signaling that the annotator is optimistic in these cases. The pessimistic ($p_i$) and optimistic ($o_i$) scores of an annotator ($i$) are entries II and III of row-normalized bias matrix. The concept of annotator’s optimism and pessimism was proposed by Dawid and Skene (1979). This method also works if we have more than two classes as long as they are ordinal. In this case, the cells above or below the diagonal are summed up. In our paper, however, we consider only binary classification of tasks.

To analyze bias matrices, we utilize these options:
1. We calculate the bias matrix for a group of annotators or all of them by averaging the bias matrices. The resulting bias matrix delineates whether the selected annotators tend to be optimistic or pessimistic. These findings assist with adjustment of annotation guidelines or the training of the annotators.

2. We utilize a 2-dimensional scatter plot of the pessimistic and optimistic scores to visualize the annotators and their biases. In contrast to comparison of inter-rater reliability scores, this visualization reveals whether annotators are more optimistic or pessimistic than the gold standard. Such information can help to detect outliers in the respective direction and to instruct the identified annotators as appropriate.

3. We can calculate a distance between two annotators based on their bias matrices ($A$ and $B$) with the Frobenius norm (Golub and Van Loan, 2013, p.71):

$$
\text{distance}(A, B) = \sqrt{\sum_{i=1}^{n} \sum_{j=1}^{n} (a_{ij} - b_{ij})^2}
$$

Visualizing these distances with a hierarchically clustered heatmap helps identify annotator groups with similar annotation behavior and outliers.

4. If the number of annotators is so large that the results of the previously proposed methods is no longer manageable, we can apply a hierarchical clustering on the bias matrices based on our distance metric. By doing so, annotators with a similar annotation behavior are clustered. If we aggregate the bias matrices according to (1), we observe how the cluster annotated the data in context of the gold standard.

5. If we have additional information about the annotators to characterize them (e.g., demographics, such as age or education), we can use the pessimistic and optimistic scores to test whether there is a significant difference between the annotation behavior of annotators with different characteristics. For this purpose, we apply the two-dimensional Kolmogorov-Smirnov (KS2D) test (Fasano and Franceschini, 1987; Peacock, 1983) to compare the distributions of the groups’ pessimistic and optimistic scores. The output of the test is the Kolmogorov-Smirnov statistic $D$ and the corresponding significance level $s$. If $D$ is larger than the predefined significance level $p$ and $p$ is larger than $s$, we can reject the null hypothesis that both samples have the same distribution. We use the Python implementation provided by Gabriel Taillon\textsuperscript{1}. In the case of the Wulczyn dataset, we have such information (Wulczyn et al., 2017). Our predefined significance level $p$ is 0.05.

4.2 Identifying Different Perspectives on Abusive Language

The previous subsection focuses on methods to measure and visualize annotator bias, answering RQ1. The underlying assumption is that there is one truth, meaning one valid perspective on abusive language, and we want to identify outliers deviating from the one truth.

Now we assume that there are more perspectives on abusive language—e.g., a group has a more liberal attitude toward abusive texts, while another group is less liberal. To examine this hypothesis, we run the following experiment. First, we split the annotators into different groups based on the pessimistic and optimistic scores. Second, for each group we create a dataset, containing the documents that all groups annotated. The labels of the documents result from the majority vote of the groups’ annotators. Third, for each group we train a classification model on its training set and evaluate it on the test sets of all groups. Suppose a classifier performs well on its test set and worse on the other test sets. Thus, the performance is comparable to a baseline classifier trained on the same data with gold labels. In that case, it indicates that this group has a coherent perspective on abusive language that differs from the other groups. This approach is based on the method proposed by Wich et al. (2020).

To split the annotators according to their pessimistic ($p_i$) and optimistic $o_i$ scores, we apply the following function:

$$
\text{group}_i(p_i, o_i) = \begin{cases} 
0 & \text{if } p_i \geq 3 \cdot o_i \\
1 & \text{if } o_i \geq 3 \cdot p_i \\
2 & \text{otherwise} 
\end{cases}
$$

The factor 3 in the function is the result of a trade-off between having a dominating dimension

---

\textsuperscript{1}https://github.com/Gabinou/2DKS
in the optimistic and pessimistic group and having enough annotators in all three groups. Increasing the factor would strengthen the dominating dimensions but reduce the number of annotators in the optimistic and pessimistic groups. Decreasing the factor would weaken the dominating dimension but increase the number of annotators in the groups.

For the classification model, we use the pre-trained English DistilBERT model 

\texttt{distilbert-base-uncased} provided by the Transformer Library from Hugging Face (Wolf et al., 2020); it is a more concise version of BERT (Sanh et al., 2019; Devlin et al., 2019) and provides a performance comparable to BERT for abusive language detection (Devlin et al., 2019).

We train each model for three epochs with a learning rate of $5 \cdot 10^{-5}$ and a batch size of 32. After the three epochs, we select the model with the lowest validation loss. 60% of the documents annotated by all groups are used as a training set, 20% as a validation set, and 20% as a test set. To compare the different classifiers, we use the macro F1 score.

5 Results

5.1 Characterizing Annotator Bias

Aggregated Bias Matrix

The problem of the inter-rater reliability analysis is that it does not reveal whether the annotators annotated more pessimistically or optimistically. This gap is addressed by the aggregated bias matrices, shown in Figure 3. The annotators of the datasets Vidgen, Guest, and Wulczyn tended to annotate more liberally because the optimistic scores (bottom-left cell) outweigh the pessimistic scores (upper-right cell). On the contrary, the annotators of the Kurrek dataset were stricter because 16% of non-derogatory documents were labeled as derogatory (pessimistic score), while only 4.5% (optimistic score) of the derogatory documents were labeled as non-derogatory.

Scatter Plot of Annotators

To gain a better understanding of the individual annotation behavior, we analyze the annotators based on their pessimistic and optimistic scores, shown in Figure 4. Considering the plots of Vidgen, Guest, and Kurrek, we observe that the annotators of Vidgen and Guest annotated more liberally due to the higher optimistic scores, while it is the opposite for the Kurrek dataset. Comparing the Guest dataset with the other two, we see that the annotators are less widely spread, meaning the annotation behavior is more coherent. Concerning the previously mentioned outliers of Vidgen and Kurrek, we can use the plots to better understand how they deviate. The outlier of Vidgen is the most right data point, the outlier of Kurrek is the uppermost data point. Their positions reveal that the outlier of Vidgen annotated more liberally, while the outlier of Kurrek was stricter. These findings can help instructors to guide the annotators if the method is used during the annotation process. A further observation concerning both datasets is that the density of annotators increases toward the origin of both dimensions. This indicates that most of the annotators have a similar annotation behavior.

In the case of the Wulczyn dataset, plotting each annotator as a data point would be confusing because the dataset contains 4,053 annotators. Therefore, we decided to cluster the annotators with a hierarchical clustering approach, facilitating data interpretation. We chose the agglomerative clustering approach with $k = 30$ and Euclidean distance function. The reason for $k = 30$ is that it is a manageable amount of data points on the scatter plot and it has the same order of magnitude as Vidgen and Kurrek. Figure 4d shows the annotators’ clusters. We observe the tendency of the annotators to annotate more liberally, as shown by the aggregated bias matrix in Figure 3d.
Figure 4: Annotators visualized based on their pessimistic and optimistic scores; in case of Wulczyn, annotators are hierarchically clustered.

**Cluster Map of Distances between Annotators**

A method to identify groups of annotators with similar annotation behavior is the hierarchically clustered heatmap based on the distances between the bias matrices of the annotators. Figure 5 shows the cluster map of the Kurrek dataset. The first thing that catches the reader’s eye is the first column and row. It shows the outlier of the dataset. Furthermore, we observe that the annotators Ann7, Ann13, Ann15, Ann3, and Ann5 (last five columns and rows) form a group. In Figure 4c, these annotators are the points above a pessimistic score of 0.2 and below 0.6. The other 15 annotators exhibit a more coherent annotation behavior. Due to the page restriction, we do not include the analysis for the other three datasets.

**Different Annotation Behavior of Demographic Groups**

The Wulczyn dataset contains demographic information for 2,190 of the 4,053 annotators (i.e., gender, age group, education, and English as the first language). We tested for each demographic feature whether there is a difference between the groups regarding the annotators’ pessimistic and optimistic scores. The result of the two-dimensional Kolmogorov-Smirnov test for the demographic feature of gender is the following:

\[
D_{\text{gender}} = 0.092 \quad s_{\text{gender}} = 0.005
\]

Based on this result, we can reject the null hypothesis \((p = 0.05)\). Consequently, there is a significant difference between the pessimistic and optimistic
scores of male and female annotators. Females are more pessimistic than males ($p_{female} = 0.107$ and $p_{male} = 0.090$), while the optimistic scores are comparable ($o_{female} = 0.192$ and $o_{male} = 0.199$). For the feature describing whether English is the first language of the annotator or not, we can also reject the null hypothesis:

$$D_{1st\ language} = 0.192 \quad s_{1st\ language} = 8.9 \times 10^{-8}$$

Native English speakers have a larger pessimistic score ($p_{native} = 0.093$ and $p_{non-native} = 0.117$) and a lower optimistic score than non-native speakers ($o_{native} = 0.160$ and $o_{non-native} = 0.204$).

Table 3a shows the output of the two-dimensional Kolmogorov-Smirnov test for the different age groups. We observe that there are significant differences in the distributions of the annotators’ pessimistic and optimistic scores between the age groups—except between the ages 30-45 and over 60 and 45-60 and over 60. Interestingly, the largest difference is between the age groups 18-30 and 45-60. While annotators between 45 and 60 are more pessimistic ($p_{45-60} = 0.146$ and $o_{45-60} = 0.128$), it is the opposite for annotators between 18 and 30 ($p_{18-30} = 0.08518$ and $o_{18-30} = 0.234$).

Table 3b shows the output for the different educational backgrounds. In contrast to the age groups, the scores of the annotators do not differ greatly between the groups; however, the difference between annotators who have a Bachelors and Masters degree is significant.

5.2 Identifying Different Perspectives on Abusive Language

Since this experiment requires a dataset with a large number of documents and annotators, we could conduct it only with the Wulczyn dataset. In the case of the other three datasets, the number of annotators is too small to meaningfully split the annotators into subsets and to have enough documents that were annotated by all subsets.

The results of the experiment to identify different perspectives and to answer RQ2 can be found in Table 2. It shows the different F1 scores for the abusive class of the classifiers that were trained on subsets of annotators (rows) and were evaluated on the test sets of these subgroups (columns).

<table>
<thead>
<tr>
<th></th>
<th>Pessimistic</th>

<tr>
<td>Optimistic</td>
<td>64.3</td>
<td>74.4</td>
<td>87.5</td>
</tr>
</tbody>
</table>

Table 2: F1 scores from classifiers of the different annotator subsets.

To answer our RQ2 on how to identify and visualize different perspectives on abusive language of the annotators, we need to focus on the pessimistic and optimistic data. We observe that the classifier trained on the annotations of the optimistic annotators performs best on its own test set (87.5%) and worst on the pessimistic test set (64.5%). When the classifier trained on the more pessimistic annotations, the result is the opposite. It performs most poorly on the optimistic test set (71.0%) and comparable well on its own test set (80.2%). Only on the test set of the medium group, the pessimistic classifier performs slightly better.

It is more relevant to our research question that the pessimistic and optimistic classifiers work well on their own test set but worse on the test set of the other extreme. The first fact indicates that the annotations are coherent, so that the classifier can learn patterns to identify abusive language. The second aspect shows that the labels of the pessimistic and optimistic subgroups’ dataset are so different that it can cause a difference of 9.2 or 23.2pp in the F1 score. Consequently, we conclude that the annotators of the pessimistic and optimistic subgroup have two different perspectives on abusive language.

An explanation for the more coherent results of the optimistic classifier can be the larger number

</table>

of annotators. While it comprises annotations from 1,708 annotators, the pessimistic subset contains only 1,312. As we can see, this difference is in line with the finding that the annotators of the Wulczyn dataset tended to annotate more liberally.

6 Discussion

The first part of our study addressing RQ1 shows that the proposed approach based on the pessimistic and optimistic scores helps to measure and visualize the difference in the annotation behavior of annotators. In contrast to the inter-rater reliability, our method reveals information about the tendency of the annotators: Did they annotate more liberally or stricter than the group average? These findings can be used to understand outliers better, instruct single annotators in the right direction to align them with the rest of the group and/or adapt the annotation guidelines. Our approach comprises a range of methods, from an aggregated perspective on all annotations to cluster analyses to evaluations of individual annotators. This variety allows handling of datasets with different numbers of annotators.

The proposed approach is unsupervised by itself because it does not require any labeled data. But it can be combined with additional data, as shown by the experiment with the demographic features. We showed that it can help to detect annotator bias caused by different demographic backgrounds. Our results are partially in line with the findings from Al Kuwatly et al. (2020), who examined the same dataset but with a different approach. We confirmed the differences between native and non-native speakers and between the age groups. In our case, we identified a significant difference between male and female annotators, which Al Kuwatly et al. (2020) did not find. In contrast to our experiment, they observed a greater difference between educational backgrounds. The reason for the discrepancy can be the different methods. They trained classifiers on different subsets and compared their performances, as we did for the second part of our study. Furthermore, they had to group the educational backgrounds to have enough data. Consequently, the results can differ. The advantage of our approach over the classifier-based method used by Al Kuwatly et al. (2020) and by Binns et al. (2017) on another dataset is that we do not rely on a classifier as we can use the full dataset.

The underlying assumption for the first part of the study is that there is only one foundational truth whether a text is abusive or not to demonstrate that we all share the same understanding. In the second part of the study, we had the controversial assumption that there are different perspectives on the perception of abusive language. Our goal was to use our proposed method to identify different perspectives and to visualize the differences. By splitting the annotators according to the ratio between the pessimistic and optimistic scores and training different classifiers for these annotators subsets, we showed that there are different perspectives on abusive language. The classifiers of the pessimistic and optimistic annotator subsets per-
form well on their own test set and poorly on the test set of the other subset. That means that the perception of abusive language within each group is coherent, but it differs from the perception of the other subset.

Multiple perspectives on abusive language should be further investigated. Akhtar et al. (2020), for example, showed that balancing different perspectives in the training set can improve the classification performance. We can also imagine building classification models that demonstrate different perspectives; each group would have a customized model based on the groups’ individual values and perceptions.

7 Conclusion
In this paper, we presented a novel approach to measure and visualize annotator bias purely on their annotation behavior. This approach fosters a better understanding of annotation behavior, detecting outliers, and gaining insights on how to adapt annotation guidelines. Furthermore, we showed that there can be different perspectives on abusive language. Using our proposed approach, we can identify these perspectives and examine the differences.

Abstract

We investigate both rule-based and machine learning methods for the task of compound error correction and evaluate their efficiency for North Sámi, a low resource language. The lack of error-free data needed for a neural approach is a challenge to the development of these tools, which is not shared by bigger languages. In order to compensate for that, we used a rule-based grammar checker to remove erroneous sentences and insert compound errors by splitting correct compounds. We describe how we set up the error detection rules, and how we train a bi-RNN based neural network. The precision of the rule-based model tested on a corpus with real errors (81.0%) is slightly better than the neural model (79.4%). The rule-based model is also more flexible with regard to fixing specific errors requested by the user community. However, the neural model has a better recall (98%). The results suggest that an approach that combines the advantages of both models would be desirable in the future. Our tools and data sets are open-source and freely available on GitHub and Zenodo.

1 Introduction

This paper presents our work on automatically correcting compound errors in real world text of North Sámi and exploring both rule-based and neural network methods. We chose this error type as it is the most frequent grammatical error type (after spelling and punctuation errors) and twice as frequent as the second most frequent grammatical error (agreement error). It also regards both spelling and grammar as the error is a space between two words, but its correction requires grammatical context.

A grammar checker is a writer’s tool and particularly relevant to improve writing skills of a minority language in a bilingual context, as is the case for North Sámi. According to UNESCO (Moseley, 2010), North Sámi, spoken in the North of Norway, Sweden and Finland, has around 30,000 speakers. It is a low resource language in a bilingual setting, and language users frequently face bigger challenges to writing proficiency as there is always a competing language. (Outakoski, 2013) Developing a reliable grammar checker with a high precision that at the same time covers a lot of errors has therefore been our main focus. Good precision (i.e. avoiding false alarms) is a priority because users get easily frustrated if a grammar checker gives false alarms and underlines correct sentences.

In this paper we focus on the correction of compound errors. This type of errors is easy to generate artificially in the absence of large amounts of error marked-up text, and we have a good amount of manually marked-up corpus for evaluation for this error type. Compound errors (i.e. one-word compounds that are erroneously written as two words) can be automatically inserted by using a rule-based morphological analyser on the corpus and splitting the word wherever we get a compound analysis. Unlike other error types (like e.g. real word errors) they are easily inserted, and existing compounds are seldom errors. In addition, they are interesting from a linguistic point of view as they are proper (complex) syntactic errors and not just spelling errors and serve as an example for higher level tools.

Two adjacent words can either be syntactically related or erroneous compounds, depending on the syntax. In North Sámi orthography, as in the majority languages spoken in the region (Norwegian, Swedish and Finnish), nouns that form a new concept are usually written together. For example, the North Sámi word boazodoalloguovlu ‘reindeer herding area’ consists of three words boazu ‘reindeer’, doallu ‘industry’ and guovlu ‘area’, and thus it is written together as a single compound. The task of our methods is to correct spellings such as
boazodoallu guovlu into boazodoalloguovlu in case the words have been written separately in error.

We develop both a rule-based and a neural model for the correction of compound errors. The rule-based model (GramDivvun) is based on finite-state technology and Constraint Grammar. The neural model is bi-directional recurrent (BiRNN). While the rule-based model has earlier produced good precision, it did not handle unknown compounds well, which is why we were interested in a neural approach. However, neural models depend on large amounts of ‘clean’ data and synthetic error generation (or alternatively marked-up data). Typical for low-resource languages and also North Sámi, the corpora are not clean and contain a fair amount of a variety of different spelling and grammatical errors (see Antonsen 2013). Therefore, efficiently preparing data as to making it available for neural model training is an important part of this paper. In our case, we make use of the existing rule-based tools to both, generate synthetic error data and clean the original data for training. For evaluation, on the other hand, we use real world error data.

Our free and open-source rule-based tools can be found on GiellaLT GitHub. The training data and the neural models are freely available on Zenodo. We hereby want to promote a wider academic interest in conducting NLP research for the North Sámi.

2 Background

Sámi open source rule-based language tools have a long and successful tradition (nearly 20 years) (Trosterud, 2004; Moshagen, 2011; Antonsen and Trosterud, 2011; Rueter and Hämiläinen, 2020). North Sámi is a low-resource language in terms of available corpus data (32.24M tokens raw data). Although there is a fair amount of data, it contains many real errors and only a small amount is marked up for errors. Applying neural approaches for high-level language tasks to low resource languages is an interesting research question due the various limitations of minority language corpora, versus the existing research in the topic in well-resourced, majority languages and artificially constrained setups (Nekoto et al., 2020). Rules have been used and are in a wide-spread use in the context of endangered Uralic languages. There is recent work on grammar checking for North Sámi (Wiechetek et al., 2019a) and spell checking for Skolt Sámi (Trosterud and Moshagen, 2021). Other rule-based approaches to grammar checking are extensively described in Wiechetek (2017).

Before the era of neural models, it was common to use statistical machine translation (SMT) as a method for grammar error correction (Behera and Bhattacharyya, 2013; Kunchukuttan et al., 2014; Hoang et al., 2016). Many recent papers on grammar checking use bi-directional LSTM models that are trained to tag errors in an input sentence. Such methods have been proposed for Latvian (Deksnis, 2019), English (Rei and Yannakoudakis, 2016) and Chinese (Huang and Wang, 2016). Similar LSTM based approaches have also been applied for error correction (Yuan and Briscoe, 2016; Ge et al., 2019; Jahan et al., 2021). Other recent approaches (Kantor et al., 2019; Omelianchuk et al., 2020) use methods that take advantage of BERT (Devlin et al., 2019) and other data-hungry models. While such rich sentence embeddings can be used for English and a few other languages with a large amount of data, their use is not viable for North Sámi.

3 Data

For evaluation and training the neural model we use the SIKOR (2018) (the Sámi International KORpus), which is a collection of texts in different Sámi languages compiled by UiT The Arctic University of Norway and the Norwegian Sámi Parliament. It consists of two subcorpora: GT-Bound (texts limited by a copyright which are available only by request) and GT-Free (the publicly available texts). As a preprocessing step, we run a rule-based grammar checker (Wiechetek, 2012) and remove sentences with potential compound errors, as we cannot automatically ensure whether these errors are real or not. This is needed as we want this data to be fully free of any compound errors as it serves as the target side of our neural model.

Thereafter, we take in each sentence in this error free data and analyse it by a rule-based morphological analyser. When the analyser sees a potential compound word, it indicates the word boundary with a compound (+Cmp#) tag. We use this information to automatically split all compounds identified by the rule-based analyser. This results in a

5 https://github.com/giellalt/lang-sme
parallel corpus of the original sentences as the prediction target and their corresponding versions with synthetically introduced compound errors. Many of the compound boundaries are ambiguous, and the algorithm decides the one used in training data based on heuristics: maximum number of compound boundaries where the splitting will not cause any other modifications of the word stems or other content.

As an additional data source, we use the North Sámi Universal Dependencies treebank (Tyers and Sheyanova, 2017). We parse the corpus with Uralic-NLP (Hämäläinen, 2019) and split the compounds the rule-based morphological analyser identifies as consisting of two or more words in order to synthetically introduce errors. We also run the rule-based morphological analyser and morpho-syntactic disambiguator to add part-of-speech (POS) information to produce an additional data set with POS tags. For the Universal Dependencies data, we use the POS tags provided in the data set.

We then make sure that all sentences have at least one generated compound error and that the only type of error the sentences have is the compound error (no other changes introduced by the rule-based models). We shuffle this data randomly and split it on a sentence level into 70% training, 15% validation and 15% testing. The size of the data set can be seen in Table 1, the sentences were tokenized based on punctuation marks.

Table 1: Training, testing and validation sizes for the neural model (corpus with synthetic errors)

For the rule-based model GramDivvun we do not generate synthetic errors. We have hand-selected a large corpus for rule development and as regression tests, consisting of representative sentences from GT-Free. The current selection for syntactic compound errors includes 3,291 sentences with real world compound errors (and possibly other errors in addition).

4 Methods

We use a neural models and a rule-based model for compound error correction.

4.1 Neural Model

We model the problem at a character instead of word level in NMT (neural machine translation). The reason for using a character-level model instead of a word-level model is that, this way, the model can work better with out-of-vocabulary words. This is important due to the low-resourced nature of North Sámi, although there are other deep learning methods for endangered languages that do not utilize character level models (Alnajjar, 2021). In practice, we split words into characters separated by white spaces and mark actual spaces between words with an underscore (_). We train the model to predict from text with compound errors into text without compound errors. As previous research (Partanen et al., 2019; Alnajjar et al., 2020) has found that using chunks of words instead of full sentences at a time improves the results in character level models, we will be training different models with different chunk sizes. This means that we will train a model to predict two words at a time, three words at a time, all the way to five words at a time.

We train the models with and without POS tags. For the models with POS tags, we surround each word with a token indicating the beginning and the end of the POS tag. The POS tags are included only on the source side, not on the target side. They are separated from the word with a white space.

An example of the data can be seen in Table 2. Even though every sentence in the training data has a compound error, this does not mean that every input chunk the model sees would have a compound error. This way, the model will also learn to leave the input unchanged if no compound errors are detected.

We train all models using a bi-directional long short-term memory (LSTM) based model (Hochreiter and Schmidhuber, 1997) by using OpenNMT-py (Klein et al., 2017) with the default settings except for the encoder where we use a BiRNN (Schuster and Paliwal, 1997) instead of the default RNN (recurrent neural network), since BiRNN based models have been shown to provide better results in character-level models (Hämäläinen et al., 2019). We use the default of two layers for both the encoder and the decoder and the default attention model, which is the general global attention presented by Luong et al. (2015). The models are trained for the default of 100,000 steps. All models are trained with the same random seed (3,435) to ensure reproducibility.
During the training of the neural models, we evaluate the models using simple sentence level scores. There we look only at full-sentence matches and evaluate their accuracy, precision and recall, as opposed to the evaluations in Section 5, where we study them more carefully at the word-level. The results of the neural models for the generated corpus (where errors were introduced by splitting compounds) can be seen in Table 3. The results indicate that both of the models receiving a chunk of two words at a time reached to the highest accuracy, and the model without the POS tags also reached to the highest precision.

Table 3: Sentence level scores for different neural models tested on a corpus with artificially introduced errors.

The POS tags were not important for the models, as the results with and without them are fairly similar. The largest gain was when the compound error correction was done for three words at a time. As this performance gain only occurred for that specific model, it suggests that it is more of an artefact of the training data and how it is fed into the model than any actual improvement.

### 4.2 Rule-based Model

The rule-based grammar checker GramDivvun is a full-fledged grammar checker fixing spelling errors, (morpho-)syntactic errors (including real word spelling errors\(^6\), inflection errors, and compounding errors) and punctuation and spacing errors.

It takes input from the finite-state transducer (FST) to a number of other modules, the core of which are several Constraint Grammar modules for tokenization disambiguation, morphosyntactic disambiguation and a module for error detection and correction. The full modular structure (Figure 1) is described in Wiechetek (2019b). This work regards predominantly the modification of the disambiguation and error detection modules mwe-dis.cg3, grc-disambiguator.cg3, and grammarchecker-release.cg3. We are using finite-state morphology (Beesley and Karttunen, 2003) to model word formation processes. The technology behind our FSTs is described in Pirinen (2014). Constraint Grammar is a rule-based formalism for writing disambiguation and syntactic annotation grammars (Karlsson, 1990; Karlsson et al., 1995). In our work, we use the free open source implementation VISLCG-3 (Bick and Didriksen, 2015). All components are compiled and built using the GiellaLT infrastructure (Moshagen et al., 2013). The code and data for the model is available for download\(^7\) with specific version tagged for reproducibility.

The syntactic context is specified in hand-written Constraint Grammar rules. The REMOVE-rules below removes the compound error reading (identified by the tag Err/SpaceCmp) if the head is a 3rd person singular verb (cf. 1.2) and the first element of the potential compound is a noun in nominative case (cf. 1.3). The context condition further specifies that there should be a finite verb (VFIN) somewhere in the sentence (cf. 1.4) for the rule to apply:

```
REMOVE (Err/SpaceCmp)
(0/0 (V Sg3))
(0/1 (N Sg Nom))
(+0 VFIN);
```

All possible compounds written apart are considered to be errors by default, unless the lexicon specifies a two or several word compound or a syntactic rule removes the error reading.

\(^6\)Real word errors are spelling errors where the outcome is an actual word that is not fit for the context.

\(^7\)https://github.com/giellalt/lang-sme/releases/tag/naacl-2021-ws
The process of rule writing includes several consecutive steps, and like neural network models they require data. The process is as follows:

1. Modelling an error detection rule based on at least one actual sentence containing the error
2. Adding constraints based on the linguist’s knowledge of possible contexts (remembered data)
3. A corpus search for sentences containing similar forms/errors, testing of the rule and reporting rule mistakes
4. Modification of constraints in the rule based on this data and testing against regression tests so that unfit constraints depending on results for precision and recall (focus on precision)

The basis of rule development is continuous integration. Typical shortcomings and bad errors can be fixed right away with added conditions. Neural models are not usually trained in this way. The frequent experience of false alarms can decrease the users’ trust in the grammar checker. Typically, full-fledged user oriented grammar checkers, e.g. DanProof focus on keeping false alarms low and precision high (Bick, 2015) because users’ experiences have shown that certain experiences will frustrate users and stop them from using the application.

For rule development, regression tests are used. These consist in error-specific YAML tests and are manually marked up. The regression test for compound errors contains 3,291 sentences (1,368 compound errors, used for development and regression) give the results as shown in Table 4.

5 Results

We evaluate the models both quantitatively and qualitatively. We evaluate on accuracy, precision and recall, and do a linguistic evaluation. The measurements are defined in this article as follows: Accuracy \( A = \frac{C}{S} \), where \( C \) is a correct sentence (1:1 string match) and \( S \) is corpus size in sentences, precision \( P = \frac{tp}{tp+fp} \) and recall \( R = \frac{tp}{tp+fn} \), where \( tp \) is true positive, \( fp \) is false positive and \( fn \) is false negative. The \( F₁ \) score is the harmonic mean of precision and recall \( F₁ = \frac{2 \times P \times R}{P+R} \). The accuracy is thus sentence level correctness rate—as used in the method section to probe model qualities—whereas precision measures how often corrections were right and recall measures how many errors we found. The word-level errors are counted once per error in the marked-up corpus. Thus, if a three-part compound contains two compounding errors it is counted towards the total as one error, but if a sentence has three separate compounds with wrong splits each, we count three errors.
The error marked-up corpus we used includes 140 syntactic compound errors (there are other compound errors that can be discovered by the spellchecker as they are word internal) and is from GT-Bound. We chose GT-Bound to make sure that the sentences had not been used to develop rules. It is part of our error-marked up corpus, which makes it possible to run an automatic analysis. This error corpus does only contain real world (as opposed to synthetic) errors.

Table 5: Sentence level scores for the neural models tested on a real world error corpus

Table 5 shows the results for the neural models on this corpus. The drop in results is expected as the models were trained on synthetic data, whereas this data consists of real world errors. However, the results stay relatively good, given that synthetic data was the only way to produce enough training data for North Sámi.

We ran the neural and rule-based model on two different corpora of compound error materials, i.e. synthetic and real world. Table 6 shows the evaluation on a real world error corpus.

Table 6: Results for both models based on a manually marked-up evaluation corpus

The neural network performs well in terms of numbers, but has the following shortcomings that are problematic for the end users. It introduces new (types of) errors unrelated to compounding, like changing \(km^2\) randomly either to \(kmy\) or \(km\) kind of unforgivable (because not understandable) for the end user. They introduce compounds like Statoileamiálbmogiid ‘Statoil (national oil company and gasstation) indigenous people’ as in ex. (1). The rule-based grammar checker presupposes that the compound is listed in the lexicon, which is why these corrections can easily be avoided.

1. **Statoil eamiálbmogiid**

   Statoil indigenous.people.ACC.PL
eatnamiid billisteani birra
land.ACC.PL. destruction GEN
about
‘about the destruction of the indigenous peoples’ territories by Statoil’

It also produces untypically long non-sense words like NorggaSámiiRiidRiidRiidRiidRiid

2. **boares eallinoainnuid** ja modearna

   old.life view.ACC.PL and modern
   servodaga váikkuhusaid gaskii.
society. GEN impact.ACC.PL between
   ‘between old philosophies and the impact of modern society’

3. **Dasalassin 137000 njealjehaskilomehtera eatnamat** in.addition 137000 square.kilometre. GEN

   eatnamat bidgejuvvojit seismalas
   land.PL. split.PASS.PL.3 seismic
   linnjáid line.ACC.PL
   ‘In addition, 137,000 square kilometres of land are split by seismic lines’

The rule-based model, on the other hand, typically suggests compounding, where both compounding and two word combinations would be adequate, for example in the case of the first part of the compound having homonymous genitive and a nominative analyses. The suggested compound is not an error. However, the written form is grammatically correct as well. These suggestions still count as false positives. Other typical errors are cases where there are two accepted ways of spelling a compound/MWE as in ex. (4), where both Riddu Riddu and Riddu-Riddu are correct spellings, and the latter one is suggested as a correction of the former one.

4. **ovdanbuktojuvvojit omd. jahkásaš** present.PASS.PRS.PL.3 e.g. annual

   Riddu Riddu festiválas.
   Riddu Riddu festival.PL.
   ‘they are presented at the annual Riddu Riddu festival.

The rule-based model also struggles predominantly
with false negatives, like *njunuš olbmot* ‘leading people’ that are due to missing entries in the lexicon like in ex. (5).

(5) *Sii leat giellda njunuš olbmot.*

They are the leading people of the municipality.

6 Discussion

In the future, we would like to look into hybrid grammar checking of other error types and other (Sámi) languages.

The neural approach gives us relatively high recall in the real world situation with lower precision, whereas the rule-based model is designed to give us high precision even at the cost of lower recall (user experience), which is why hybrid approaches that combine the best of two worlds are interesting.

Noisy data is to be expected in any endangered language context, as the language norms are to a lesser degree internalized. We will therefore need a way of preparing the data to train neural networks, which can either consist in creating synthetic data or automatically fixing errors and creating a parallel corpus.

When creating synthetic data for neural networks, the amount of data is hardly the main issue. Many generative systems are capable of overgenerating data. The main question that arises is the quality and representatives (Hämäläinen and Alnajjar 2019) of the generated data. If the rules used to generate the data are not in line with the real world phenomenon the neural model is meant to solve, we cannot expect very high quality results in real world data.

Generated sentences can easily be less complex ‘text book examples’ that are not representative of real world examples. In the case of agreement errors between subjects and verbs, for example, there are long distance relationships and complex coordinated subjects including personal pronouns that can change the structure of a seemingly straightforward relation. Therefore, we advocate the use of high quality rule-based tools to prepare the data, i.e. fix the errors and create a parallel corpus.

While synthetic error data generation for compound errors is somewhat more straightforward as it only affects adjacent words, the generation of synthetic error corpora for other error types is not as straightforward, in part also because generating synthetic errors of other kind can potentially create valid and grammatically correct sentences with different meanings. We therefore predict that (hybrid) neural network approaches for other error types that either involve specific morphological forms (of which there are many in North Sámi) or changes in word order will be more difficult to resolve.

7 Conclusion

In this paper, we have developed both a neural network and a rule-based grammar checker module for compound errors in North Sámi. We have shown that a neural compound-corrector for a low-resource language can be built based on synthetic error data by introducing the compound errors using a high level rule-based grammar models. It is based on the rule-based tools to both generate errors and clean the data using both part-of-speech analysis, disambiguation and even the error detector.

The rule-based module is embedded in the full-fledged *GramDivvun* grammar checker and achieves a good precision of 81% and a lower recall of 61%. A higher precision, even at the cost of a lower recall, is in line with our objective of keeping false alarms low, so users will be comfortable using our language tools. The neural network achieves a slightly lower precision of 79% and a much higher recall of 98%.

However, the rule-based model has more user-friendly suggestions and some false positives are simply other correct alternatives to the ones in the text, while the neural network’s false positives sometimes introduce new and unrelated errors. On-the-fly fixes that avoid false positives are an advantage of rule-based models. Rule-based models, on the other hand, are not so good at recognizing unknown combinations. Hybrid models that combine the benefits of both approaches are therefore desirable for efficient compound error correction in the future.

Abstract

It has been widely recognized that syntax information can help end-to-end neural machine translation (NMT) systems to achieve better translation. In order to integrate dependency information into Transformer based NMT, existing approaches either exploit words’ local head-dependent relations, ignoring their non-local neighbors carrying important context; or approximate two words’ syntactic relation by their relative distance on the dependency tree, sacrificing exactness. To address these issues, we propose global positional encoding for dependency tree, a new scheme that facilitates syntactic relation modeling between any two words with keeping exactness and without immediate neighbor constraint. Experiment results on NC11 German$\rightarrow$English, English$\rightarrow$German and WMT English$\rightarrow$German datasets show that our approach is more effective than the above two strategies. In addition, our experiments quantitatively show that compared with higher layers, lower layers of the model are more proper places to incorporate syntax information in terms of each layer’s preference to the syntactic pattern and the final performance.

1 Introduction

Over the past few years, end-to-end neural machine translation (NMT) has shown remarkable progress, achieving promising results on various machine translation tasks. Although NMT models can perform well even only trained on parallel corpus, they have been found to still benefit from external linguistic knowledge (e.g., lexical analysis and parsing) (Sennrich and Haddow, 2016), and the same finding was also observed in other tasks (Strubell et al., 2018; Zhang et al., 2019). Therefore, several studies have started to to investigate how to incorporate dependency information into NMT based on Transformer, which is currently the most advanced end-to-end machine translation backbone.

There exist two broad categories of approaches to integrating a sentence’s dependency structure into the Transformer. The first category of approaches (Bugliarello and Okazaki, 2020; Strubell et al., 2018; Bastings et al., 2017) takes the dependency tree as a general graph structure data. A graph neural network or a sublayer with a similar mechanism was introduced at the bottom of the Transformer’s encoder to represent and encode the dependency relations among the words in the sentence. In this paradigm, however, a word focuses only on its immediate neighbors and ignores nodes that are multi-hop away from it, which may carry important context that helps disambiguate and enrich the current word’s representation in terms of syntactic structure.

In contrast, methods from the second category seek to model two words’ syntactic relation relying on their distance from the dependency tree. The distance can be two words’ relative depth on the tree or the length of the path between the two nodes (Wang et al., 2019a; Omote et al., 2019). This strategy can be seen as extended relative position representations (Shaw et al., 2018) where the relative distance is defined based on the tree. The advantage of this strategy is that the syntactic relations between a word and all other words can be modeled, not just those of its immediate neighbors. Nevertheless, this approach is also unsatisfactory because the distance on the dependency tree is a simple proxy for the syntactic relationship between two words and does not represent how a word reaches another word on the dependency tree. Therefore, this type of approach has limitations in expressiveness.

For these considerations, we propose to model the position of the word on the dependency tree in addition to its normal sequential position in the input text. We use the path from the root node to a
word on the dependency tree to represent the global syntactic position of the word. This representation facilitates the modeling of syntactic relations between two words at arbitrary distances while enabling the model to learn more powerful correlation functions by exploiting dependency labels rather than simply relying on the distance of word pairs.

Our main contributions are as follows:

- We propose a new scheme, global positional encoding for syntax (GPS), to integrate the dependency tree into the Transformer’s encoder, enabling efficient word pairs’ syntax correlation modeling (Section 3).
- Experimental results demonstrate that our method outperforms both the Transformer baseline and other two competitive models in terms of BLEU score (Section 4.2).
- We found that when external syntax annotation is combined at lower layers of the encoder, it gives better results and has larger weights; and the weights, which indicate a layer’s reliance on syntactic information, declines rapidly near the output layer of the encoder (Section 4.3).

## 2 Related Work

Previous studies showed that end-to-end NMT models could be further improved by combining source-side or target-side syntax structure into RNN encoder-decoder framework (Aharoni and Goldberg, 2017; Wu et al., 2017; Eriguchi et al., 2016). Since the Transformer has become the de facto standard architecture for NMT, researchers have also begun to explore strategies to incorporate syntax information into Transformer-based NMT.

For phrase structures, Currey and Heafield (2019) used source-side linearized constituency parses to improve Transformer-based NMT by multi-task learning. Ma et al. (2019) used neural syntactic distance (Shen et al., 2018) for constituent parsing as input and output sequence.

For dependency grammar, researchers mainly focused on how to integrate the dependency structure into the Transformer. As mentioned in the introduction, there are two different viewpoints to look upon this problem. The first line of works extended the relative positional encoding (Shaw et al., 2018) defined on sequence to tree structures. Omote et al. (2019) defined the relative distance between two words on the dependency tree in terms of their relative depth. Wang et al. (2019b) used the length of the shortest path between two nodes on the dependency tree as their relative distance, and the depth of each node as their absolute position, in addition to each word’s normal sequential position. Another perspective is to take the dependency tree as a general graph structure, focusing on local connection relations and apply methods from graph neural networks (or use similar mechanisms). Bastings et al. (2017) use a graph-convolutional networks to encode the source syntax structure, and more recently, Bugliarello and Okazaki (2020) directly encode the dependency structure inside the Transformer’s self-attention module, achieving state-of-the-art results.

By contrast, we neither treat the dependency tree as a simple sequential structure extension nor as general graph data. We seek to represent each word’s role on the dependency tree, where the representation is tailored for the dependency grammar’s tree structure, making it sensible to the syntactic connection with other words.

Our work is also inspired by researches on making Transformer sensible to structured input. Shiv and Quirk (2019) proposed a tree-structure positional encoding to make the Transformer sensible to source code’s tree structure in the code processing task. The main idea is to define the path from the root node to a leaf node as the leaf node’s position on the tree. We extend this idea from unlabeled directed trees to labeled trees and break the limitation of the tree depth and the number of child nodes. Moreover, we choose to use a sequence encoder instead of concatenating sub-vectors to compute the final path embedding, which utilizes the whole vector space and enables more powerful modeling of the interaction between two path embeddings.

## 3 Model

In this section, we first recap the basic Transformer architecture and then describe the proposed global syntactic position encoding mechanism.

### 3.1 Transformer Architecture

Transformer (Vaswani et al., 2017) is an encoder-decoder architecture composed of stacked encoder and decoder layers. Each encoder layer has three main components: residual connections, feed-forward layer, and self-attention. The decoder layer has extra decoder-encoder attention to access the output of the encoder. Among these components,
the self-attention mechanism is the key feature that sets Transformer apart from CNN-based and RNN-based sequence to sequence (seq2seq) models. Self-attention is used for improving a word’s representation by focusing on critical context words that help to enrich and disambiguate it.

Given an input sequence \( x = \{x_0, ..., x_n\} \), self-attention outputs a new sequence \( z = \{z_0, ..., z_n\} \). Each word’s representation in the new sequence are contextualize by a weighted sum over all words in the old sequence.

\[
z_i = \sum_j^n \alpha_{ij} (x_j W^V)
\]  

Each weight, \( \alpha_{ij} \), is normalized by a softmax function:

\[
\alpha_{ij} = \frac{\exp(e_{ij})}{\sum^n_{k=1} \exp(e_{ik})}
\]  

\( e_{ij} \) is computed by the dot product of \( word_i \)’s query vector and \( word_j \)’s key vector

\[
e_{ij} = \frac{(x_i W^Q) (x_j W^K)^T}{\sqrt{d_z}}
\]  

where \( \sqrt{d_z} \), a scale factor, reduces the peak of the attention distribution to alleviate the vanishing gradients problem.

### 3.1.1 Sequential Positional Encoding

Transformer’s self-attention can access information directly from other words no matter how far away they are from the current word, making it easier to model long-range dependencies. However, unlike RNN’s intrinsic order-variant forward process, the self-attention module is computationally insensible to the word order. Thus we need to put the word order information into the representation of the input sequence. In practice, we often simply add the positional embedding and input word embedding together as inputs to the model. Transformer’s default positional embeddings has the following formulation:

\[
PE_{(pos,2i)} = \sin \left( \frac{pos}{10000^{2i/d_{model}}} \right) \\
PE_{(pos,2i+1)} = \cos \left( \frac{pos}{10000^{2i/d_{model}}} \right)
\]  

where \( pos \) is the index of a word in the sequence and \( i \) is the dimension of the positional encoding vector.

### 3.2 Positional Encoding for Dependency Structure

A sentence exists as a sequence of words, but it also has structural organization. Dependency parsing describes a sentence as a labeled directed tree, whose vertices correspond to words, and labeled edge denotes head-dependent relation between words. Besides each word’s sequential position, we would like to represent their positions on the dependency tree to exploit prior linguistic knowledge behind the sentence.

We follow similar steps of encoding position in sequential structure to represent a word’s position on the dependency tree. We need first to index a word and then transform the index into a vector, also called positional embedding, and the computation between two positional embeddings should reflect their relationship on the target structure. For sequential structure, the relation is the distance, and for the dependency tree, the relation is the grammatical relation denoted by how a node reaches another node. Therefore, we can represent
a words’ tree position through the path from the root node to it. Figure 1 showing an example, John can be represented by a sequence of grammatical labels \([\text{root} \rightarrow \text{conj} \rightarrow \text{cc}]\) and school can be represented by \([\text{root} \rightarrow \text{obl}]\).

In this setting, the syntactic relation between two words can be inferred from their position representation on the syntactic tree.

To acquire the final syntactic positional embedding, we only need to vectorize the path. First, we replace all the labels with index from the dependency label vocabulary, then we encode the sequence into a vector, as if we are dealing with a sequence of words. Any neural network that can transform a sequence into a vector fits this job well, and we take LSTM as our syntactic position encoder:

\[ s_i = LSTM(p_i) \]

where \(s_i\) is the syntactic positional embedding for \(x_i\), and \(p_i = \{\text{label}_0, \ldots, \text{label}_n\}\) is the path from root to \(x_i\) on dependency tree.

### 3.3 Combining the Two Positional Embeddings

Once we can represent a word’s position on the dependency tree, the next question is how to enrich a word’s hidden representation by its position on the syntactic tree, in addition to its position in the sequence. Following Transformer’s initial setup to incorporate sequential positional embedding, we may add the syntactic positional embedding into the input word embedding. However, this approach suffers from two drawbacks. First, when summing up heterogeneous embeddings, we are implicitly model correlation between different types of embedding in the self-attention module, which is noticed by Ke et al. (2021). To realize the problem here, we can split the hidden representation of a word \(x_i\) into the word embedding \(w_i\), positional embedding \(p_i\), and syntactic positional embedding \(s_i\), and see how the self-attention computes the attention weight:

\[
\hat{e}_{ij} = \frac{(w_i + s_i + p_j)W^Q}{\sqrt{d_z}} - \frac{(w_j + s_j + p_i)W^K}{\sqrt{d_z}} \tag{4}
\]

After expanding the above equation, we can see that the attention weight of word \(i\) to word \(j\), denoted by \(e_{ij}\), consists of the correlation between heterogeneous embeddings, e.g., the correlation between syntactic positional embedding and sequential positional embedding, which is not reasonable.

More importantly, when a source sequence contains multiple sentences, mixing the syntactic positional embeddings with word embedding allows two words from different sentences to interact with each other syntactically in the self-attention module. However, two words’ syntax annotations are supposed to affect each other only within a sentence.

Therefore, we decouple the syntactic positional embedding and word embedding:

\[
\hat{e}_{ij} = \frac{(x_iW^Q) (x_jW^K)^T}{\sqrt{d_z}} + \frac{(s_iW^Q_s) (s_jW^K_s)^T}{\sqrt{d_z}} \tag{5}
\]

\[
x_i = w_i + p_i \tag{6}
\]

where \(x_i\) is the word representation as in Transformer’s typical setting, and \(s_i\) denotes the syntactic positional embedding of word \(i\). In this manner, we can eliminate the unnecessary correlation between heterogeneous embeddings and avoid undesired syntactic correlation for two words from different sentences by simply mask the second term in equation (5).

### 4 Experiment

#### 4.1 Experimental Setup

**Model and Baselines.** We compare our approach with a strong baseline, Transformer, and other two types of dependency information augmented strategies: (1) Parent scaled self-attention (PASCAL) proposed by Bugliarello and Okazaki (2020), in which a word’s attention distribution is scaled to have larger weight on its head word. (2) Absolute and relative structural position proposed by Wang et al. (2019b), which augment encoder by each word’s depth and word-pair’s relative distance on the dependency tree. We implement our models and reimplement Transformer with structural position (Wang et al., 2019b) based on the Fairseq (Ott et al., 2019) toolkit. We deploy the syntactic positional encoding at the bottom layer for our model and report the performance in the main results section. See section 4.3 for further analysis of this design choice.

**Data.** We use datasets with different sizes and source languages to evaluate the efficiency of our
We can see from Table 2 that in all three syntax-augmented NMT systems, syntax information improves the performance of the baseline model at least 0.5 BLEU points.

On the other hand, although the distance-based approach (Structure Position) can theoretically model the syntactic relationship between any pair of words, it performs slightly inferior (0.1–0.3 BLEU points) than the PASCAL model, which only represents local head-dependent relations; this may be caused by information loss when using distance to approximate the syntactic relation between two words. In contrast, our strategy represents each word’s global position on the syntax tree, facilitating efficient syntax relation modeling between non-local word pairs on the dependency tree. This further leads to consistent improvements over other models.

4.2 Effects of Syntax at Different Layers

Previous researches empirically found that combining the syntax information at the bottom layer of the encoder gives the best result (Strubell et al., 2018; Bugliarello and Okazaki, 2020). In this subsection, we measure how our model’s performance changes over the layer that we choose to combine the syntactic position, and quantify the syntax’s impact on each layer’s self-attention module.

First, we change the layer used to combine the syntactic position and train the model on the NC11 De-En dataset. We present the performance over the selected layer in Table 3. Consistent with previous studies, we observed that combining syntax structure at lower layers gives better results and achieves the best at the bottom layer. However, though the syntactic information brings performance gains no matter at which layer we combine it, these improvements are not complementary. When we combine the syntactic position at all six layers of the encoder, we observe comparable results than only combining it at the first layer of the encoder while accompanied by severe overfitting and much more training time.

In our setting, the syntactic information exerts influence directly on the self-attention distribution. Nevertheless, it remains unclear to what extent the model relies on the supplied syntax information, whose answer would provide us more interpretability and understanding of what is happening inside the model. To figure out this problem, we define the Average Weight of Syntax Logits (AWSL) as a metric to indicates the weight of syntax in the self-attention module. For each sample and attention head, we compute the weight of syntax logits as:

\[
w = \frac{1}{N^2} \sum_i \sum_j |e_{ij}| + |e_{ij}^s|
\]

where \(N\) is the number of words in the sentence, \(e_{ij}\) and \(e_{ij}^s\) denotes the normal attention weight and the syntax correlation weight of word \(i\) to word \(j\), respectively. We then average the weight \(w\) for each sample and attention head to compute \(AWSL_L\) for layer \(L\), as plotted in Figure 3.

Through the lens of AWSL, we can observe that the model relies on the abstract syntax patterns more at the lower layers. Such reliance becomes gradually smaller as the layer becomes deeper but drops sharply near the output layer.

One possible explanation for the two trends about model performance and feature importance is that combining syntax information at lower layers not only leads to better utilization across all subsequent layers but also reaches a closer match in terms of the abstraction level between the layer and the supplied information. We note that this finding is in line with previous studies on probing the hidden representations of the deep language model (Raganato and Tiedemann, 2018; Tenney et al., 2019; Vig and Belinkov, 2019), which found that the model tends to encode more syntactic features in lower layers while more complex semantic features in higher layers.

Table 4: We can see through the two cases that the baseline model generates syntactically incorrect translation due to the misunderstanding of the source sentence’s syntactic structure, and the supplied syntax structure helps it achieve more faithful translation.

4.4 Case Study

Table 4 presents several representative cases that indicate how syntactic knowledge helps the model achieve better translation, while linguistically-uninformed baseline makes mistakes. In the first case, the meeting is the object to be rejected. However, the baseline takes meeting as nsubj (nominal subject) of the verb rejected, while our model correctly identified the meeting as the verb’s object. A more complex example is the second case, where the adjective anfällig (means fragile) governs the nominal Neuronen (means neurons). The baseline wrongly and indirectly connects therapy and vulnerable, establishing misleading connection “therapy is made vulnerable”, while our model correctly set up the second-order relation between neurons and vulnerable: “make neurons vulnerable”.

5 Conclusion and Future Work

In this paper, we propose a global position encoding scheme for the dependency tree. We leverage the dependency labels and represent each word’s syntactic role on the dependency tree using the path, which enables efficient syntactic correlation modeling between any pair of words in a single layer. In the experiment, we show that our model outperforms other syntax augmentation strategies. In addition, we quantitatively analyze the model’s reliance on syntax information and show that the model pay more weight and achieves better performance when we combine syntax information at lower layers.

For future works, the following problems are worth noting:

1. Since it is commonly known that off-the-shelf parser’s performance may drop dramatically when facing out-of-domain data, it is important to assess the parser’s accuracy on different machine translation benchmarks and evaluate those syntax augmented NMT systems’ tolerance of parsing errors.

2. Previous works have shown that human-
designed patterns are not the only option to establish dependency relations among words; trees induced from the Pre-trained Language Models also exhibit promising results in downstream applications (Wu et al., 2020; Dai et al., 2021). The induced tree is an attractive solution, especially when considering the expensive annotation and domain adaption problem for supervised dependency parser. Therefore, it is desirable to compare the performance of model using trees produced by the supervised parser and trees induced from the Pre-trained Language Models.

Abstract
Contemporary tobacco-related studies are mostly concerned with a single social media platform while missing out on a broader audience. Moreover, they are heavily reliant on labeled datasets, which are expensive to make. In this work, we explore sentiment and product identification on tobacco-related text from two social media platforms. We release SentiSmoke-Twitter and SentiSmoke-Reddit datasets, along with a comprehensive annotation schema for identifying tobacco products’ sentiment. We then perform benchmarking text classification experiments using state-of-the-art models, including BERT, RoBERTa, and DistilBERT. Our experiments show F1 scores as high as 0.72 for sentiment identification in the Twitter dataset, 0.46 for sentiment identification, and 0.57 for product identification using semi-supervised learning for Reddit.

1 Introduction
Smoking tobacco causes more than 8 million deaths each year1. While cigarette smoking has fallen globally, e-cigarettes remain the commonly used tobacco product among the US youth2.

So far, 2,807 cases and 68 deaths have been recorded due to e-cigarette use-associated lung injury in the US2 alone. These developments prompted the US government to enforce a countrywide ban on addictive flavors and sales to minors. As smokers are more likely to develop severe COVID-19 symptoms, WHO has introduced the world’s first digital health worker Florence based on AI to fill the gap between overburdened medical system users who are trying to quit3. Health-related discourses on social media have risen substantially over the years (Tamersoy et al., 2015) since social media provides an opportunity to informally express opinions freely with like-minded individuals across geographical and societal barriers.

Twitter boasts of 330 million active monthly users who send out half a billion tweets daily4 while Reddit has 430 million monthly users and has 100k+ communities 5. Reddit provides expendable and pseudo-anonymous accounts that are well suited for controversial discussions, including the perception of electronic cigarettes and marijuana, which might be inappropriate to discuss on non-anonymous forums (Park and Conway, 2018).

In Salathé and Khandelwal (2011), we see that information flows more often between users who share the same sentiments. Studying trends of first-person accounts of experience and sentiment towards different tobacco products in these forums becomes imperative in the ongoing bio-surveillance and regulatory efforts (Kim et al., 2015; Pant et al., 2019). Real-time monitoring of public sentiment and informativeness gives us an opportunity for bottom-up discovery of emergent patterns, especially in vulnerable and ethnically diverse populations that may not be readily detectable by traditional methods (Myslín et al., 2013; Lienemann et al., 2017). Although Yanamandra et al. (2020) identified tobacco products on Twitter, they leave a gap in identifying the products’ sentiment.

This work explores tobacco products’ identification and their sentiments in texts extracted from two commonly-used social media platforms. We release two datasets for multiclass classification annotated with tobacco products and their sentiment: SentiSmoke-Twitter and SentiSmoke-Reddit. 6 We

Further benchmark state-of-the-art text classification models for the supervised and semi-supervised learning tasks of identifying product and sentiment in Twitter and Reddit. To the best of our knowledge, this is the first cross-platform semi-supervised attempt in tobacco research.

## 2 Related Work

There has been considerable work in the field of health and social media. While Salathé and Kandelwal (2011) explored Spatio-temporal sentiment towards the new influenza vaccine in Twitter, Cole et al. (2016) studied the quality characteristics of information found in online health forums like Reddit, Mumsnet, and Patient covering HIV, diabetes, and chickenpox. Moreover, Park and Conway (2018) tracked public interest in Ebola, e-cigarettes, influenza, and marijuana on Reddit.

Recent academic works have analyzed tobacco-related trends in multiple social media platforms, including Twitter, Reddit, Instagram, and YouTube (Allem et al., 2019; Carroll et al., 2012; Yanamandra et al., 2020; Zhang et al., 2018). While Allem et al. (2018) explored a thematic analysis of hookah Twitter posts, Allem et al. (2017a) explored e-cigarette trends with an emphasis on social bot behaviour. In Kim et al. (2015), an infouvelle study was performed on e-cigarette tweets on the themes of marketing and usage locations. Moreover, Chen et al. (2015) compared consumer experiences across online discussion forums, including Reddit. They focused on hookah, e-cigarette, and cigarettes using topic modelling and visualization. Sharma et al. (2016) performed a qualitative thematic analysis to determine the limitations and motivations for e-cigarette users with mental illness on Reddit.

The analysis of tobacco sentiment analysis is a relatively less-explored problem. In Allem et al. (2017b), the authors conducted the sentiment analysis of hookah-related tweets using SVM. Moreover, Myslín et al. (2013) performed content and sentiment analysis on tobacco-related tweets using Naive Bayes, KNN, and SVM.

## 3 Dataset

We use the SmokPro (Yanamandra et al., 2020) dataset, which consists of 2,116 tobacco-related tweets classified into the following five distinct product classes: traditional tobacco product mention, modern tobacco product mention, general mention of smoking, narcotics & other drug mentions, and ambivalent mentions. The authors consider cigarette, hookah, pipe, cigar, bidis, cigarillo, shisha, and baccy as traditional tobacco products. Moreover, they consider e-cigarette, e-juice, e-hookahs, e-liquid, mods, vape pens, vapes, tank systems, and electronic nicotine delivery systems (ENDS) as modern tobacco products.

![Table 2: List of subreddits used to scrape data for SentiSmoke-Reddit.](image)

Table 3 illustrates the schema used to determine each product’s sentiment. Our guidelines are centered around the type of tobacco product based on the content. We have also considered street terms and colloquial slangs associated with tobacco product usage. We compile a list of 20 subreddits to scrape data that contained tobacco-related content. They include both information and cessation platforms and are listed in Table 2.

Using PRAW\(^7\), we scrape a sample of Reddit posts made in the last year. We use Reddit’s Top filter and only consider posts with more than 10 upvotes to reduce spam and fewer interacted-with posts. While Twitter’s character limit is 280, Reddit’s maximum character limits for the title and the body are 300 and 40,000 characters, respectively. To avoid cross-platform discrepancies, we only consider the post’s title for this task due to its

\(^7\)https://github.com/praw-dev/praw
similar character length compared with the tweets. Moreover, the effect of title in a Reddit post has been previously studied by Horne and Adali (2017). The scraped dataset consists of 10,023 titles.

We divide the dataset into three splits: training, consisting of 9,023 titles, val, consisting of 100 titles, test, consisting of 900 titles. Since we utilize semi-supervised learning for this task, we only annotate the val and test splits to determine the quality of the learning process. We annotate product labels using the SmokPro’s product annotation schema. We then use the aforementioned sentiment schema (Table 3) for annotating sentiment labels. The annotation process was done by two human annotators having a fluent English background. To assess the annotation standard, we calculate the Inter-Annotator Agreement (IAA) using Cohen’s Kappa coefficient (Fleiss and Cohen, 1973). We obtain Kappa Scores of 0.896 for sentiment annotation for the SentiSmoke-Twitter dataset and 0.840, and 0.927 for sentiment and product identification for the SentiSmoke-Reddit dataset, respectively. These indicate the high quality of all three annotation processes.

4 Methodology

This section briefly describes the methodology used for our benchmarking experiments and details the semi-supervised text classification for the Reddit-based dataset.

4.1 Models Used

4.1.1 FastText

FastText (Joulin et al., 2016) is an open-source, free, lightweight NLP library. It maintains a memory-efficient mapping of n-grams and shares information across classes through a hidden representation. FastText uses a hashtable for the word and character n-grams, with the hashtable size directly impacting the size of a model. This library’s accuracy has been found on par with deep neural networks while requiring a fractional amount of training time.

4.1.2 BERT

BERT (Devlin et al., 2019) is a contextualized language representation model based on bidirectional transformers. It uses novel pre-training objectives like masked-language modelling and next-sentence prediction, which enhance the modelling of a relationship between two sentences. In masked-language modelling, the model randomly masks a random subset of the input tokens, and the objective is to predict the correct tokens based purely on context. On the other hand, the next-sentence prediction simultaneously pre-trains text-pair representations. These features help BERT outperform previous state-of-the-art techniques by a large margin. It uses word-piece tokenization and embeddings, which splits parts of words to get better word information and decreases overall vocabulary.
size effectively. We benchmark *cased BERT\textsubscript{Base} and *cased BERT\textsubscript{Large}, and fine-tune them for our classification experiments.

### 4.1.3 RoBERTa
RoBERTa (Liu et al., 2019) is a BERT-based model with improved training methods, larger training data size, and higher computational power. It is trained on ten times the training data as BERT. RoBERTa has been used in multiple online NLP studies published in the last few years in areas including disclosure modelling (Dadu et al., 2020).

In the improved training methodology, dynamic masking replaces BERT’s next-sentence prediction. In dynamic masking, masked tokens change in between epochs. RoBERTa uses larger byte-pair encoding (BPE) vocabulary compared to BERT. These changes led RoBERTa to outperform BERT on GLUE benchmarks. We use the large variant of RoBERTa, RoBERTa\textsubscript{Large}, and fine-tune it for our experiments.

### 4.1.4 DistilBERT
DistilBERT is another BERT-based model utilizing knowledge distillation leading to a much smaller and faster model. It uses 40% less parameters than *Uncased BERT\textsubscript{Base}, runs 60% faster and preserves 95% of *Uncased BERT\textsubscript{Base}’s performance measured on GLUE benchmark. Distilled models have been previously used in downstream tasks with a good predictive performance including subjective bias detection (Pant et al., 2020). We fine-tune the pre-trained *cased base variant of the model for our experiments.

### 4.2 Transfer Learning
We exploit pseudo-labelling to use the unannotated data scraped from Reddit to enhance the process of cross-platform transfer from Twitter to Reddit. For this task, we utilize the predictions from the best-performing model for each subtask. We then use the pseudo-labelled corpus and splits of the original Twitter-based datasets to predict labels for the Reddit evaluation split. This semi-supervised learning methodology is used to exploit the learnings from both Reddit and Twitter.

### 5 Experiments
In this section, we describe the text classification experiments performed using both supervised and semi-supervised learning. We also highlight the experimental settings along with the experimental results for each of the three experiments.

We conduct three experiments with the aforementioned datasets:
Sentiment Identification in Twitter is a supervised experiment that entails predicting the text’s sentiment in the manually annotated SentiSmoke-Twitter dataset.

Product Identification in Reddit is a semi-supervised experiment that entails predicting the tobacco product of the text in the SentiSmoke Reddit dataset. We use the cased variant of BERT<sub>Large</sub>, which had the highest predictive performance in the Twitter dataset (Yanamandra et al., 2020), to pseudo-label the dataset as described in Subsection 4.2.

Sentiment Identification in Reddit is another semi-supervised experiment that entails predicting the sentiment of the text in the SentiSmoke-Reddit dataset. We use RoBERT<sub>Large</sub> to pseudo-label the dataset since it performed the best on Twitter.

We evaluate all the models on the following metrics: F1, Precision, Recall, and Accuracy. Moreover, for FastText, we use its automatic hyperparameter optimization functionality and validate it for 100 validation trials. For all BERT-based models and their distilled variants, we use a learning rate of $1 \times 10^{-5}$ with a weight decay of 0.01, and an `adam epsilon` value of $1 \times 10^{-8}$ while fine-tuning the models. We use a maximum sequence length of 100 and fine-tune the models for 2 epochs.

5.1 Results

We observe that RoBERT<sub>Large</sub> outperforms all other models for all metrics for all the three experiments. From Table 4, we see that it obtains a high F1 score of 0.724 for the Sentiment Identification in Twitter (Supervised) task.

As illustrated in Table 5, experimental results show that RoBERT<sub>Large</sub> again outperformed all other models for all metrics getting an F1 score of 0.573 for the Product Identification in Reddit (Semi-Supervised) task. For the Sentiment Identification in Reddit task, we see that RoBERT<sub>Large</sub> outperformed all other models in F1 and Precision, scoring 0.456 and 0.551 on both metrics, respectively. On the other hand, Cased BERT<sub>Large</sub> obtains the highest Accuracy of 49.00% and Recall of 0.490. The performance of the models in the semi-supervised domain shows that the inductive transfer from Twitter to Reddit setting was effective for the tobacco-product-identification and sentiment-identification task.

For all three experiments, we infer that DistilBERT performs competitively with the large variant of its undistilled counterpart while taking the significantly lower time and computation power for the process of pre-training and fine-tuning.

6 Discussion

In the year 2016 alone, an estimated 10.5 million US youth were exposed to e-cigarette advertise-
ments through the internet. CDC and FDA also discourages e-cigarette-related purchases through informal sources like friends or online market-places and forums. Reddit was one of these online forums aforementioned where sales of tobacco products like e-cigarettes happened until the recent policy update prohibiting the sale of controlled substances like guns and drugs. Therefore, we find it necessary to understand tobacco-related discussions and public sentiment to help shape better policies aimed at bio-surveillance and tobacco control measures.

Previous research (Benson et al., 2020; Pant et al., 2019) in sentiment analysis, and topical tobacco research is heavily reliant on manually annotated datasets. These pose several challenges: expensive to make, limited in scope, difficult to modify, and harder to scale. Additionally, previous research in this sphere is mostly concentrated only on a single social media platform. Both Reddit and Twitter have similar user demographics and a comparable number of monthly active users with a vibrant discourse on health-related issues. Our cross-platform supervised learning approach helps solve data scarcity and scalability while leveraging insights and context from one platform to another. We can see similarities of frequently used words like smoking, vaping, weed, cigar in word clouds generated for SentiSmoke-Twitter in Figure 2 and SentiSmoke-Reddit in Figure 3.

Moreover, extracting data from moderated topic subreddits directly instead of general keyword search used in previous studies (Park and Conway, 2017, 2018) helps us access targeted tobacco-related discourse while weeding out spam and un-

We also perform a part-of-speech-based analysis for comparing between the SentiSmoke-Twitter and SentiSmoke-Reddit, illustrated in Table 6. We have used spaCy for this task. We note a high degree of similarity between the two datasets in terms of part-of-speech.

7 Conclusion and Future Works

This work explored sentiment and product identification on tobacco-related text from two social media platforms: Twitter and Reddit. We released two datasets for multiclass classification annotated across two axes: tobacco product and sentiment. We utilized semi-supervised learning on Reddit text using manually annotated text for Twitter. We then perform benchmarking experiments for sentiment and product identification in Reddit and Twitter using commonly used text classification models like FastText, BERT, RoBERTa, and DistilBERT. We obtain F1 scores as high as 0.72 for supervised sentiment identification in Twitter text, using manually annotated data. Our semi-supervised experiments on product and sentiment identification in Reddit text, using features learned from the Twitter text, obtain the F1 scores of 0.57 and 0.46, respectively.

Future work may involve using the predicted information in recommender systems, expanding the tasks for other social media platforms, and exploring the use of metadata-derived information and comments for the task. Our study can also be extended to real-time monitoring and bio-surveillance tools for social media, which takes continuous inflow of unseen data.

Improving Evidence Retrieval with Claim-Evidence Entailment

Abstract
Claim verification is challenging because it requires first to find textual evidence and then apply claim-evidence entailment to verify a claim. Previous works evaluate the entailment step based on the retrieved evidence, whereas we hypothesize that the entailment prediction can provide useful signals for evidence retrieval, in the sense that if a sentence supports or refutes a claim, the sentence must be relevant. We propose a novel model that uses the entailment score to express the relevancy. Our experiments verify that leveraging entailment prediction improves ranking multiple pieces of evidence.

1 Introduction
Claim verification verifies the credibility of a textual claim by inferring relevant and reliable textual evidence. An example in this space is FEVER, which regards Wiki pages as potential evidence and creates claims by crowdsourcing (Thorne et al., 2018). They propose a three-step pipeline: (i) document-level evidence retrieval; (ii) sentence-level evidence retrieval; (iii) claim-evidence entailment. Some works follow the pipeline and propose new models to improve claim verification (Yoneda et al., 2018; Nie et al., 2019; Hanselowski et al., 2018; Zhou et al., 2019), while other works combine the second and the third step and leverage all possible sentences for claim verification (Yin and Roth, 2018; Ma et al., 2019). We refer to the former as the pipeline framework and the latter as the multi-task framework.

The pipeline framework restricts a few sentences, and therefore it may not cover relevant evidence. The multi-task framework includes all possible sentences, where irrelevant ones may bring overwhelming noise and hurt claim verification. We argue that previous works focus on improving individual components but neglect to examine how those components connect. For example, will the entailment improve the retrieval?

We hypothesize that claim-evidence entailment can provide useful signals for evidence retrieval: if a sentence supports or refutes a claim, the sentence must be relevant. As in Table 1, the first candidate (actual evidence) shares more words and longer phrases than the other candidates. In contrast, the other two candidates may be relevant to the claim to some extent: the second sentence mentions Roddick and masters series and the third sentence mentions masters series and 2002. Thus, we propose a novel method to link the entailment prediction to the relevance score. Our method predicts the entailment for all retrieved candidates and utilizes the entailment score to express the relevancy.

To our knowledge, this is the first work that

Table 1: The entailment result can imply whether the candidate is relevant or not.

<table>

The paper was done before the author joined Amazon.com Inc.
uses the entailment prediction to measure relevancy. Our experiment demonstrates that a reliable entailment prediction improves evidence retrieval. This is beyond previous works that merely share low-level text encoder and train the two steps together.

2 Method

We adopt two base models, the Decomposable Attention (DA) model (Parikh et al., 2016) and the Enhanced Sequential Inference (ESI) model (Chen et al., 2017a), to encode claim-evidence pairs. Both models are designed for textual entailment (Dagan et al., 2005; Bowman et al., 2015; Parikh et al., 2016; Williams et al., 2018). Although there are more methods in the area of textual entailment (Sha et al., 2016; Chen et al., 2017b; Conneau et al., 2017; Nie et al., 2019; Munkhdalai and Yu, 2017; Tay et al., 2018; Ghaeini et al., 2018), we prefer the DA model and the ESI model because they have been widely applied for sentence retrieval and claim-evidence entailment (Thorne et al., 2018; Hanelowski et al., 2018; Nie et al., 2019; Yoneda et al., 2018).

2.1 Claim Verification Pipeline

We follow the three-step pipeline as proposed in (Thorne et al., 2018). We first apply the strategy proposed in (Hanelowski et al., 2018) to retrieve documents. It employs the constituency parser from AllenNLP (Gardner et al., 2018) to find entities. It uses MediaWiki API to obtain relevant articles by matching the title of the article with claim entities. Once we collect \( K \) document candidates, we treat each sentence of the article as potential evidence. Evidence retrieval considers the claim and all candidate sentences as the input and outputs evidence by selecting a subset of sentences. We use \( h_i^R = \text{Enc}^R(w_i^c, w_i^e) \) to denote the process that the relevance encoder encodes the claim \( w_i^c \) and the \( i \)-th evidence candidate \( w_i^e \) into the representation \( h_i^R \).

We obtain the relevance score \( s_i \) by giving \( h_i \) to a fully connected network (FCN). After sorting the relevance score of evidence candidates, we collect the top \( K \) candidates as the evidence. Claim-evidence entailment predicts three probable outcomes: (i) the evidence supports the claim; (ii) the evidence refutes the claim; (iii) the evidence needs more information. The entailment encoder encodes the claim \( w^c \) and the retrieved evidence \( w^e \), and we denote the process as \( h^E = \text{Enc}^E(w^c, w^e) \). Then we feed \( h^E \) to another FCN for the entailment probability.

2.2 Sentence Pair Encoder

We design the relevance encoder and the entailment encoder to share the same architecture, because they both take two sentences as input and produce vector representation that captures claim, evidence, and the correlation of them. Although we consider the DA model and the ESI model in this work, we do not limit the choice of architectures. Let \( a \) and \( b \) be two sentences. The core idea of the two models is to obtain the attention weights \( e_{j,k} \) of word \( a_j \) and word \( b_k \) as in equation 1, where \( F(x) \) follows either DA or ESI to encode a single sentence. With the attention weights \( e \), we obtain \( \bar{a} \) and \( \bar{b} \):

\[
e = F(a)^	op F(b), \ e \in \mathbb{R}^{n_a \times n_b} \tag{1}
\]

\[
\bar{a}_j = \sum^K_{k=0} \frac{\exp(e_{j,k})}{\sum^K_{m=0} \exp(e_{j,m})} F(b)_k \tag{2}
\]

\[
\bar{b}_k = \sum^K_{j=0} \frac{\exp(e_{j,k})}{\sum^K_{m=0} \exp(e_{m,k})} F(a)_j \tag{3}
\]

Then DA and ESI introduce \( G(x_1, x_2) \) to update the representation by taking \((F(a), \bar{a}), \) or \((F(b), \bar{b})\), as the input. Formally, \( h^a = G(F(a), \bar{a}) \) and \( h^b = G(F(b), \bar{b}) \). We recommend readers to refer the origin papers for the implementation of \( F(x) \) and \( G(x_1, x_2) \). We concatenate the two representations as the final output of the encoder, \( h = [h^a, h^b] \). We use the encoder for the retrieval step and the entailment step by varying the input pairs.

2.3 Entailment Score as Relevance Measure

A common design of \( V(x) \) is to generate three values \([v^S, v^R, v^N]\), representing the evidence supports the claim, the evidence refutes the claim, and the evidence does not have enough information, respectively. The largest value decides the entailment: \( v = \max([v^S, v^R, v^N]) \). Intuitively, if one sentence supports or refutes the claim, the sentence must be relevant. Thus, we apply \( V(x) \) on all candidate sentences and propose a new form of the relevance score in Equation 4.

Also, we can combine the new relevance score with the old one that intends to capture the relevance on a single sentence. We introduce the final relevance score \( r^{\text{com}} \) in Equation 5, where \( \alpha \) and \( \beta \) can be learnable parameters or fixed hyperparameters, and \( r^{rFCN} \) is the common way that ob-
tains the relevance score via a fully connected network.

\[ r^{v\text{Diff}} = \max([v^S, v^R]) - v^N \quad (4) \]

\[ r^{\text{com}} = \alpha \cdot r^{\text{FCN}} + \beta \cdot r^{v\text{Diff}} \quad (5) \]

We optimize the retrieval objective as in Equation 6, by ranking the minimum score of evidence and the maximum score of irrelevant sentences. We use cross-entropy as in Equation 7 for the entailment objective. We sum the two as the joint training objective: \( \mathcal{L} = \mathcal{L}^R + \mathcal{L}^V \).

\[ \mathcal{L}^R = \frac{1}{Nc} \sum_i^{Nc} \max(0, \min([r^{+}_{i,0} \ldots r^{+}_{i,N+}]) \]
\[ - \max([r^{-}_{i,0} \ldots r^{-}_{i,N-}]) + m) \]

\[ \mathcal{L}^V = -\frac{1}{Nc} \sum_i^{Nc} y_i^c \log(v_i) \quad (7) \]

One may wonder if a claim requires multiple sentences to form evidence. In that case, \( v \) may predict a single sentence irrelevant. We argue it is not a concern because the \( r^{+} \) in our design is capable of taking a negative value while the \( r^{-} \) can take a positive value. As long as \( r^{+} \) is greater than \( r^{-} \), we can retrieve the right evidence.

3 Experiments

The focus of the experiments is to understand if the entailment score can benefit the retrieval. We conducted experiments on the FEVER dataset (Thorne et al., 2018). FEVER contained 80,035 Support claims, 29,775 Refute claims, and 35,639 NotEnoughInfo claims for training. The shared task of FEVER released 6,666 Support claims, 6,666 Refute claims, and 6,666 NotEnoughInfo claims for validation, and held another blind test set of 6,666 Support claims, 6,666 Refute claims, and 6,666 NotEnoughInfo claims. We considered two scenarios in our experiment, and we describe them as follows:

**EC**: short for Entailment Comparison. We explored the claim-evidence entailment by augmenting gold evidence with irrelevant sentences. We varied the irrelevant sentences so that we maintained the recall of the evidence retrieval. This scenario emphasizes the importance of evidence retrieval.

**RC**: short for Retrieval Comparison. We followed the three-step pipeline and focused on sentence retrieval. At the document retrieval step, we adopted the strategy of (Zhou et al., 2019; Hanselowski et al., 2018). At the sentence retrieval step, we trained on gold evidence and applied retrieved documents for validation.

3.1 The Importance of Evidence Retrieval

We first experimented against the EC to understand the importance of evidence retrieval. The irrelevant sentences are sampled from the same document as the evidence. For claims that did not have gold evidence, we sampled sentences from high ranked documents. We evaluated cases where the evidence contained [5, 10, 15, 20, 25, 30] sentences, while we constructed evidence with [5, 15, 25] sentences for training. Besides, we included the oracle setting that claims were paired with only gold evidence.

We report the result in Figure 1. We notice a clear trend that having irrelevant sentences hurt claim verification, which strengthens the importance of evidence retrieval. We also see that the ESI model performs better than the DA model in all cases, possibly because the ESI model leveraged sequential orders.

3.2 Evidence Retrieval

We conducted experiments against the RC scenario to investigate if the claim-evidence entailment can enhance evidence retrieval. We considered three variants of the sentence retrieval step for comparison: \( R \) was the baseline that no entailment signal was used; \( R+V-J \) measured the relevance score as in Equation 5; \( R-J \) also leveraged the entailment task but only used \( r^{v\text{FCN}} \) for the relevance score.

We selected three previous works to compare against: **TwoW** (Yin and Roth, 2018) combined the retrieval step and the entailment step as **R-J**.
We evaluated the retrieval step on three metrics: **F-recall** is the FEVER recall that measures if the top five sentences contained evidence. F-recall would count true positive if at least one evidence was found; **MRR** stands for mean reciprocal rank. Not only measuring if one evidence was selected, but it also considers the highest ranking position of the evidence. MRR favors to select one evidence as confident as possible; **MAP** stands for mean average precision. It cares for all evidence to be highly ranked and encourages the retrieval step to have all evidence confidently selected so that the retrieved candidates had less irrelevant sentences.

We report the result in Table 2. Since GEAR only reported results on the top five sentences, we calculated MRR and MAP on top five sentences (MRR@5 and MAP@5) and all sentences (MRR@A and MAP@A). We first observe that leveraging the entailment signal improves evidence retrieval on the ESI model, whereas it shows no improvement in the DA model. One possible reason is that the DA model did not perform well on claim verification compared to the ESI model. Therefore, the DA model could not provide a reliable entailment signal to enhance the retrieval. The ESI model, showing better accuracy to predict the entailment, improves MAP and MRR when we leveraged the entailment prediction (ESI-R+V-J v.s. ESI-R), which reinforced the thought that leveraging the entailment signal would require a good entailment predictor.

We also observe that TwoW and HAN could not efficiently retrieve relevant evidence as other methods. Although they show descent accuracy on claim-evidence entailment, a low F-recall means that filtering out low-rank candidates removed relevant evidence as well. Thus, these models show a disadvantage when people care about the evidence that leaded to a verification result.

Finally, we observe that leveraging the entailment signal did not offer an improvement in terms of F-recall. This might indicate that our method benefits ranking multiple pieces of evidence, as we see better performance on MAP and MRR. Besides, GEAR deployed an ensemble of ten models for retrieval, which could explain the difference.

Table 2: Evidence Retrieval Comparison. R is the retrieval baseline. R-J leverages the entailment signal via joint training. R+V-J measures the relevance score as in Equation 5. We use T-test, and **∗∗∗**, **∗∗**, and **∗** means the difference was significant under level $\alpha < 0.01$, $\alpha < 0.05$, and $\alpha < 0.1$, respectively.

![Figure 2: The visualization of the equation 1 using ESI. Each row corresponds to a token of the claim, and each column is a token of the evidence. A darker color means a higher attention score.](image-url)
3.3 Visualization

In Figure 2 we provide one visualization of the claim-evidence attention. We see that the claim and the evidence are attending on the same words and phrases. This explains why the entailment can benefit the retrieval: they reinforce each other to find similar lexicons.

4 Conclusion

In this work, we show that leveraging the entailment prediction can improve evidence retrieval when the entailment step produces a reliable result. In the future, we will adopt pre-trained models, e.g., BERT (Devlin et al., 2019), for our experiments. We expect improvement because BERT shows competitive results on the textual entailment tasks (Zhou et al., 2019).

Ethical consideration This work conducts experiments on benchmark datasets that have been extensively studied in the literature. Although the datasets used in the work was manually annotated, there is no identity characteristics. Also, we use RNN-based models with only a few layers, which are more eco-friendly compared to transformer based models.

Sentence Structure and Word Relationship Modeling for Emphasis Selection

Haoran Yang, Wai Lam
The Chinese University of Hong Kong
{hryang, wlam}@se.cuhk.edu.hk

Abstract

Emphasis Selection is a newly proposed task which focuses on choosing words for emphasis in short sentences. Traditional methods only consider the sequence information of a sentence while ignoring the rich sentence structure and word relationship information. In this paper, we propose a new framework that considers sentence structure via a sentence structure graph and word relationship via a word similarity graph. The sentence structure graph is derived from the parse tree of a sentence. The word similarity graph allows nodes to share information with their neighbors since we argue that in emphasis selection, similar words are more likely to be emphasized together. Graph neural networks are employed to learn the representation of each node of these two graphs. Experimental results demonstrate that our framework can achieve superior performance.

1 Introduction

Emphasis Selection recently proposed by (Shirani et al., 2019) aims to select candidate words for emphasis in short sentences. By emphasizing words, people’s intent can be better conveyed, which is useful in a variety of applications. For example, it can be used in spoken language processing to generate more expressive sentences and be used to enable automated design assistance in authoring, i.e., labeling important parts in a paragraph or in a poster title. Although it seems that this task is highly similar to the task of keyword extraction (Gupta, 2017), there are two different fundamentals. The first difference is that emphasis selection focuses on a paragraph which is composed of multiple sentences while emphasis selection aims to choose words from a short sentence. This difference implies that modeling sentence structure is more effective in emphasis selection. The second difference is that many global word statistics methods employed in keyword extraction such as TF-IDF and word co-occurrence frequency will not work in this task, because for short sentences, it is meaningless to count word frequency and whether the word should be emphasized has nothing to do with the frequency of the word. In addition, keyword extraction requires that the collected keywords are diverse, which means that if two words have similar meaning, only one should be kept. However, in emphasis selection, similar words tend to be emphasized together. Emphasis selection also shares some similarities with entity recognition (Yadav and Bethard, 2018). But one major difference is that the parts of speech of emphasized words are more diverse and the relation of adjacent words is weaker in the emphasis selection task.

Figure 1: Two examples of the emphasis selection. Words with darker background indicate that more people agree to emphasize.

Generally speaking, emphasis selection can be modeled as a sequence classification task where the input is a sentence and the output is each word’s probability to be emphasized. Shirani et al. (Shirani et al., 2019) propose a model which is based on the Recurrent Neural Network (Mikolov et al., 2010) and KL-Divergence loss function. Despite the fact that it looks like a straightforward task, there still exist some challenges. The first challenge is about how to incorporate sentence structure information into the model. Sentence structure information includes what role (subject, predicate, object, etc.) the word plays as well as the position of the word in a sentence. Obviously, this kind of information is very useful. Existing works (Shi-
rani et al., 2019) fail to model the global structure of a sentence. The second challenge is that there is no given context except a short sentence, so it requires the model to be able to capture some common patterns or regularities of most people. More concretely, if two words are similar, they are more likely to be emphasized together. For example, in Figure 1, persistence and victory are more likely to be emphasized together. This observation can also be found in the second example: Never and impossible. Moreover, we analyze the training dataset and get a more concrete understanding of this phenomenon through the following procedures: For each training sentence, we consider the most popular emphasized word called word A. Then, we identify the most similar word called word B to the word A based on GloVe embedding (Pennington et al., 2014). We find that the word B is also emphasized with a higher probability than other words in this sentence and this phenomenon occurs in about 26% of the training dataset. Therefore, modeling this kind of relationship between words definitely can help improve the performance of models.

In this paper, we propose a sentence structure graph to handle the sentence structure issue. Specifically, the sentence structure graph is derived from the parse tree of a sentence which contains useful information for this task. For example, as illustrated in Figure 2, when the path is S→NP→PRP, the word I is not inclined to be emphasized since this path indicates that this word is a subject. However, when the path is S→VP→S→VP→NP→NN, the word basketball is likely to be emphasized since this word is a noun in a verb phrase. Generally, such sentence structure graph can reveal the role of words in a sentence which is beneficial for emphasis selection. Another important information - word relationship information is captured by a word similarity graph. Through the word similarity graph, words can share information with their neighbours, resulting in similar emphasized probabilities of similar words. Next, graph neural networks (Vaswani et al., 2017; Cai and Lam, 2020; Kipf and Welling, 2017; Wu et al., 2019; Yun et al., 2019; Veličković et al., 2018) which have been demonstrated effective in modeling graph structure data are employed to learn the representation of each node of these two graphs. We conduct extensive experiments based on different word embeddings, i.e., GloVe (Pennington et al., 2014), ELMo (Peters et al., 2018), RoBERTa (Liu et al., 2019) and the experimental results show that our model can achieve superior performance.

2 Related Work

Emphasis selection is a new task proposed by (Shirani et al., 2019) which aims to choose a subset of words to emphasize in a sentence. Shirani et al. (Shirani et al., 2019) propose a model which is based on the Recurrent Neural Network (Mikolov et al., 2010). KL-Divergence loss function is adopted to conduct the label distribution learning (LDL) (Geng and Zhao, 2014). This method achieves competitive performance over the sequence labeling model: CRF (Lafferty et al., 2001).

In Recent years, graph neural networks (Wu et al., 2019; Kipf and Welling, 2017; Yun et al., 2019; Veličković et al., 2018; Cai and Lam, 2020) have demonstrated superiority in modeling the structure of graphs. Kipf et al. (Kipf and Welling, 2017) propose a graph convolutional network which is based on the fourier theory. One drawback of this model is that the edge weight of the graph needs to be known in advance. To overcome this shortcoming, Petar et al. (Veličković et al., 2018) use a masked self-attention layer to calculate the weight of node’s neighbours dynamically and then aggregate information by conducting a weighted addition operation. Currently, graph neural networks are applied to various tasks. Feria et al. (Feria et al., 2018) construct a word graph by calculating the word embedding similarity and apply the community detection algorithm to find different communities. Through the graph, they can find named entities for a bilingual language base in an
unsupervised manner. Sun et al. (Sun et al., 2019) put forward a diverse graph pointer network for keyword extraction. They first construct a word graph based on the distance of two words and then use the graph convolutional network as an encoder to obtain each node’s representation, finally a pointer network decoder and the diverse mechanism are employed to generate diverse keywords. The graph encoder can capture document-level word salience and overcome the long-range dependency problem of RNN.

3 Methodology

We follow the same problem setting given by (Shirani et al., 2019). Suppose a sentence is composed of $n$ words $C = (x_1, x_2, ..., x_n)$. Our goal is to obtain a subset $S$ of words in $C$ as selected words for emphasis where $1 \leq |S| \leq n$.

We model this task as a prediction problem:

$$(p_1, p_2, ..., p_n) = \text{model}(x_1, x_2, ..., x_n) \quad (1)$$

where $p_i$ is $i$-th word’s probability to be emphasized. Then $S$ contains the top-$|S|$ words with high probability.

Figure 3 depicts the architecture of our proposed model which is composed of three parts: (i) the middle part - sequence encoder (ii) the left part - word similarity graph encoder (iii) the right part - sentence structure graph encoder. Next, we will provide a detailed description of each part.

3.1 Sequence Encoder

The sequence encoder is composed of an embedding layer and a bidirectional GRU. It is mainly used to model the sequence information, i.e., word sequence and tag sequence. Formally, given a sentence $C = (x_1, x_2, ..., x_n)$ with $n$ words, the embedding layer is responsible for converting each word into a $d_1$-dimensional vector and converting the corresponding POS tag into a $d_2$-dimensional vector:

$$(w_1, ..., w_n) = \text{WordEmbed}(x_1, ..., x_n) \quad (2)$$

$$(e_1, ..., e_n) = \text{TagEmbed}(t_1, ..., t_n) \quad (3)$$

where $(t_1, ..., t_n)$ is the POS tag sequence and $w_i \in \mathbb{R}^{d_1}, e_i \in \mathbb{R}^{d_2}$. Then the word embedding and the tag embedding are concatenated and fed into a encoder $E$ to encode the sequence information.

3.2 Word Relationship Modeling

Given a sentence, we take each word as a node and the weight of the edge is calculated by the word embedding similarity. The weight matrix is denoted by $A \in \mathbb{R}^{n \times n}$. After the graph is constructed, a $L$-layer graph convolutional network (GCN) (Kipf and Welling, 2017) is employed to encode the word similarity graph:

$$H^{l+1} = \text{ReLU}(D^{-\frac{1}{2}}AD^{-\frac{1}{2}}H^{l}W^{l}) \quad (5)$$

where $W^l$ is a parameter and $H^l$ denotes the nodes’ representation in the $l$-th layer. $D \in \mathbb{R}^{n \times n}$ is a diagonal matrix and $D_{ii} = \sum_j A_{ij}$.

Recall that the WSG is a complete graph since each two words are connected by a weighted edge. There exists a serious problem: Useful information may be overwhelmed by useless information, because a majority number of words do not need to be emphasized, causing the information in words that are not emphasized dominates the words that should be emphasized. To alleviate this problem, we adopt two strategies: residual module (He et al., 2016) and gate mechanism (Gehring et al., 2017; Dauphin et al., 2017). The residual module makes the current node’s representation as the addition
between the former representation and the aggregated information from its neighbours. The gate mechanism controls the magnitude of the aggregated information. Through this way, the current node’s representation will not be significantly affected by its neighbours. Therefore Equation (5) can be rewritten as:

\[ M^{l+1} = H^l W^l \] (6)

\[ C = s(H^l W^g) \] (7)

\[ H^{l+1} = M^{l+1} + D^{-\frac{1}{2}} AD^{-\frac{1}{2}} M^{l+1} \otimes C \] (8)

where \( s(\cdot) \) is the sigmoid function and \( \otimes \) is the point-wise multiplication.

We obtain \( H^0 \) from the word embedding matrix and obtain the \( L \)-th layer output \( H^L = (w^L_1, ..., w^L_n) \) as each node’s features of the word similarity graph.

### 3.3 Sentence Structure Modeling

SSG is constructed by parsing the sentence using NLTK\(^1\) and StandfordNLP\(^2\). Then, we remove the leaf nodes (which are the words) and the remaining part is the SSG. Each node of the graph is a kind of POS tag and the path from the root to a specific word can reveal what role the word plays in the sentence.

Apparently, the weight of edges is important. For example, in Figure 2, the root node S has two children nodes NP and VP. The edge (S, NP) should have a smaller weight than the edge (S, VP) since people tend not to emphasize the subject in most circumstances. Different from WSG where the weight can be calculated by the word embedding similarity explicitly, it is not appropriate to calculate the weight in the SSG by the node similarity. Hence, we integrate the idea of Transformer (Vaswani et al., 2017; Cai and Lam, 2020) and masked self-attention (Veličković et al., 2018) to the SSG modeling. Firstly, we generate three vectors: key, query, value, according to the current node’s representation:

\[ k^{l+1}_i = W^k_i (v^l_i) \] (9)

\[ q^{l+1}_i = W^q_i (v^l_i) \] (10)

\[ v^{l+1}_i = W^v_i (v^l_i) \] (11)

where \( W^k_i, W^q_i, W^v_i \) are parameters. \( k^l_i, q^l_i, v^l_i \) correspond to the \( l \)-th layer key, query, value vector respectively. \( v^l_i \) is initialized from the tag embedding matrix. Then, a masked self-attention is employed to allow nodes aggregating information only from their neighbours.

\[ v^{l+1}_i = \sum_{j \in \mathcal{N}(i)} a_{ij} v^{l+1}_j \] (12)

\[ a_{ij} = \frac{\exp(q^{l+1}_i k^{l+1}_j)}{\sum_{z \in \mathcal{N}(i)} \exp(q^{l+1}_i k^{l+1}_z)} \] (13)

where \( \mathcal{N}(i) \) is the neighbour set of the node \( i \). After the graph is encoded with a \( L \)-layer network, we obtain the leaf nodes (the green nodes shown in Figure 2) representation \( V = (v^L_1, v^L_2, ..., v^L_n) \).

### 3.4 Loss Function

After obtaining these three modules’ output, we conduct a concatenation operation and calculate the probability:

\[ p_i = \text{softmax}(f([h_i, v^L_i, w^L_i])) \] (14)

where \( p_i \in \mathbb{R}^3 \) is \( i \)-th word’s probability distribution. \( f \) represents a fully connected neural network. We adopt negative log likelihood as the loss function:

\[ L = - \sum_{C \in \mathcal{D}_{train}} \sum_{i=1}^{\left| C \right|} \log p_{iy_i} \] (15)

### 4 Experiment and Results

#### 4.1 Dataset

We use the dataset\(^3\) provided by (Shirani et al., 2019). The dataset contains 2742 training sentences and 392 test sentences. Each sentence is

Table 2: Results of our model and baselines on GloVe and ELMo. The best performance is boldfaced.

Table 3: A sample case. Numbers outside the brackets indicate the word’s probability of being emphasized. Numbers in the brackets are the ranking of the corresponding word. (a/b) means that two words have the same ranking.

labeled by nine annotators. Table 1 gives a sample record of one sentence. B, I, O represent the beginning word to be emphasized, the interior word to be emphasized, and the word not to be emphasized respectively. Since there exists different opinions about whether the word should be emphasized, the labels given by nine annotators are slightly different.

4.2 Experimental Setup

We regard each annotator’s labeling as a sample in the dataset. In other words, each sentence is associate with nine samples. In order to verify the robustness of our model, we conduct experiments on two pre-trained word embeddings: 300-d GloVe (Pennington et al., 2014) and 2048-d ELMo (Peters et al., 2018). For the above two kinds of embeddings, we adopt GRU as the encoder $E$. The GRU hidden state size is 512 and 1024 respectively. The word similarity graph’s node embedding size is 300 and 2048 respectively. The sentence structure graph’s node embedding size is 300 and 512 respectively. Moreover, we initialize the sentence structure graph’s node embedding by training a classifier which only uses the sentence structure graph encoder. We adopt a two-layer bidirectional GRU. The sentence structure graph and the word similarity graph are encoded by a two-layer graph neural network. The batch size is set to 16. The negative slope of the ReLU function is set to 0.2. We use the Adam optimizer and the learning rate is 0.0001. The number of epoch is 100. We also add a dropout layer and the dropout rate is 0.5.

Since generalized pretrained language models such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) are demonstrated effective in a large bunch of downstream tasks, we also report results obtained by fine-tuning the RoBERTa on the emphasis selection dataset. There are two different experimental settings. The first setting is that only the RoBERTa model is used as the encoder $E$. The second setting is that a GRU layer is added on the top of the RoBERTa model, i.e., RoBERTa+GRU is the encoder $E$. The sentence structure model and the word relationship model remain unchanged. Adam optimizer is adopted and the learning rate is set to 1e-5.

4.3 Evaluation Metric

We adopt $\text{Match-m}$ (Shirani et al., 2019) as the evaluation metric which is defined as below:

\begin{align*}
\text{Match-m} & \quad \text{For a sentence } C, \text{ we choose } m \text{ words (denoted by } S_m(C) \text{) with the top-m probability (probability of the label B + probability of the label I) in the ground truth and } m \text{ words (denoted} \\
\end{align*}
Table 4: Results of our model and baselines based on two different architectures, RoBERTa and RoBERTa+GRU. The best performance is boldfaced.

Experimental results based on RoBERTa are listed in Table 4. Compared with the results based on GloVe and ELMo, RoBERTa and its variants achieve higher average match score which shows that a better initialized word embedding is helpful for a better performance. For the same RoBERTa encoder, Ours can obtain the highest score on Average and Match-2. For RoBERTa+GRU encoder, Ours can obtain the highest score on Average, Match-3 and Match-4. However, one interesting finding is that RoBERTa encoder performs much better than RoBERTa+GRU encoder. Two possible reasons may interpret this phenomenon. The first reason is the overfitting problem and the second reason is that the larger network is harder to train due to some optimization issues, e.g., gradient vanishing.

4.4 Results and Analysis

4.4.1 Experimental Results

We compare our model with the existing model based on RNN proposed by Shirani et al. (2019) and the convolutional neural network (CNN). We report results evaluated by the metrics Match-1, Match-2, Match-3, Match-4 and the average of these four metrics. From Table 2, we can see that CNN lags behind other models on the whole.

When the word embedding is GloVe, models with at least one graph surpass RNN on almost all the metrics except Match-2. In particular, our model can achieve an improvement on Match-1 and Match-4. Our model without WSG (word similarity graph) achieves an excellent performance on Match-3 and Average. When the word embedding is ELMo, ours is superior to RNN-based on all the evaluation metrics. Compared to these two ablated models, Ours can also achieve better performance. Ours w/o WSG is better than RNN-based on all the evaluation metrics except Match-2 and Ours w/o SSG is better than RNN-based except Match-3. On the whole, models with graphs can obtain better results on most metrics compared to the baseline models, which shows the advantage of these two components.

Experimental results based on RoBERTa are listed in Table 4. Compared with the results based on GloVe and ELMo, RoBERTa and its variants achieve higher average match score which shows that a better initialized word embedding is helpful for a better performance. For the same RoBERTa encoder, Ours can obtain the highest score on Average and Match-2. For RoBERTa+GRU encoder, Ours can obtain the highest score on Average, Match-3 and Match-4. However, one interesting finding is that RoBERTa encoder performs much better than RoBERTa+GRU encoder. Two possible reasons may interpret this phenomenon. The first reason is the overfitting problem and the second reason is that the larger network is harder to train due to some optimization issues, e.g., gradient vanishing.

4.4.2 Case Study

To gain some insights of our proposed model, we present a sample case generated by the ELMo-based model as shown in Table 3. We can see that Ours not only predicts the ranking accurately, but also obtains very close probability to the ground truth probability derived by annotators. Besides that, the probabilities of foolish and sane predicted by our model are very close than that predicted by RNN-based, which shows that the word similarity graph can impel similar words to have similar probabilities.
We also provide a failed case in Table 5. It is intrinsically harder to rank the words in this sentence even for human beings. Our model does not rank them correctly on these cases where multiple words may be emphasized.

4.4.3 Some Useful Tips

We conclude some tips on the experiment that leads to better performance. (1) We can firstly train a classifier only using the SSG, then use the pre-trained embeddings as an initialization of the sentence graph nodes embeddings. It can obtain higher score and faster convergence of the model. (2) We also consider another method to model the relationships between words using a self-attention operation proposed by Lin et al. (2017) above the hidden vectors of RNN. However, the performance is slightly degraded compared to removing this operation. So we think it is much better to model words relationships and sequence information separately.

5 Conclusions

The sentence structure graph and the word similarity graph are proposed to solve two issues found in emphasis selection. The sentence structure graph helps to model the structure information of the sentence and the word similarity graph is useful in modeling relationships between words. With the development of graph neural network, the two graphs can be properly encoded and integrated into existing models. Experimental results demonstrate that our framework can achieve superior performance.

Abstract

This study proposes an utterance position-aware approach for a neural network-based dialogue act recognition (DAR) model, which incorporates positional encoding for utterance’s absolute or relative position. The proposed approach is inspired by the observation that some dialogue acts have tendencies of occurrence positions. The evaluations on the Switchboard corpus show that the proposed positional encoding of utterances statistically significantly improves the performance of DAR.

1 Introduction

The recognition of dialogue acts (DAs), which represent the intention or function of each utterance in a dialogue, is useful for various dialogue applications, such as dialogue systems and dialogue summarization. Recently, neural network- (NN-)based approaches have become dominant in dialogue act recognition (DAR) because NN-based models obtained higher performance than other approaches. Most existing NN-based DAR models treat DAR as a sequence labeling problem, where utterances are first encoded with a hierarchical recurrent neural network (RNN), and subsequently, the sequence of DAR labels is identified from the encoded representations using the Conditional Random Field (CRF) (Kumar et al., 2018; Chen et al., 2018; Li et al., 2019; Raheja and Tetreault, 2019). These CRF-based models can capture the local dependencies of DA sequences; however, they cannot model global dependencies due to the first-order Markov assumption. To alleviate this problem, Colombo et al. (2020) proposed a sequence-to-sequence (seq2seq) architecture for DAR, which could learn global dependencies, and achieve the state-of-the-art performance. We focus on this work and employ it as the basis of our proposed model.

Existing NN-based DAR models focus on the context of a dialogue and dependencies between DAs but do not focus on the position of an utterance. However, we have found that some DAs have tendencies of occurrence positions. For example, the “Open-Question” DA in the Switchboard corpus tends to appear at the beginning of a telephonic conversation.

Inspired by this observation, this study proposes an utterance position-aware approach for a NN-based DAR model, which explicitly encodes the position of an utterance by positional encoding and generates DA label sequences based on the hidden vectors augmented with the positional encoding of utterance. In particular, we implement two types of positional encodings of utterances: (1) sinusoidal positional encoding used in Transformer neural machine translation (Vaswani et al., 2017), which represents the absolute position of each utterance; (2) length-ratio positional encoding, which is a positional encoding based on the ratio of the position of an utterance to the dialogue length (i.e., the total number of utterances in the dialogue). The second encoding aims to encode relative positional information to alleviate the variation of dialogue length.

The evaluations on the Switchboard corpus (Stolcke et al., 2000), which is one of the most popular benchmark datasets in DAR, show that the performance of DAR is statistically significantly improved by incorporating the proposed positional encoding of utterances (up to +0.31 precision). Our analysis demonstrates that the proposed model statistically significantly improves the performance of long dialogues.

2 Proposed DAR Model

Figure 1 shows an overview of the proposed model. The proposed model incorporates positional encoding of utterances (Section 2.2) into the baseline seq2seq DAR model (Section 2.1).
2.1 Baseline DAR Model

Our DAR model takes a dialogue document $D = (U_1, \cdots, U_{|D|})$, which is the sequence of utterances $U_i$ as an input and predicts the sequence of DA labels $Y = (\hat{y}_1, \cdots, \hat{y}_{|D|})$ from $D$, where $y_i$ is the DA label of $U_i$ and each utterance is the sequence of words (i.e., $U_i = (w_{i1}, \cdots, w_{i|U_i|})$).

The baseline model is a seq2seq model that consists of a hierarchical encoder and a decoder with guided attention proposed by Colombo et al. (2020). The hierarchical encoder hierarchically encodes a dialogue document using two types of RNN layers, a word layer and an utterance layer. Particularly, the word layer first generates the sequence of intermediate word vectors $(u_{i1}, \cdots, u_{i|U_i|})$ of each utterance $U_i$, from the sequence of word embedding vectors $(w_{i1}, \cdots, w_{i|U_i|})$. Subsequently, the utterance layer generates the sequence of intermediate utterance vectors $(h_{1enc}, \cdots, h_{|D|enc})$ from the outputs of the word layer. We use bi-directional gated recurrent unit (Cho et al., 2014) as RNN. The computations in the encoder are as follows:

$$
  u_{ij} = \text{BiGRU}_{\text{word}}(u_{ij-1}, w_{ij}),
$$

(1)

$$
  h_{ienc} = \text{BiGRU}_{\text{att}}(h_{i-1enc}, u_{i|U_i|}).
$$

(2)

The decoder autoregressively generates the sequence of DA labels after receiving the previous hidden state and the previous output as inputs. In each timestep $i$, the previous label $\hat{y}_{i-1}$ is first converted into an embedding vector $f_{\text{embed}}(\hat{y}_{i-1})$ in the same way as word embedding, following which the hidden vector $h_{i}^{dec}$ is generated as follows:

$$
  e_i = \begin{cases} f_{\text{embed}}(\langle \text{SOS} \rangle) & (i = 1) \\ f_{\text{embed}}(\hat{y}_{i-1}) & (\text{otherwise}), \end{cases}
$$

(3)

$$
  h_{i}^{dec} = \begin{cases} \text{GRU}(h_{i|D|enc}, e_i) & (i = 1) \\ \text{GRU}(h_{i-1}^{dec}, e_i) & (\text{otherwise}), \end{cases}
$$

(4)

where $h_{i}^{enc}$ denotes the encoder’s final hidden state and $\langle \text{SOS} \rangle$ denotes the special label. Finally, the $i$-th DA label is predicted by applying hard guided attention (Colombo et al., 2020), which attends only to the corresponding encoder’s hidden state, as follows:

$$
  z_i = [h_i^{dec}, h_i^{enc}],
$$

(5)

$$
  \hat{y}_i = \text{LogSoftmax}(\text{ReLU}(Wz_i)),
$$

(6)

where $[;]$ indicates a concatenation operation, and $W$ denotes a parameter matrix.

2.2 Positional Encodings of Utterances

The proposed model incorporates positional encoding of utterances into the baseline DAR model described in Section 2.1 to explicitly consider the position of an utterance in the inference of its DA label. Specifically, the proposed model predicts the $i$-th DA label from the following $z_i$, which is the concatenation of the original one and the positional encoding of the $i$-th utterance $h_i^{pos}$ rather than Equation (5).

$$
  z_i = [h_i^{dec}; h_i^{enc}; h_i^{pos}].
$$

(7)

In this work, we implement two types of positional encodings of utterances as $h_i^{pos}$ in Equation (7): (1) absolute positional encoding (PE$_{abs}$), which encodes the absolute positional information of each utterance, and (2) relative positional encoding (PE$_{rel}$), which encodes the relative positional information of each utterance considering the dialogue length.

**Absolute Positional Encoding (PE$_{abs}$)**

We incorporate the absolute positional information of utterances by applying sinusoidal positional encoding used in the Transformer (Vaswani et al.,

Note that our PE_{rel} is the same formulation as the one of Takase and Okazaki (2019). However, Takase and Okazaki (2019) have used the positional encoding for controlling the output length in document summarization. The purpose is different from ours, and our work is the first attempt to introduce a relative positional encoding to DAR.

3 Experiments

3.1 Settings

We evaluated our proposed method on the DAR task with the Switchboard corpus (SwDA) (Stolcke et al., 2000), consisting of 1,155 telephonic conversations using the standard splitting of the corpus (Lee and Dernoncourt, 2016). Table 1 shows the statistics of the SwDA dataset. The corpus comprises 43 different kinds of DA labels, and the vocabulary size is 19K.

We compared our two types of proposed models (s2s+PE_{abs} and s2s+PE_{rel}), each of which incorporates the positional encoding of utterances, described in Section 2.2, into the baseline DAR model (s2s), described in Section 2.1. We measured the performance of DAR as precision. We used Adam optimizer (Kingma and Ba, 2015) to train each DAR model, which is updated using a scheduler with a patience of 20 epochs and a reduced rate of 0.5. We used weight decay, gradient norm clipping, and dropouts (Srivastava et al., 2014). Each model was implemented using PyTorch and trained on a single NVIDIA GeForce GTX 1080 Ti. The hyperparameters of each model were optimized using

2017) to positional encoding of utterances in DAR. Let $d$ be the dimension of the positional encoding. The $k$-th element of the positional encoding of the $i$-th utterance, $PE_{abs}(i,k)$, is calculated as follows:

$$PE_{abs}(i,2k) = \sin \left( \frac{i}{10000^{2k/d}} \right), \quad (8)$$

$$PE_{abs}(i,2k+1) = \cos \left( \frac{i}{10000^{2k/d}} \right). \quad (9)$$

Relative Positional Encoding (PE_{rel})

We incorporate the relative positional information of utterances by length-ratio positional encoding, which encodes the ratio of the position of an utterance to the dialogue length. $PE_{abs}$ could not capture an occurrence phase (e.g., the beginning, middle, or last part) in a dialogue because the same absolute position can appear at different phases. For example, the 10th utterance belongs to the beginning part of a long dialogue (e.g., dialogue length = 100) whereas it belongs to the last part of a short dialogue (e.g., dialogue length = 10). To alleviate the variation of dialogue length, $PE_{rel}$ encodes positional information normalized by the dialogue length $|D|$ as follows:

$$PE_{rel}(i,2k|D|) = \sin \left( \frac{i}{D^{2k/d}} \right), \quad (10)$$

$$PE_{rel}(i,2k+1|D|) = \cos \left( \frac{i}{D^{2k/d}} \right). \quad (11)$$

We compared our two types of proposed models (s2s+PE_{abs} and s2s+PE_{rel}), each of which incorporates the positional encoding of utterances, described in Section 2.2, into the baseline DAR model (s2s), described in Section 2.1. We measured the performance of DAR as precision. We used Adam optimizer (Kingma and Ba, 2015) to train each DAR model, which is updated using a scheduler with a patience of 20 epochs and a reduced rate of 0.5. We used weight decay, gradient norm clipping, and dropouts (Srivastava et al., 2014). Each model was implemented using PyTorch and trained on a single NVIDIA GeForce GTX 1080 Ti. The hyperparameters of each model were optimized using

Table 4: Precision (%) for the top 10 most frequent DA labels.

3.2 Results

Table 3 shows the results of the experiment, wherein the numbers in bold represent the best scores, and * indicates that the improvement over the baseline “s2s” is statistically significant according to the Wilcoxon signed-rank test ($p \leq 0.01$). The results show that the performance of a seq2seq-based DAR model can be significantly improved by incorporating PE\textsubscript{abs} or PE\textsubscript{rel}. In particular, PE\textsubscript{abs} and PE\textsubscript{rel} increase precision by 0.31 and 0.22, respectively. This demonstrates the effectiveness of our proposed method.

4 Analysis

4.1 Precision for Each DA Label

To analyze the effectiveness of the proposed method, we examined the precision of each model for each DA label. For simplicity, we evaluated the top 10 most frequent DA labels on the SwDA corpus. Table 5 shows the top 10 DA labels, accompanied by the number of occurrences. For the top 10 labels, Figure 2 shows the histograms of the label’s absolute and relative positions in the training data, where the vertical axis is the number of occurrences, and the horizontal axis is the relative or absolute position. The relative positions are normalized by the dialogue length.

Table 5: The number of occurrences of the top 10 most frequent DA labels.
Figure 2: Histograms of absolute and relative positions for the top 10 most frequent DA labels. The relative positions are scaled from 0 to 1 according to the dialogue length.

Table 6: Distribution of dialogue length.

4.2 Analysis of Similar DA Labels in Appearance

One of the difficulties in DAR is the recognition of DA labels in a confused group (Kumar et al., 2018; Bothe et al., 2018). In SwDA, “Backchannel,” “Agree or Accept,” and “Yes Answer” are easily confused with each other, and so are “Wh-Question,” “Open-Question,” and “Rhetorical-Question.” This is because these labels have common expressions (e.g., “Yes” and “Yeah” may belong to “Backchannel,” “Agree or Accept,” and “Yes Answer”). In this section, we analyze the performance of the proposed models for DA labels in a confused group.

Figure 3 shows the confusion matrix of “Backchannel,” “Agree or Accept,” and “Yes Answer.” As can be seen in Figure 3, the misrecognition as “Yes Answer” is widely reduced and the precision of “Yes Answer” is highly improved. This might be because “Yes Answer” has a tendency to appear at the beginning part, which is different from the appearance patterns of the other two labels (see Figure 2). This demonstrates that the proposed methods are effective to DA labels in a confused group as well.

Figure 4 shows the confusion matrix of “Wh-Question,” “Open-Question,” and “Rhetorical-Question,” and Figure 5 shows the histograms of the absolute positions for the three labels in addition to those of the relative positions in the training data. As presented in Figure 4, for PE_{rel}, the precision of “Wh-Question” is improved, but the misrecognition of “Wh-Question” as “Open-Question” increases. This might be because “Wh-Question” has a tendency of relative occurrence positions, and so does “Open-Question.” As for PE_{abs}, the
4.3 Impact of Dialogue Length

We analyze the effectiveness of the proposed method on various dialogue lengths. We divide the test data into four groups according to the dialogue length and measure precision on each group. Tables 6 and 7 show the statistics of each group and the results, respectively. In Table 7, the numbers in bold represent the best scores, and * indicates that the improvement over the baseline “s2s” is statistically significant according to the Wilcoxon signed-rank test ($\alpha \leq 0.01$).

Table 7 shows that the precision of “s2s” tends to decrease as the dialogue length increases. In contrast, both proposed models alleviate the tendency of “s2s” and preserve precision for long dialogues. Additionally, Table 7 shows that the proposed models statistically significantly outperform “s2s” on the group with the dialogue lengths of 300 or more. This indicates that our proposed models are effective for long dialogues.

In Table 7, the improvement of “s2s+PE_{rel}” over “s2s” is greater than that of “s2s+PE_{abs}.” This indicates that “s2s+PE_{rel}” could successfully encode positional information of utterances with large absolute position by normalizing their positions.

5 Conclusions

In this paper, we have proposed an utterance position-aware approach for a seq2seq-based DAR

Abstract

This paper investigates the effectiveness of automatic annotator assignment for text annotation in expert domains. In the task of creating high-quality annotated corpora, expert domains often cover multiple sub-domains (e.g., organic and inorganic chemistry in the chemistry domain) either explicitly or implicitly. Therefore, it is crucial to assign annotators to documents relevant with their fine-grained domain expertise. However, most of existing methods for crowdsourcing estimate reliability of each annotator or annotated instance only after the annotation process. To address the issue, we propose a method to estimate the domain expertise of each annotator before the annotation process using information easily available from the annotators beforehand. We propose two measures to estimate the annotator expertise: an explicit measure using the predefined categories of sub-domains, and an implicit measure using distributed representations of the documents. The experimental results on chemical name annotation tasks show that the annotation accuracy improves when both explicit and implicit measures for annotator assignment are combined.

1 Introduction

Preparation of training data has been a critical issue in applying the supervised and semi-supervised methods to real world problems. Training data construction is often quite costly and the quality is hard to assure, especially when the task requires expert knowledge of the target domain such as chemistry and medicine. A possible solution to alleviate the lack of annotated data is the use of a crowdsourcing platform. Crowdsourced annotation has proven to be successful for lowering the annotation costs in tasks that require general knowledge, such as POS tagging (Hovy et al., 2014), textual entailment, word sense disambiguation (Snow et al., 2008), or recognition of general named entities like PERSON and ORGANIZATION (Finin et al., 2010; Nguyen et al., 2017). Meanwhile, there is limited success in using crowdsourcing for annotation in expert domains mainly because of the poor annotation quality made by annotators with low domain expertise. In the medical domain, for example, Nye et al. (2018) combine both non-expert crowdsourced annotators and expert annotators for text annotation.

We hypothesize that a key challenge of crowdsourced annotation in expert domains lies in the difficulty of estimating the candidate annotators’ expertise in terms of the relevance to the documents to be annotated. Some crowdsourcing platforms such as Amazon Mechanical Turk 1 provide the feature to specify workers that have the expertise in particular domains. However, it is still not optimal for annotation tasks of documents such as scientific papers, as they tend to require expertise in various specific sub-domains. For example, inorganic chemistry and drug discovery fields belong to a broader category of the chemical domain. Annotation on drug discovery papers would be difficult for experts in inorganic chemistry because it substantially differs from the drug discovery field. However, limiting the candidate annotators to the experts in drug discovery would result in insufficient number of annotators that is not enough for obtaining a large size annotated corpus within limited time. Moreover, it is even hard to identify the required domain knowledge to understand each document with such high granularity.

A practical solution to this issue would be to find a way to estimate the relevance between an annotator and a document and to assign annotators to documents based on the relevance between

---

1https://www.mturk.com/
them. It is expected that even if we can not recruit a sufficient number of annotators for each particular sub-domain, we can assign annotators with expertise in different but relevant sub-domains and obtain better quality annotations.

This motivated us to investigate the annotator assignment problem for text annotation in expert domains. The main question is whether we can improve the overall text annotation quality by using not only explicit information such as the annotators’ major fields of study but also implicit information estimated by other kinds of information available before the annotation process. To answer the question, we conduct a series of experiments on chemical name annotation tasks in academic paper abstracts from various sub-fields of chemistry. The annotators are graduate students in chemistry departments, so they have expertise in different chemistry sub-domains. As the explicit knowledge of the annotators’ expertise, we asked the annotators their fields of expertise from predefined categories. We also asked them to submit information about the literature strongly related to their study. We use the literature information to estimate more fine-grained implicit relevance between the annotated document and the annotators that can not be captured by the explicit information. The experimental results indicate that combining both the explicit and implicit information helps estimate the document-annotator relevance and results in better annotation quality.

Our approach is orthogonal to the annotation aggregation methods (Nguyen et al., 2017; Li et al., 2014) commonly used in the crowdsourced annotation. While the annotation aggregation methods improve the annotation quality by aggregating the annotations from different annotators after the annotation process, our approach improve the annotation by assigning more relevant domain experts to each text before the annotation process. The difference comes from the fact that most of the studies on crowdsourced annotation focus on annotation tasks that require general knowledge or a single expert domain, where the assignment of annotators has relatively small effect on the final annotation quality. Thus, it is possible that our approach and the annotation aggregation methods complement each other. Our approach is also different from the existing methods to select the best annotators which requires training based on the previous annotation results by the candidate annotators (Donmez et al., 2010; Kamar et al., 2013; Kamar and Horvitz, 2015; Tran-Thanh et al., 2014). We believe that estimation of the relevance between documents and annotators can also be helpful for such methods as prior knowledge.

2 Related Work

Preserving the quality of the crowdsourced work is difficult as annotators possess very diverse abilities, skills, or interests (Daniel et al., 2018). For this reason, many researchers have proposed their methods for improving the quality of annotations or maintaining it without increasing the cost. Some strategies deal with the problem of the ground truth absence – from increasing the number of annotators (Sheng et al., 2008), through intelligently weighting them based on their inferred expertise (Donmez et al., 2009; Raykar et al., 2010; Welinder et al., 2010) to recruiting a small group of top quality workers (Zhao et al., 2013; Li et al., 2014; Li and Liu, 2015; Carvalho et al., 2016) or seeing how they learn over time (Pan et al., 2016). When it comes to methods used for selecting the best annotators, Donmez et al. (2010) utilize a sequential Bayesian estimation algorithm for continuous tracking and selecting the best annotators over time. Markov Decision Process can be used to model agent conduct during the consensus tasks and to predict a candidate annotator’s work (Kamar et al., 2013; Kamar and Horvitz, 2015). Tran-Thanh et al. (2014) introduce a recruiting algorithm based on a variation of the multi-armed bandit model (MAB) outperforming previous methods by up to a remarkable 300%. Recommendation of tasks to workers has also been studied with use of a worker’s task browsing history (Yuen et al., 2015), or taking into account implicit negative feedback (Lin et al., 2014).

However, all these approaches focus on annotators, not the target data. Unlike these methods, our approach is to assign documents to experts in potentially different sub-domains so that their expert domains are as close as possible to those of the assigned documents. An example of annotation improvement in a scenario requiring specialized expertise (clinical NLP) is given in Dumitranche et al. (2015), where authors pay attention to documents being annotated. The main problem they aim to solve is not only the lack of ground truth for training and benchmarking but also ambiguity in the target documents. They have shown that, with proper processing, the crowd performs just
as well as medical experts in terms of the quality and efficacy of annotations, while being cheaper and more readily available. However, their results indicate that at least ten workers per sentence are needed to get the highest quality annotations, while we aim at acquiring high-quality results with fewer workers by assuring assignments of targets well-fit to the annotators.

Assignment of experts has been studied in the context of paper-reviewer assignment problem at academic conferences (Dumais and Nielsen, 1992; Charlin and Zeme, 2013; Dumais and Nielsen, 2016). These methods use previous publications of reviewers and those publications are used to build reviewers’ profiles. Methods for building profiles include not only use of words in publications, but also Latent Semantic Indexing (Salton and McGill, 1983) and Latent Dirichlet Allocation (Blei et al., 2003). Submitted papers are also encoded with the same methods for building reviewer profiles. Then, the similarity between submitted papers and each reviewer’s profile is calculated based on the encoded representations and assignment is done just with the calculated similarity or by casting assignment as an Integer Linear Programming problem (Karimzadehgan and Zhai, 2009). Our work is in the similar spirit as this line of work. The experimental results indicate that such an approach is also promising in selecting annotators for expert domain annotation tasks.

To sum up the related work: current crowdsourcing-based annotation methods integrate several annotation results into one final annotation, utilize machine learning with several annotation results, or target experts where the most skillful annotators are automatically discovered. To the best of the authors’ knowledge, the proposed task of automatic assignment of documents for annotation is the first of its kind. Besides, this is the first research that evaluates the effectiveness of consideration of annotator’s expertise in quality.

3 Expertise-Based Annotator Assignment

3.1 Problem Description

We consider the annotator assignment problem for text annotation, where the goal is to assign the most relevant annotators to the given document for better annotation quality. In particular, we consider annotation tasks on documents that require special knowledge for full understanding such as scientific papers and clinical records. We also assume that the required sub-domain of knowledge differs depending on the document to be annotated. For the chemistry domain, the sub-domains may include inorganic chemistry, drug discovery, and so on. As clues of annotator’s expertise, we consider two types of information: explicit expertise such as predefined sub-domains and implicit expertise that is estimated from the information available before the annotation process and potentially represents more fine-grained relevance between documents and annotators. The implicit expertise can be helpful not only for complementing explicit expertise, which might not be available or might be insufficient but also for capturing the similarity between different sub-domains to estimate the relevance of the papers to the annotators in different sub-domains. We describe these two types of expertise in more details in the following section.

In this paper, we evaluate our approach on the chemical name annotation task using chemistry paper abstracts. In what follows, we describe our proposed method based on this specific task. However, the method can be generalized to different domains and tasks where similar type of prior information about the target documents and the candidate annotators is available. It is worth noting that our approach depends only on the type of information about the documents and the annotators available before the annotation process, and is independent of the type of the annotation task.

3.2 Prior Information of Annotator Expertise

3.2.1 Explicit Expertise

For explicit expertise, we assume existence of predefined categorical labels representing expert sub-domains. Both the documents to be annotated and the candidate annotators should be associated with categorical labels representing the sub-domains of the documents’ or the annotators’ expertise. In practice, the labels can be the conference venues of papers, IPC classification of patents, and so on. Multiple labels can be associated with each document and annotator. We use the binary indicator $I_{cat}(i, j) \in \{0, 1\}$ for the explicit expertise-based relevance score between the annotator $i$ and the document $j$, which indicates whether the annotator $i$’s areas of expertise include at least one of the categories of the document $j$ or not.
3.2.2 Implicit Expertise

In addition to the explicit expertise measure, we propose document-annotator relevance based on implicit expertise that captures more fine-grained and multi-dimensional aspects of the domain expertise. We assume that we have access to a small subset of documents that each annotator is the most familiar with from the same domain as those to be annotated (hereinafter called annotators’ documents). This requires the candidate annotators to present additional information, but it is not hard for annotators to present. For example, it can be a few papers relevant to their fields of study.

We encode both the annotators’ documents and the documents to be annotated into a low-dimensional vector in some way. These document representations include semantic knowledge about the specific sub-domains of the documents and the annotations that can not be captured by the categorical information alone. Suppose that we have a set of candidate annotators \( I \) and a set of documents to be annotated \( J \). Let \( d^{(i)}_{il}(t) \) \((t \in \{1, \ldots, L\})\) be the representation of the \( i \)-th annotator’s documents (assuming that each annotator presents \( L \) relevant documents), and \( d^{(j)}_{j}(t) \) be the representation of the \( j \)-th document to be annotated. For annotators that have expertise in multiple sub-areas, each of the annotators’ documents may represent different aspects of their expertise. Therefore, we compare two different ways to aggregate these paper representations and compute the final relevance score. The first one is to compare each document to be annotated with the average of the document representations of the annotator’s documents:

\[
s_{av}(i, j) = \text{sim}(\frac{1}{L} \sum_{l=1}^{L} d^{(s)}_{il}, d^{(t)}_{j}),
\]

where \( \text{sim}(\cdot, \cdot) \) denotes the cosine similarity. The second one is to compute the similarity between each of the annotator’s documents and the document to be annotated, and take the score from the most relevant one:

\[
s_{\text{nearest}}(i, j) = \max_{l} \text{sim}(d^{(s)}_{il}, d^{(t)}_{j}).
\]

3.2.3 Relevance Scores

In our experiments, we evaluate the effect of combining these explicit and implicit relevance measures. We employ the following combinations:

- \( \text{cat}: I_{\text{cat}}(i, j) \),
- \( \text{catsim-av}: I_{\text{cat}}(i, j) + s_{av}(i, j) \), and
- \( \text{catsim-nearest}: I_{\text{cat}}(i, j) + s_{\text{nearest}}(i, j) \).

Note that as \( I_{\text{cat}}(i, j) \) takes the value 0 or 1 and \( s_{av}(i, j) \) and \( s_{\text{nearest}}(i, j) \) is between \([0, 1]\), the agreement based on the explicit expertise has priority over that of implicit expertise in terms of the final relevance score. Therefore, the implicit expertise-based relevance is expected to work as the auxiliary information that provides the knowledge that can not be captured by the explicit expertise-based measure.

3.3 Calculating Annotator Assignment

The document-annotator assignment is calculated by solving the following Integer Linear Programming (ILP) problem:

Maximize \[ \sum_{i \in I, j \in J} s_{i,j} \cdot x_{i,j} \] (3)

\[ \text{s.t. } k_{\text{min}} \leq \sum_{j \in J} x_{i,j} \leq k_{\text{max}} \quad \forall \ i \in I \] (4)

\[ \sum_{i \in I} x_{i,j} = n_{\text{ann}} \quad \forall j \in J, \] (5)

\[ x_{i,j} \in \{0, 1\} \quad \forall i \in I, \forall j \in J, \] (6)

where \( s_{i,j} \) is one of the relevance scores between the \( i \)-th annotator and the \( j \)-th document introduced above. The problem is to find the assignment \( x_{i,j} \) that maximizes the total relevance scores of the assigned pairs of documents and annotators. \( x_{i,j} \) is the indicator variable that becomes 1 if the \( i \)-th annotator is assigned to the \( j \)-th document, and 0 otherwise. The first constraint represents the maximum \( k_{\text{max}} \) and the minimum \( k_{\text{min}} \) numbers of documents that can be assigned to a single annotator. In order to evenly assign documents to annotators, we use \( k_{\text{min}} = \lceil |J|/|I| \rceil \) and \( k_{\text{max}} = k_{\text{min}} + 1 \) in our experiment. The second constraint means that each document should be assigned to \( n_{\text{ann}} \) annotators. \( n_{\text{ann}} \) is set to 1 in our experiment.

4 Experimental Settings

We evaluated the proposed annotator assignment method on a chemical name annotation task using the abstracts of chemistry papers.

4.1 Datasets and Guidelines

We used chemistry papers in two different languages: English and Japanese. The papers are selected randomly from the predefined categories to construct a dataset of approximately 500 abstracts for each language. The sub-domain categorization used for each language is shown in Table 1.
4.1.1 English Papers

We used CHEMDNER corpus (Krallinger et al., 2015) for the English annotation task. It consists of 10,000 abstracts of chemistry-related publications that were chosen according to journal titles. These titles helped us assign categories to English texts (listed in Table 1; multiple categories for each paper were allowed). Each abstract in the CHEMDNER corpus was annotated with seven types of chemical term classes defined by the CHEMDNER task organizer. To evaluate our annotation, we used paper abstracts from the CHEMDNER test set which consists of 3,000 abstracts. We randomly sampled 504 abstracts while maintaining an approximately even number of papers in every category.

For annotation evaluation, we followed the annotation guidelines of the CHEMDNER corpus\(^2\). The labels in the CHEMDNER test set were used as the gold standard. The original paper reports an inter-annotator agreement of 85.26%.

4.1.2 Japanese Papers

We obtained Japanese chemistry paper abstracts from JDREAM III\(^3\) repository of scientific publications based on their categories as of September, 2017. JDREAM III provides predefined categories corresponding to the first eight of those in Table 1. We retrieved 2,500 papers for each category, and the total number of papers was 20,000. We applied to them an in-house chemical named entity recognizer to select the paper abstracts that were likely to include some chemical compound names or chemistry-related terms. Finally, we randomly sampled 520 abstracts from the selected abstracts so that the number of abstracts in each category was 65.

For annotation of Japanese texts, we prepared a new annotation guideline defining 20 mention types for chemical entities. We defined twelve entity types for chemical substances including organic and inorganic molecules and eight entity types for chemistry-related concepts such as drug names, products, properties, and numerical expressions. An example of annotated document is shown in Appendix A.

To prepare the gold standard data, we employed 17 in-house expert annotators to annotate chemistry-related terms in these paper abstracts. In order to create a reliable gold standard, each abstract was checked by three annotators. First, two annotators annotated each abstract, and then the remaining annotator, who had not annotated the abstract, checked and integrated the annotations. The inter-annotator agreement between the two annotators was 0.449 in terms of exact match entity-level F\(_1\) score.

4.2 Annotators

We employed 49 graduate students who major in chemistry at their universities. 40 and 20 students performed annotation for English and Japanese, respectively. Some students annotated both English and Japanese texts.

As prior information for estimating the subdomain expertise of each student, we asked the students to provide the following information:

- Expertise category as listed in Table 1. Multiple choice was allowed.
- Titles and abstracts of five scientific papers each that were relevant to their study.

\(^2\)To be precise, we used the annotation guidelines for CHEMDNER patent corpus as CHEMDNER server was not accessible during our experiment. However, the guidelines of the patent corpus defined the same seven mention types and in our preliminary evaluation we confirmed that the differences between them are small.

\(^3\)https://jdream3.com/
The distribution of their expertise categories is shown in Table 1.

All annotations were conducted using the BRAT annotation tool (Stenetorp et al., 2012). For both English and Japanese papers, we provided the annotators with the same annotation guidelines that had been used to construct the gold-standard dataset (i.e. the CHEMDNER patent guideline for English and our new guideline for Japanese). In order to alleviate the problem of lower quality caused by inexperience in annotation and to assure proper understanding of the annotation guidelines, we first trained all the annotators by asking them to annotate the same five paper abstracts in a trial stage. After that, we asked each annotator to annotate the assigned abstracts.

In addition to cat, catsim-av and catsim-nearest, we also evaluated the performance of non-experts who have no expertise in chemistry. The non-experts’ fields of expertise were other than chemistry, such as architectonics, physics and electricity. Abstracts assignment to the non-experts was random.

4.3 Annotator Assignment

As the measure of the implicit expertise, we calculated semantic representations of submitted paper abstracts using a simple sentence embedding method. For each paper, we averaged the sum of embeddings of all content words in the title and abstract of the paper after normalizing the Euclidean norm of each word vector to 1. We used 200-dimensional word embeddings trained with word2vec (Mikolov et al., 2013) for both English and Japanese. Training data for the English word embeddings was the whole CHEMDNER corpus in addition to the titles and abstracts of papers obtained from MEDLINE 2017 version that appear in the same set of journals used in the CHEMDNER corpus. Training data for the Japanese word embeddings were the titles and abstracts of 20,000 papers from JDREAM III.

The ILP problem for the assignment was solved with the COIN CBC solver of PuLP and the optimum solutions were obtained for all the assignments. The optimization result was obtained within a few seconds. Each annotator was asked to annotate the combined set of abstracts assigned by the three assignment methods. The order of the abstracts given to each annotator was random and the annotators were not informed which method was used to assign each abstract. As some of the annotation jobs were canceled after the assignment, we ended up doing the evaluation with 323 paper abstracts for English and 375 paper abstracts for Japanese for which we obtained results from all the assignment methods.

5 Results

5.1 Main Results

Table 2 shows the annotation performance with different assignment methods. We use the standard evaluation metrics for named entity tagging, i.e. recall, precision and F-measure \( F_1 \) based on the exact match of the tagged entities compared with the gold standard.

The performance by non-experts is significantly worse than those of domain experts, indicating the importance of domain expertise for our evaluation task. On the other hand, the performance of expertise-based assignments is higher than the agreement between experts (0.449) for the Japanese documents. \(^7\) Compared to (cat), which only uses the explicit expertise for assignment, catsim-nearest showed higher \( F_1 \) for both English and Japanese data set. catsim-av demonstrated higher \( F_1 \) for English but lower \( F_1 \) for annotations in Japanese. A possible reason why catsim-nearest measure generally performs better than catsim-av is that the former is better at capturing expertise over multiple sub-domains. When an annotator has expertise in multiple sub-domains, catsim-av represents their expertise with a single vector by averaging the representations of all the annotator’s documents. On the other hand, catsim-nearest keeps the individual representations of all the annotator’s documents and uses the one that is the most relevant to each target document for the relevance score. The improvement is relatively higher in recall than in precision for both English and Japanese, indicating that sub-domain expertise helps annotators in detecting more technical terms in the documents.

---

\(^4\)We used NLTK (Bird, 2006) and Mecab (Kudo et al., 2004) tokenizers for English and Japanese, respectively, to identify content word using part-of-speech tags.

\(^6\)https://github.com/coin-or/pulp

\(^7\)Although the reported inter-annotator agreement of the English corpus is 85.26%, it is hard to directly compare the result with ours as no details are provided for the calculation of the agreement. In addition, the annotators of the corpus were also involved in revising the annotation guideline, indicating higher proficiency in the guideline.

To compare the results of annotations, we employed a McNemar paired test on the labeling disagreements following the procedure introduced in Sha and Pereira (2003). As in Kudo et al. (2004) for morphological analysis, we compared the results based on character-based IOB2 format (Tjong Kim Sang and Veenstra, 1999) instead of the usual word-based version, because the endings or beginnings of chemical terms do not always correspond to word boundaries. The results confirmed statistical significance ($p < 0.01$) of the differences between cat and catsim-nearest for both English and Japanese.

5.2 Error Analysis

Table 3 shows the statistics of the annotation results with respect to the types of errors. We classified the annotation errors into four types: incorrect tags assigned to characters other than chemical terms (Ex), chemical terms which were not annotated (Miss), annotations whose spans are different from the correct annotation (SD), and annotations where spans are correct, but the type of the chemical terms is incorrect (TD). An example of each error type is shown on the right-hand side of the table. The results show that assigning more relevant domain experts to the task helps to reduce the number of missed annotations while slightly increasing the number of excessive annotations. It is understandable though that annotators are likely to give more labels to documents relevant to their expertise.

We also evaluated proposed methods by mention-wise comparison of annotation results. The results show that the annotations corresponding to implicit expertise-based assignments are better than explicit expertise-based ones in terms of the number of correctly annotated mentions. McNemar paired test showed statistical significance ($p < 0.05$) of the improvement in English results, while no significance was observed in Japanese results. We also computed the correlation between the relevance scores and the annotation accuracy as shown in Table 5. Similarly to the mention-wise comparison, we observed significant correlation between implicit expertise-based relevance scores and the corresponding F1 scores for the English task, while no significant correlation was observed for the Japanese task. Possible reasons why the proposed method is less efficient in the Japanese task is discussed in the following section.

6 Discussion and Conclusion

Good quality corpora of specialized scientific texts could become important not only for specialists from various fields, but also for the promising AI subfield of automatic scientific discovery. This paper proposes a novel method for automatic annotation task assignment based on the expertise of the annotator estimated with scientific paper abstracts that the annotator has presented as relevant to their own research interests. The experimental annotation results of English and Japanese chemistry-related paper abstracts showed that our method contributes to higher accuracy compared to the annotation by non-experts and use of predefined technical field categories.

We could not cover all possible experimental settings (e.g. assignment using only implicit expertise) due to the time and budget restrictions. In our experimental design it is required that all assignments to be compared are calculated on the same set of annotators and then annotated together, which makes adding other experimental settings afterwards difficult. Improvement in experimental design is needed in order to compare different factors more flexibly.

An interesting observation is that the cause of annotation errors is not always the lack of annotator expertise. For example, we found that errors which result from poor understanding of annotation guidelines are not negligible. For the Japanese task,

In which we failed to find any significant improvement, as many as 20 of mention types might have made the annotation task too complicated for annotators that are domain experts but not experts in linguistic annotation. As shown in Table 3, a large number of annotation errors in the Japanese task are span difference (SD). This type of errors is often less relevant to domain expertise: an example is “Sb(CN)3(2,2’-bipy)” vs. “[Sb(CN)3(2,2’-bipy)]”.

Another future work topic is designing an annotation framework for domains requiring expertise knowledge. For experiments described in this paper, we recruited students who major in chemistry with the help of university faculties. However, in order to continue building corpora for domains requiring expertise knowledge, this procedure is not optimal. In fact, it took about three weeks just to hire annotators for the experiments. In the future, it is necessary to develop not only accurate assignment methods, but also an annotation framework for expert domains. In order to apply our method to documents other than scientific papers, it is also necessary to find alternatives for the “relevant scientific papers” that represent the annotators’ domain expertise. The application fields include Q&A texts and blogs that feature domain specific topics. It is reported that annotation accuracy on such texts gets worse when the task requires specific knowledge of cartoons and TV programs and so on (Komiya et al., 2016). For such cases, it might be helpful to use cartoon titles, TV-show titles, news articles, blog posts, etc., recently read or watched by annotators.

A Annotation of Japanese Documents

Figure 1 shows an example of an annotated part of a Japanese paper.

Figure 1: An example of annotated Japanese text.
Abstract

Neural sequence-to-sequence (Seq2Seq) models and BERT have achieved substantial improvements in abstractive document summarization without and with pre-training, respectively. However, they sometimes repeatedly attend to unimportant source phrases while mistakenly ignore important ones. We present new reconstruction mechanisms on two levels to alleviate this issue. The sequence-level reconstructor reconstructs the whole source document from the hidden layer of the target summary, while the word embedding-level one rebuilds the average of word embeddings of the source at the target side to guarantee that as much critical information is included in the summary as possible. Based on the assumption that inverse document frequency (IDF) measures how important a word is, we further leverage the IDF weights in our embedding-level reconstructor. The proposed frameworks lead to promising improvements for ROUGE metrics and human rating on both the CNN/Daily Mail and Newsroom summarization datasets.

1 Introduction

Single document summarization is designed to automatically compress a document into its short version without changing the main idea. The summarization task is generally divided into two categories: extractive methods that copy certain sentences or phrases directly from the source text, and abstractive methods that paraphrase the source text by using novel words. Abstractive summarization has the potential to produce summaries in the same way that humans do.

Recent years have witnessed significant progress in the abstractive summarization task performed by Seq2Seq models, which encode a source text and decode its summary. A hybrid of the extractive and abstractive techniques, called pointer-generator network (PGN) (Gu et al., 2016; See et al., 2017), has been widely used as a basis for many studies (Gehrmann et al., 2018; Shen et al., 2019; Shi et al., 2019) thanks to its capability of copying words from the source document and generating new words. With the rich contextual representations, pre-trained encoders (Devlin et al., 2018) have also improved the state-of-the-art on this task (Liu and Lapata, 2019; Raffel et al., 2020). However, the conventional PGN and BERT face two main problems: 1) When generating summaries, PGN tends to frequently pay attention to some source parts while neglecting other parts, which are regarded as over- and under-attention respectively. Therefore, the model requires a mechanism to make sure that as much salient information is transformed from the source to the target as possible. 2) Additionally, BERT is pre-trained for sentences (Xu et al., 2020), thus it is deficient in distinguishing key points from non-key points within long-range dependencies, which leads to inconsequential phrases or words being copied into the summary. This is mainly due to the lack of ability to recognize topic-signifying words from the document (Baziotis et al., 2019).

Similar problems have been encountered in neural machine translation (NMT) (Tu et al., 2016). Tu et al. (2017) developed an encoder-decoder-reconstructor framework with a two-step process that first translates a sentence into another language and then reconstructs the translation back to the source language. The newly added reconstructor rewards the model when it correctly reconstructs the input source sentence from the decoder hidden layer, which forces the salient information to be transferred from the source to the target. Baziotis et al. (2019) applied this concept to unsupervised sentence compression, where the model consists of two encoder-decoder pairs so that no large text-summary dataset is needed.

Inspired by the above, we propose three recon-
struction methods for neural document summarization. The intuitive approach is a reconstructor that rebuilds the source document from the decoder hidden layer in an encoder-decoder architecture that assigns the corresponding likelihood as a reconstruction loss. When the reconstructed text is significantly different from the original one due to the model incorrectly omitting or repeating some parts to generate the summary, the reconstructor penalizes it during training. We refer to this approach as sequence-level reconstruction and choose it as our first implementation of the idea.

In contrast to the sequence-level reconstruction, reconstructing the word embeddings of source articles would be a rather simple and effective method for document summarization. The embedding-level reconstruction alleviates the length discrepancy between articles and summaries by calculating the distance between the average word embeddings of the source and target sides. We therefore propose the average word embedding reconstructor as our second reconstruction method.

We also present the third reconstructor that focuses on the saliency of words. Generally, certain words that appear frequently in documents have little importance and should not be kept in the summary. In contrast, words that signify the main idea are supposed to be maintained in the summary. As inverse document frequency (IDF) can measure how important a token is and extract salient information (Salton et al., 1983), we reconstruct the IDF-weighted word embeddings of the source at the target to keep topic-signifying words in the summary. Since the summary has far fewer tokens than the document, it is not appropriate to directly incorporate the term frequency (TF) value into our reconstructor. We therefore consider the IDF as the weight of embeddings, rather than the TF-IDF.

In this work, we mainly adopt the PGN as baseline and incorporate the above three reconstructors upon it. We then assign a loss for each reconstructor and leverage each of them as a complement to the baseline objective. On one hand, the reconstruction objectives facilitate the model to generally focus on the entire text rather than parts of it, thereby avoiding under-attention. On the other hand, the IDF-weighted method serves as a selector by giving more weights to topic-signifying words such that it can identify essential parts (Table 1) and prevent over-attention to less important words.

We performed experiments on two datasets and compared our methods with the baselines. Experimental results on the Newsroom dataset demonstrate that we outperformed the baselines by more than 2 points in ROUGE-1, 2, and L. Our methods also led to significant improvements on the CNN/Daily Mail dataset.

2 Preliminaries

In the PGN, a document $x$ that consists of a sequence of tokens $x = \{x_1, x_2, ..., x_T\}$ is fed into a bidirectional LSTM encoder, producing a sequence of hidden states $h_i$. Then a unidirectional LSTM decoder generates its corresponding summary $y = \{y_1, y_2, ..., y_T\}$ word by word with the limitation of $T \ll I$. $I$ and $T$ indicate the lengths of the source article and the summary, respectively.

The PGN adopts the attention mechanism to learn the alignment and yield target tokens simultaneously. Conditioned on decoder hidden state $s_t$ and context vector $c_t$ for the $t$-th decoding step, vocabulary distribution $P_{\text{vocab}}$ is as follows:

$$P_{\text{vocab}}^{t} = \text{softmax}(W_s s_t + W_c c_t + b_s + b_c),$$  

$$c_t = \sum_{i=1}^{I} \alpha_{t,i} h_i,  \tag{1}$$

$$\alpha_{t,i} = \exp(\alpha'_{t,i}) / \sum_{k=1}^{I} \exp(\alpha'_{t,k}),  \tag{2}$$

$$\alpha'_{t,i} = W_\alpha \tanh(W_h h_i + W_s s_t + b_\alpha),  \tag{3}$$

where $W_s$, $W_c$, $W_\alpha$, $W_h$, $W_s'$, $b_s$, $b_c$, $b_\alpha$ are trainable parameters, and $\alpha_t = \{\alpha_{t,1}, ..., \alpha_{t,I}\}$ is the
attention distribution over the source hidden states.

The PGN additionally employs the copy mechanism to decide whether to copy a word from the source document or to generate a new word through soft switch $p_{gen,t} \in [0, 1]$. $p_{gen,t}$ can be obtained by a feed-forward network whose inputs are the context vector and the encoder and decoder hidden states. The copy distribution is sampled from attention distribution $\alpha_t$, that is, the copy probability of a source token $w$ is calculated as the sum of attentions towards all occurrences of $w$. Thus, the joint distribution is calculated as

$$P(y_t) = p_{gen,t} \times P_{vocab,t}(y_t) + (1 - p_{gen,t}) \times \sum_{i:x_i = y_t} \alpha_{t,i}.$$  

During training, we use the negative log-likelihood as the loss function:

$$L_{PGN} = -\sum_{t=1}^{T} \log P(y_t).$$  

### 3 Proposed Model

We next describe the details of our proposed methods, which can be split into two main components:

- **Pointer-generator**: a neural Seq2Seq framework with the attention and copy mechanisms, as introduced in Sec. 2.

- **Reconstructor**: a module that manages to reconstruct the salient information of the original document in its summary. We put forward three independent reconstructors that will be explained in the next subsections. Moreover, our proposed approaches are applicable to any attention-based Seq2Seq summarization architectures.

#### 3.1 Sequence-level Reconstruction

The first reconstructor, as shown in Fig. 1, is expected to recover the full input sequence from the decoded summary, i.e., to reconstruct the one-hot representations of the tokens in the source document to reward the summary with the complete source information. Specifically, the reconstructor generates a reconstructed sequence $\hat{x} = \{\hat{x}_1, \hat{x}_2, ..., \hat{x}_I\}$ word by word from decoded summary sequence $y$ and decoder hidden state $s_t$. We obtain a probability distribution over the vocabulary through reconstructor hidden state $\hat{h}_t$ and inverse context vector $\hat{c}_i$:

$$\hat{P}_{vocab,i} = \text{softmax}(\hat{W}_h \hat{h}_t + \hat{W}_c \hat{c}_i + \hat{b}_s),$$  

$$\hat{c}_i = \sum_{t=1}^{T} \hat{\alpha}_{t,i} \hat{s}_t,$$  

where inverse attention $\hat{\alpha}_t$ for reconstructing step $i$ has the same structure as the original attention, except taking the decoder and reconstructor hidden states as inputs and owning independent weighted vectors. Then, we try to minimize the reconstruction loss, which is the negative log-likelihood assigned by $\hat{x}$ to the original document $x$:

$$L_{\text{recon}} = -\sum_{i=1}^{I} \log \hat{P}_{vocab,i}(\hat{x}_i = x_i).$$  

In general, the reconstruction phase can be treated as an inverse process of a standard encoder-decoder.

It is obviously impossible to reduce the loss to a low level because a summary must contain fewer tokens and less information than its original text. However, we can reasonably expect the reconstruction loss to urge the encoder-decoder to embed complete information of the source document.

#### 3.2 Word Embedding-level Reconstruction

In order to ensure the generated summary maintains a similar sequence representation with the source article, we compute the average word embeddings of $x$ and $y$, and attempt to minimize their cosine distance. For a source word $x_i$ in the input document, we simply utilize vector $e_{x_i}$ obtained from the encoder embedding layer. To represent token $y_i$, we first concatenate context vector $c_{t-1}$ and embedding $e_{y_{t-1}}$ of the word generated at the previous step. $e_{y_{t-1}}$ keeps and shares part of the word embedding information at the input side, while $c_{t-1}$ simultaneously adds new information about context at the output side. Then, a linear transformation is applied to combine above two vectors:

$$e_{y_{t}} = W_e [c_{t-1}; e_{y_{t-1}}] + b_e,$$

where $W_e$ and $b_e$ are trainable parameters. Considering the difference of the embedding representations between the document and its summary, we take the following actions: 1) the embedding matrix is shared between the encoder and
decoder for unity, 2) the method pays fair attention (weight) to each word in the sequence to restrain under-attention, and 3) to prevent the effect of length difference, we calculate the average of the word embeddings for each sequence, i.e., divide the sum by their respective lengths.

We calculate the embedding representations for original article $x$ and summary $y$ as follows:

$$r(x) = \frac{1}{I} \sum_{i=1}^{I} e_{x_i}, r(y) = \frac{1}{T} \sum_{t=1}^{T} e_{y_t}. \quad (11)$$

The reconstruction loss is then examined by the cosine similarity between summary representation $r(y)$ and source representation $r(x)$ accordingly as

$$\mathcal{L}_{\text{recon}} = 1 - \cos(r(x), r(y)). \quad (12)$$

### 3.3 IDF-weighted Embedding-level Reconstruction

The abstractive summarization task is intended to remove duplicate or unimportant words and to paraphrase the rest. The second approach, introduced above, takes the average of word embeddings (i.e., fair weights) as the goal of reconstruction. However, attending to all words equally does not suit the objective of this task. Thus, we propose an advanced version of the word embedding reconstruction by incorporating IDF's, as shown in Fig. 2.

Intuitively, some words, e.g., "the", appear in many documents, while others, e.g., "Harry Potter", are not so frequent. Therefore, words with lower IDF values usually have no specific meaning and can be omitted without confusing the main idea. Conversely, higher valued words might signify the topic of an article. This assumption allows the model to distinguish key points from non-key points, thereby avoid over-attention to less important parts. Consequently, IDF-weighted embeddings are used as an alternative, changing Eq. 11 to

$$r(x) = \frac{\sum_{i=1}^{I} \text{IDF}_{x_i} e_{x_i}}{\sum_{i=1}^{I} \text{IDF}_{x_i}}, r(y) = \frac{\sum_{t=1}^{T} \text{IDF}_{y_t} e_{y_t}}{\sum_{n=1}^{T} \text{IDF}_{y_n}}. \quad (13)$$

The same form of reconstruction loss as Eq. 12 is implemented here as well.

The IDF values can be computed on the basis of the training dataset. They are calculated separately from a corpus of original articles and reference summaries to create source and target-side dictionaries, respectively. Given a token $w$, its inverse document frequency can be obtained by

$$\text{IDF}_w = \log \frac{1 + n_d}{1 + DF(d, w)} + 1, \quad (14)$$

where $n_d$ denotes the total number of documents in the corpus and $DF(d, w)$ is the number of documents where $w$ appears. 1) At the source side, the model takes the encoder input $x_i$ as a key to search for $\text{IDF}_{x_i}$ from the source-side dictionary. 2) Whereas at the target side, the decoder outputs a probability distribution at each time step according to Eq. 5. We choose the word with the highest probability as the output and look for its corresponding $\text{IDF}_{y_t}$ in the target-side dictionary.

### 3.4 Training Loss

We use $\lambda$ as a hyperparameter to balance $\mathcal{L}_{\text{PGN}}$ with $\mathcal{L}_{\text{recon}}$. The overall loss can be defined as

$$\mathcal{L} = \mathcal{L}_{\text{PGN}} + \lambda \mathcal{L}_{\text{recon}}. \quad (15)$$

![Figure 2: IDF-weighted word embedding reconstruction model.](image)
4 Experiments

4.1 Datasets and Settings

Datasets  We carried out the experiments on two benchmark datasets, namely CNN/Daily Mail (Nallapati et al., 2016) and Newsroom (Grusky et al., 2018). Using these two datasets is challenging since we need to compress long news articles into short multi-sentence summaries. To split the CNN/Daily Mail dataset into training/validation/test sets, we followed See et al. (2017) to use the non-anonymized version. We replicated the pre-processing steps released by Shi et al. (2019) to generate the splits of the Newsroom dataset. The basic statistics of the datasets, including the splitting details, are summarized in Table 2. In both datasets, the document and summary were truncated to 400 and 100 tokens, respectively. Additionally, 50K of the most frequently occurring tokens in the training dataset were selected to form a vocabulary for both the source and target.

Evaluation metrics  We evaluated our models with the ROUGE metrics (Lin, 2004), which compare model-generated summaries with reference summaries by referring to the overlap of unigram (ROUGE-1), bigram (ROUGE-2), and longest common subsequence (ROUGE-L).

Experimental settings  We trained our models on a single GeForce RTX 2080Ti GPU (11GB RAM). 128-dimensional word embeddings with random initialization were fine-tuned during training. We utilized a single-layer bidirectional LSTM for the encoder and a unidirectional LSTM for the decoder. Both the encoder and decoder have 256-dimensional hidden states. As for the optimizer, Adam (Kingma and Ba, 2015) with a learning rate of 0.0001 and an initial accumulator value of 0.1 was used. The maximum norm of gradient clipping was set to 2.0. We set the batch size to 8 on the CNN/Daily Mail dataset whereas 32 on the Newsroom dataset. Summaries were decoded through beam search with a beam size of 4 at test time. The maximum iterations on CNN/Daily Mail and Newsroom were 500,000 and 450,000, which are both approximately equal to 14 epochs. The same settings were applied to the baselines for comparison.

Training our embedding-level reconstruction model on the CNN/Daily Mail dataset took 41.6 hours, while it took 34.7 hours on the Newsroom dataset. We noticed that embedding-based approaches do not increase training time significantly compared to the baselines. Our approach can improve the performance without introducing too many parameters or sacrificing training efficiency.

When setting the scaling factor $\lambda$ (in Eq. 15), we found that the baselines with embedding-level reconstructors (in Sec. 3.2, 3.3) achieved the best results when the reconstruction loss was weighted to $\lambda = 2.0$ on the CNN/Daily Mail validation dataset and $\lambda = 2.5$ on the Newsroom validation dataset. However, the sequence-level reconstructor (in Sec. 3.1) worked best when $\lambda$ was set to 0.1.

Baselines  We employed the following excellent baselines for comparison and to demonstrate that our approaches can be transplanted to various Seq2Seq models. As our original intention to design the reconstructors, the PGN in Sec. 2 was treated as our main baseline for both datasets. We also adopted PGN+Coverage and PreSumm (Liu and Lapata, 2019)\(^1\) on the CNN/Daily Mail dataset to further examine the adaptability of our reconstructors. The coverage mechanism (Tu et al., 2016; See et al., 2017) maintains a vector, i.e., a sum of attention distributions over all the former decoding steps, to prevent repeating words. PreSumm employs and fine-tunes the pre-trained context representations of BERT (Devlin et al., 2018) as an encoder. On the Newsroom dataset, we additionally utilized LeafNATS (Shi et al., 2019)\(^2\) as our baseline. LeafNATS is an open-source toolkit that can train and evaluate neural Seq2Seq models for the abstractive summarization. The authors modified the PGN by adding an intra-decoder (Paulus et al., 2018) to it.

4.2 Results

CNN/Daily Mail  Table 3 shows our main results on the CNN/Daily Mail test set with ROUGE. Underlines indicate statistically significant differences from the baseline using the bootstrap test (Dror et al., 2018). The results for the Lead-3 baseline method are shown at the top, with excellent abstractive representatives in the middle, and our reconstruction methods at the bottom.

From Table 3, we can explicitly observe that the sequence-level reconstruction mechanism beats the baseline but took three times as long as the original model to train (117.9 hours), which is computationally expensive and time-consuming. Therefore, even though the sequence-level reconstruction has

been proved to work well for NMT (Tu et al., 2017), it is not suitable for the summarization task. One of the most likely explanations is that NMT is a sentence or document transformation between two languages, which attempts not to lose any information during the process. However, summarization is designed to compress the information to form a shorter version of the original article. The nature of this task makes it extremely difficult to reproduce the whole input sequence from the generated summary. Furthermore, recovering the entire original information is not necessary and does not match the summarization objective. Therefore, we report the results of the PGN-based sequence-level reconstructor only on this dataset.

For both the PGN and the Coverage baseline, we can see higher ROUGE scores achieved by the word embedding-level reconstructions, which demonstrates the their effectiveness. In addition, our third reconstructor with IDF-weighted embeddings outperformed the baselines and two other reconstruction methods, despite far fewer training epochs.

Even though we did not observe as much improvements as the previous two baselines with the PreSumm-based reconstruction, the statistical significance test shows the stability and effectiveness of our method. To overcome the appearance of rare words, PreSumm tokenize words into subwords with Byte Pair Encoding (Sennrich et al., 2016). However, one subword may appear in words with various IDF values, which makes it meaningless to calculate IDF in the granularity of subwords. Therefore, in our experiments, we still calculated IDF on the word-level while we gave the IDF weights for the words only to their first subword. We believe that the difference of the granularity between IDFs and embeddings is the main reason of the slight improvement. We leave how to solve this issue as our future work.

Newsroom Table 4 lists the comparison results on the Newsroom dataset. Following the previous one, we enumerated extractive methods, abstractive or mixed Seq2Seq models, and our reconstruction architectures in three blocks in turn. Obviously, our reconstruction-based models were largely superior to the extractive methods and two abstractive approaches, while achieving comparable ROUGE scores with ExtConSumm, which is the state-of-

Table 5: Human evaluation of model-generated summaries.

The art mixed method. The IDF-weighted word embedding reconstruction was still the best among the reconstructors, which achieved an average improvement of 2.05 ROUGE points over the PGN baseline.

To sum up, these results indicate that simply adding the IDF-weighted embedding-level reconstruction to a Seq2Seq model is a very useful method in abstractive document summarization. However, the training time for introducing the sequence-level reconstructor greatly increased while it gains only a small improvement compared with the other two effective word embedding-level reconstruction methods. We leave the problem of how to successfully reconstruct a long document from a short summary with a neural Seq2Seq model as future work.

5 Analysis

5.1 Human Evaluation

Next, we performed the experiments with a manual evaluation to investigate the quality of summaries in three aspects: informativeness, readability, and redundancy. We randomly selected 100 examples from each dataset. Forty volunteers on Amazon Mechanical Turk (AMT) with a U.S. high school diploma or higher qualification were asked to rate each summary on a scale of 1-5 (higher is better). The average scores for the summaries of each model are shown in Table 5.

As we can see, the baseline model suffered from low informativeness and high redundancy, which can be considered as under-attention and over-attention, respectively. Incorporating the reconstruction architectures could alleviate these problems, whereas better summaries were generated with the help of the IDF values. We consider two reasons for this, as follows. 1) When average word vectors of summaries differ from their source texts, the summaries tend to be penalized by the reconstruction loss. There was no big difference observed between using and not using the IDF weights in terms of informativeness because the word embeddings play an important role in covering all the input tokens. 2) The IDF value for each word serves as a discriminator for avoiding fair attention. The redundancy was reduced with the IDF weights because higher-valued words control the summary content while lower-valued words tend to be ignored.

5.2 Case Study

Table 1\(^3\) shows example summaries obtained by the PGN with and without the IDF-weighted embedding reconstruction. For ease of understanding, we marked four most important passages in the source article with different colors. By observing these example summaries, we identified the following issues: 1) The baseline model tended to incorrectly

\(^3\)Refer back to page 2.
focus on unimportant details in the original text, and 2) The whole sentences or paragraphs were frequently copied from the source even if half of them were meaningless or redundant. For example, the second sentence of the baseline summary indicates that the cause of the fire accident has not been investigated. Compared to other elements in the news, e.g., the incident, location, consequences, and solution, the cause is not essential and should not appear in the summary. Moreover, the redundancy can be reduced if the model ignores the attributive clause containing four alarms instead of copying the whole sentence from the article.

All of the four key messages were included in the summary generated by our IDF-weighted embedding reconstruction method, while only one of them appeared in the baseline. Even the reference misses one key piece of information. This example demonstrates the efficacy of our reconstruction mechanism in keeping the salient information in text summarization in addition to the improved ROUGE scores.

6 Related Work

Compared to the extractive summarization, abstractive methods are more challenging and attract attention because they can generate new words through the source document representation (Liddy, 2001; Nallapati et al., 2016). With the popularity of deep learning, many neural network-based models, especially Seq2Seq models (Rush et al., 2015; Chopra et al., 2016), have been widely applied to natural language processing tasks, such as machine translation (Bahdanau et al., 2015) and dialogue systems (Lei et al., 2018). Since the work of Rush et al. (2015), neural Seq2Seq networks with an attention mechanism have been widely utilized in the abstractive summarization tasks.

However, the attention mechanism is sometimes not enough to address different problems. For example, repetitions at the word or phrase level cause grammatical errors and insufficient reflection of the main idea of the source article. Therefore, the distraction method (Nema et al., 2017) imposes a constraint over the attention that can reduce the probability of repeated content. Tu et al. (2016) and See et al. (2017) found that the original attention often leads to over- or under-focus without the memory of past alignment information. Thus, they used the coverage concept from statistical machine translation to keep track of the attention history with an additional loss. Moreover, the inability to handle out-of-vocabulary (OOV) tokens also limits the fluency and readability of generated summaries. To alleviate this problem, hybrid models that combine the extractive and abstractive methods through the copy mechanism account for the vast majority of models used in the summarization task (Vinyals et al., 2015; Gu et al., 2016; See et al., 2017).

Pre-trained language models (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2018), essentially word embeddings presenting contextual representations, that were learned from large-scale corpora, have recently emerged and achieved state-of-the-art performances in a variety of NLP tasks (Zhang et al., 2019; Liu and Lapata, 2019; Rothe et al., 2020). Due to the subword tokenizer, out-of-vocabulary words are rarely observed in their output even without the pointer mechanism.

However, neither non-pretrained Seq2Seq models nor BERT can measure the proportion of information transmitted from the source to the target. The idea of reconstruction can be implemented in many forms so as to adapt to different types of tasks. For example, Srivastava et al. (2015) proposed an LSTM encoder-decoder model that encodes the video and reconstructs its frame sequence. Tu et al. (2017) proposed a reconstruction model based on NMT that consists of three sequences. If the original sentence can be reconstructed from the target, it proves that the information has been effectively transferred. Another work is $SEQ^2$ (Baziotis et al., 2019) with a triple sequence structure, which rebuilds the input sentence from the latent representation of the decoder in the unsupervised sentence compression task.

7 Conclusion

In this work, we presented three reconstruction mechanisms for the neural Seq2Seq abstractive summarization task that reconstruct the essential information from the source document to its target summary. The proposed reconstruction methods are applicable to any attention-based Seq2Seq summarization architectures. Experimental results on both the CNN/Daily Mail and Newsroom datasets showed the improvements from the baselines in terms of ROUGE metrics and human evaluation. Our analysis also indicated that the proposed reconstruction approaches can restrict the under-attention to key points and over-attention to redundant parts.

Abstract

Online users today are exposed to misleading and propagandistic news articles and media posts on a daily basis. To counter thus, a number of approaches have been designed aiming to achieve a healthier and safer online news and media consumption. Automatic systems are able to support humans in detecting such content; yet, a major impediment to their broad adoption is that besides being accurate, the decisions of such systems need also to be interpretable in order to be trusted and widely adopted by users. Since misleading and propagandistic content influences readers through the use of a number of deception techniques, we propose to detect and to show the use of such techniques as a way to offer interpretability. In particular, we define qualitatively descriptive features and we analyze their suitability for detecting deception techniques. We further show that our interpretable features can be easily combined with pre-trained language models, yielding state-of-the-art results.

1 Introduction

With the rise of the Internet and social media, there was also a rise of fake (Nguyen et al., 2020), biased (Baly et al., 2020a,b), hyperpartisan (Potthast et al., 2018), and propagandistic content (Da San Martino et al., 2019b). In 2016, news got weaponized, aiming to influence the US Presidential election and the Brexit referendum, making the general public concerned about the dangers of the proliferation of fake news (Howard and Kollanyi, 2016; Faris et al., 2017; Lazer et al., 2018; Vosoughi et al., 2018; Bovet and Makse, 2019).

There were two reasons for this. First, disinformation disguised as news created the illusion that the information is reliable, and thus people tended to lower their barrier of doubt compared to when information came from other types of sources.

Second, the rise of citizen journalism led to the proliferation of various online media, and the veracity of information became an issue. In practice, the effort required to fact-check the news, and its bias and propaganda remained the same or even got more complex, compared to traditional media, since the news was re-edited and passed through other media channels.

Propaganda aims to influence the audience with the aim of advancing a specific agenda (Da San Martino et al., 2020b). Detecting it is tricky and arguably more difficult than finding false information in an article. This is because propagandistic articles are not intended to simply make up a story with objective errors, but instead use a variety of techniques to convince people, such as selectively conveying facts or appealing to emotions (Jowett and O’Donnell, 2012).
While many techniques are ethically questionable, we can think of propaganda techniques as rhetorical expressions that effectively convey the author’s opinion (O’Shaughnessy, 2004). Due to these characteristics, propagandistic articles are often produced primarily for political purposes (but are also very common in commercial advertisement), which directly affect our lives, and are commonly found even in major news media outlets, which are generally considered credible.

The importance of detecting propaganda in the news has been recently emphasized, and research is being conducted from various perspectives (Rashkin et al., 2017; Barrón-Cedeno et al., 2019a; Da San Martino et al., 2019b). However, while previous work has done reasonable job at detecting propaganda, it has largely ignored the question of why the content is propagandistic, i.e., there is a lack of interpretability of the system decisions, and in many cases, there is a lack of interpretability of the model as well, i.e., it is hard to understand what the model actually does even for its creators.

Interpretability is indispensable if propaganda detection systems are to be trusted and accepted by the users. According to the confirmation bias theory (Nickerson, 1998), people easily accept new information that is consistent with their beliefs, but are less likely to do so when it contradicts what they already know. Thus, even if a model can correctly predict which news is propagandistic, if it fails to explain the reason for that, people are more likely to reject the results and to stick to what they want to believe. In order to address this issue, we propose a new formulation of the propaganda detection task and a model that can explain the prediction results. Figure 1 compares the coverage of the explanations for pre-existing methods vs. our proposal.

Our contributions can be summarized as follows:

- We study how a number of information sources relate to the presence and the absence of propaganda in a piece of text.
- Based on this, we propose a general framework for interpretable propaganda detection.
- We demonstrate that our framework is complementary to and can be combined with large-scale pre-trained transformers, yielding sizable improvements over the state of the art.

2 Task Setup

Given a document \( d \) that consists of \( n \) sentences \( d = \{d_i\}_{i=1}^n \), each sentence should be classified as belonging to one of 18 propaganda techniques or as being non-propaganda. The exact definition of propaganda can be subtly different depending on the social environment and the individual’s growth background, and thus it is not surprising that the propaganda techniques defined in the literature differ (Miller, 1939; Jowett and O’Donnell, 2012; Hobbs and McGee, 2014; Torok, 2015; Weston, 2018). The techniques we use in this paper are shown in Table 1. Da San Martino et al. (2019b) derived the propaganda techniques from the literature: they selected 18 techniques and manually annotated 451 news articles with a total of 20,110 sentences. This dataset\(^1\) has fragment-level labels that can span over multiple sentences and can overlap with other labeled spans.

This granular labeling went beyond our scope and we had to restructure the data. First, we divided the data into sentences. Second, in order to reduce the complexity of the task, we changed the multi-label setup to a multi-class one by ignoring duplicate labels and only allowing one technique per sentence (the first one), breaking ties at random. As a result, we obtained 20,111 sentences labeled with a non-propaganda class or with one of 18 propaganda techniques. Based on this data, we built a system for predicting the use of propaganda techniques at the sentence level, and we provided the semantic and the structural information related to propaganda techniques as the basis of the results.

3 Proposed Method

Our method can detect the propaganda for each sentence in a document, and can explain what propaganda technique was used with interpretable semantic and syntactic features. We further propose novel features conceived in the study of human behavioral characteristics. More detail below.

3.1 People Do Not Read Full Articles

Behavior studies have shown that people read less than 50% of the articles they find online, and often stop reading after the first few sentences, or even after the title (Manjoo, 2013). Indeed, we found that 77.5% of our articles use propaganda techniques in the first five sentences, 65% do so in the first three sentences, and 31.07% do so in the title.

\(^1\)http://propaganda.math.unipd.it/
We define the relative position of a sentence as $f_i$ with respect to the title (Fang et al., 2019) fine-tuned on the Fake News Challenge dataset (Hanselowski et al., 2018). The title of an article typically contains the topic and also the author’s view of that topic. Thus, we hypothesize that propaganda should also focus on the topic expressed in the title.

We represent the relationship between the target sentence and the title by measuring the semantic similarity $f_{i}^{sim}$ between them as the cosine between the sentence-BERT representations ($\phi(x)$) (Reimers and Gurevych, 2019) of the target sentence $d_i$ and of the title $d_t$.

$$f_{i}^{sim} = \frac{\phi(d_i) \cdot \phi(d_t)}{|\phi(d_i)||\phi(d_t)|} \quad (1)$$

We further model the stance of a target sentence with respect to the title $f_{i}^{sent}$ using a distribution over five classes: related, unrelated, agree, disagree, and discuss. For this, we use a BERT model (Fang et al., 2019) fine-tuned on the Fake News Challenge dataset (Hanselowski et al., 2018).

</tbody>
</table>

We used three types of features ($f_{i}^{dp}$, $f_{i}^{sent}$, $f_{i}^{doc}$) to account for these observations, which we describe below.

#### 3.1.1 Relative Position of the Sentence

We define the relative position of a sentence as $f_{i}^{dp} = i/n$, where $i$ is the sequence number of the sentence, and $n$ is the total number of sentences in the article.

#### 3.1.2 Topic Similarity and Stance with Respect to the Title

The title of an article typically contains the topic and also the author’s view of that topic. Thus, we hypothesize that propaganda should also focus on the topic expressed in the title.

We represent the relationship between the target sentence and the title by measuring the semantic similarity $f_{i}^{sim}$ between them as the cosine between the sentence-BERT representations ($\phi(x)$) (Reimers and Gurevych, 2019) of the target sentence $d_i$ and of the title $d_t$.

$$f_{i}^{sim} = \frac{\phi(d_i) \cdot \phi(d_t)}{|\phi(d_i)||\phi(d_t)|} \quad (1)$$

We further model the stance of a target sentence with respect to the title $f_{i}^{sent}$ using a distribution over five classes: related, unrelated, agree, disagree, and discuss. For this, we use a BERT model (Fang et al., 2019) fine-tuned on the Fake News Challenge dataset (Hanselowski et al., 2018).

#### 3.2 Syntactic and Semantic Information

Some propaganda techniques have specific structural or semantic characteristics. For example, Loaded Language can be configured to elicit an emotional response, usually using an emotional noun phrase. To model this, we define the following three features: $f_{i}^{dp}$, $f_{i}^{sent}$, and $f_{i}^{doc}$.

#### 3.2.1 Syntactic Information

We used a syntactic parser to extract structural features about the target sentence $f_{i}^{dp}$. Our hypothesis is that such information could help to discover techniques that have specific structural characteristics such as Doubt and Black and White Fallacy. We considered a total of 27 clause-level classes and phrase-level labels, including the unknown class. The set is shown in Table 2.

#### 3.2.2 Sentiment of the Sentence

The sentiment of the sentence $f_{i}^{sent}$ is another important feature for detecting propaganda. This is because many propagandistic articles try to convince the readers by appealing to their emotions and prejudices. Thus, we extract the sentiment using a sentiment analyzer trained on social media data (Hutto and Gilbert, 2014), which gives a probability distribution over the following three classes: positive, neutral, and negative. It further outputs compound, which is a one-dimensional normalized, weighted composite score. We use all four scores as features.

Table 2: The syntactic labels we used as features.

<table>
<thead>
<tr>
<th>Level</th>
<th>Phrases</th>
</tr>
</thead>
<tbody>
<tr>
<td>Clause</td>
<td>S, SBAR, SBARQ, SINV, SQ</td>
</tr>
<tr>
<td>Phrase</td>
<td>ADJP, ADVP, CONJP, FRAG, INTJ, LST, NAC, NP, NX, PP, PRN, PRT, QP, RRC, UCP, VP, WHADJP, WHAVP, WHADVP, WHNP, WHPP, X</td>
</tr>
</tbody>
</table>

The class unrelated indicates that the sentence is not related to the claim made in the title, while agree and disagree refer to the sentence agreeing/disagreeing with the title, and finally discuss is assigned when the topic is the same as that in the title, but there is no stance. We further introduce the related class as the union of agree, disagree, and discuss. We use as features the binary classification labels and also the probabilities for these five classes.
3.2.3 Document-Level Prediction

If the document is likely to be propagandistic, then each of its sentences is more likely to contain propaganda. To model this, we use as a feature \( f^{doc} \) the score of the document-level propaganda classifier Proppy (Barrón-Cedeno et al., 2019a). Note that Proppy is trained on articles labeled using media-level labels, i.e., using distant supervision. Therefore, all articles from a propagandistic source are considered to be propagandistic.

4 Experimental Results

In this section, we present our experimental setup for interpretable propaganda detection and the evaluation results from our experiments. Specifically, we perform three sets of experiments: (i) in Section 4.1, we quantitatively analyze the effectiveness of the features we proposed in Section 3; (ii) in Sections 4.2 and 4.3, we compare our feature-based model to the state-of-the-art model described in (Da San Martino et al., 2019b) using the experimental setup from that paper; (iii) in Section 4.4, we analyze the performance of our model with respect to each of the 18 propaganda techniques.

4.1 Quantitative Analysis of the Proposed Features

Figure 2 shows the absolute value of the covariance between each of our features \( f \) and each of the 18 propaganda techniques \( T \). We calculated the values of the features on the training and on the development datasets, and we standardized their values. Then, we formulated this as a problem of calculating the covariance between continuous and Bernoulli random variables as follows:

\[
\text{cov}(f, T) = p \cdot (1 - p) \cdot (E[f|T = 1] - E[f|T = 0]).
\]

The total number of sentences used is 16,137 (for the training and for the development datasets, combined), among which there are 4,584 propagandistic sentences. In Figure 2, the vertical axis represents the proposed features, and the horizontal axis shows the individual propaganda techniques and the total number of instances thereof. Each square shows an absolute value of the covariance between some feature and some propaganda technique. We show absolute values in order to ignore the direction of the relationship, and we apply a threshold of 0.001 in order to remove the negligible relations from the figure.

Although the most frequent propaganda techniques appear in less than 10% of the examples, they do show qualitatively meaningful associations. Indeed, we do not expect a feature to correlate with multiple techniques, as they are fundamentally different. We believe that having features that strongly correlate with one technique might be an advancement towards detecting that technique.

We can see that the structural information \( f^{dp} \) and the sentiment of a sentence \( f^{sent} \) are closely associated with certain propaganda techniques. For example, Loaded Language has a strong correlation with features identifying words bearing either a positive or a negative sentiment. This makes sense as the authors are more likely to use emotional words rather than neutral ones, and Loaded Language aims to elicit an emotional response. Similarly, Doubt has high correlation with certain syntactic categories.

There are a number of interesting observations about the other features. For example, the relative position of sentences \( f^{rp} \) is associated with more than half of the propaganda techniques. Moreover, the similarity to the title \( f^{sim} \) and the stance with respect to the title \( f^{sts} \) are strongly correlated with the likelihood that the target sentence is propagandistic. The features that indicate whether a sentence is related to the subject of the title are complementary, and thus the covariances are the same when absolute values are considered.

4.2 Comparison to Existing Approaches

Table 3 shows a performance comparison for our model vs. existing models on the sentence-level propaganda detection dataset (Da San Martino et al., 2019b). This dataset consists of 451 manually annotated articles, collected from various media sources, and a total of 20,111 sentences. Unlike the experimental setting in the previous sections, the task here is a binary classification one: given a sentence, the goal is to predict whether it contains at least one of the 18 techniques or not. For the performance comparison, we used BERT (Devlin et al., 2019), which we fine-tuned for sentence-level classification using the Multi-Granularity Network (MGN) (Da San Martino et al., 2019b) architecture on top of the [CLS] tokens (trained end-to-end), as this model improves the performance for both tasks by controlling the word-level prediction using information from the sentence-level prediction and vice versa.

Table 4: Ablation study for our model on binary propaganda detection at the sentence level.

4.3 Ablation Study

Next, we performed an ablation study of the binary (propaganda vs. non-propaganda) model discussed in Section 4.2. The results are presented in Table 4. The values in the last row of the table, i.e., \(- f_{sent}\), are obtained by applying the document-level classifier, i.e., the feature \(f_{doc}\), to all sentences. We can see that the structural information about the sentence \(f_{dp}\) is the best feature for this task. This is due to the nature of some propaganda techniques that must have a specific sentence structure, such as Doubt. In addition, as described above, since there are many techniques related to inducing emotional responses in the readers, it can be understood that the sentiment of a sentence may be a good feature, e.g., for Loaded Language. These results are consistent with our findings in Section 4.1 above. Moreover, the novel features we devised based on a human behavioral study for propaganda detection \(f_{frp}, f_{sim}, f_{stn}\) improved the performance further. Overall, we can see in the table that all features contributed to the performance improvement.

4.4 Detecting the 18 Propaganda Techniques

For the experiments described in the following, we revert back to the task formulation in Section 2, but we perform a more detailed analysis of the outcome of the model: for a given article, the system must predict whether each sentence uses propaganda techniques, and if so, which of the 18 techniques in Table 1 it uses.

Table 5 shows the performance of our model on this task. We can see in the rightmost column that some techniques appear only in a very limited number of examples, which explains the very low results for them, e.g., for Red Herring and Straw Man. In an attempt to counterbalance the lack of gold labels for some of the techniques, we used sentence embeddings with the proposed features to capture more semantic information. Since this task is more challenging than the binary classification problem, we can intuitively expect a performance reduction, resulting in a weighted average F1 score of 42.88. However, this formulation of the problem has the advantage of providing more granular predictions, thus enriching the propaganda detection results.

---

We followed the original data split when training and testing the model, which is 14,137/2,006/3,967 for training/development/testing. We trained a Support Vector Machine (SVM) model\(^2\) using the above-mentioned features and we optimized the values of the hyper-parameters on the development dataset using grid search. We used an RBF kernel with gamma=\{1e-3, 1e-4\} and C=\{10, 100\}.

We can see in Table 3 that our proposed model, which is based on interpretable features, performs relatively well when compared to fine-tuned BERT without direct semantic information about the target sentence. While our model is not state-of-the-art by itself, we managed to outperform the existing models and to improve over the state of the art by simply adding to it sentence embeddings as features (Reimers and Gurevych, 2019), which were not fine-tuned on propaganda data. However, when the stance of the sentence and the embedding of the sentence are used together, performance decreases. This may be due to the two techniques based on semantic similarity being somewhat inconsistent.

A more fine-grained propaganda analysis was proposed by Da San Martino et al. (2019b), who developed a corpus of news articles annotated with 18 propaganda techniques which was used in two shared tasks: at SemEval-2020 (Da San Martino et al., 2020a) and at NLP4IF-2020 (Da San Martino et al., 2019a). Subsequently, the Prta system was released (Da San Martino et al., 2020c), and improved models were proposed, addressing the limitations of transformers (Chernyavskiy et al., 2021). The Prta system was used to perform a study of COVID-19 disinformation and associated propaganda techniques in Bulgaria (Nakov et al., 2021a) and Qatar (Nakov et al., 2021b). Finally, multimodal content was explored in memes using 22 fine-grained propaganda techniques (Dimitrov et al., 2021a), which was also used in a SemEval-2021 shared task (Dimitrov et al., 2021b).

6 Conclusion and Future Work

We proposed a model for interpretable propaganda detection, which can explain which sentence in an input news article is propagandistic by pointing out the propaganda techniques used, and why the model has predicted it to be propagandistic. To this end, we devised novel features motivated by human behavior studies, quantitatively deduced the relationship between semantic or syntactic features and propaganda techniques, and selected the features that were important for detecting propaganda techniques. Finally, we showed that our proposed method can be combined with a pre-trained language model to yield new state-of-the-art results.

In future work, we plan to expand the dataset by creating a platform to guide annotators. The dataset will be updated continuously and released for research purposes. We also plan to release an interpretable online system, with the aim to foster a healthier and safer online news environment.

Abstract

Encoder-decoder models have been commonly used for many tasks such as machine translation and response generation. As previous research reported, these models suffer from generating redundant repetition. In this research, we propose a new mechanism for encoder-decoder models that estimates the semantic difference of a source sentence before and after being fed into the encoder-decoder model to capture the consistency between two sides. This mechanism helps reduce repeatedly generated tokens for a variety of tasks. Evaluation results on publicly available machine translation and response generation datasets demonstrate the effectiveness of our proposal.

1 Introduction

Sequence-to-sequence (seq2seq) models are a dominant paradigm in various natural language generation tasks, such as machine translation (Luong et al., 2015b; Tu et al., 2016), text summarization (Kiyono et al., 2018; Li et al., 2017), and response generation (Miller et al., 2017; Pasunuru and Bansal, 2018). As Mi et al. (2016) reported, however, basic seq2seq models (Bahdanau et al., 2015; Luong et al., 2015b) sometimes suffer from a repetition problem. One reason is that the attention mechanism does not explicitly consider which source side tokens have already been covered in the past attentions. As a result, the encoder repeatedly attends to the same token in the decoding steps, which leads to redundant generation.

Many researchers have proposed variants of the seq2seq model to tackle the problem. The coverage mechanism (Tu et al., 2016; Mi et al., 2016) prevented the model from generating redundant outputs by taking into account the coverage of the attention distribution. These approaches can be easily incorporated into the seq2seq model with only a single attention distribution between the encoder and the decoder. However, for seq2seq models with multiple attentions, such as Transformer (Vaswani et al., 2017), we cannot calculate the coverage of attentions, because the encoder attempts to attend to multiple attentions on each layer in the decoder. Thus, it is challenging to incorporate the coverage mechanism into the multi-attention based seq2seq models.

As another solution, Suzuki and Nagata (2017) proposed word-frequency estimation (WFE) that predicts the upper-bound frequency for each output token from the given input tokens to control redundancy in the output. Furthermore, Kiyono et al. (2018) proposed a source-side prediction module (SPM) that estimates the occurrences of input tokens from the hidden states of the decoder in the seq2seq model to reduce repetition. While WFE and SPM have an advantage in not depending on the structure of a seq2seq model, it is difficult to apply these approaches to some tasks other than text summarization because WFE and SPM assume that the input sentence contains more tokens than the output.

To cope with the above problems, in this work, we propose a generic approach for reducing the repetition, focusing on the differences between the embedding spaces of the source and target sides. Based on the assumption of distributional semantics, our approach regards the representations of an input sentence on both sides as word vectors, and attempts to minimize their difference during the training step. Hence, the seq2seq model can explicitly take into account the source side context also in the decoder.

Our experimental results on the IWSLT 2014 German-to-English translation task (Cettolo et al., 2014) and the PERSONA-CHAT response generation task (Zhang et al., 2018) showed that the proposed method effectively alleviates the repetition
problem for both tasks.

2 Seq2seq Model

Given a source sentence \( X = \{x_1, ..., x_I\} \), the seq2seq model generates a target sentence \( Y = \{y_1, ..., y_J\} \), where \( I \) and \( J \) are the numbers of source and target tokens, respectively. The seq2seq model consists of two main parts: encoder and decoder. The encoder computes the representation of a source sentence \( X \), and the decoder generates a target sentence by decomposing the conditional probability:

\[
p(Y|X) = \prod_{j=1}^{J} p(y_j|y_{<j}, X).
\]

(1)

3 Repetition Reduction Module

3.1 Overview

An overview of our proposed method, the repetition reduction module (RRM), is illustrated in Figure 1. We employ Transformer for both the encoder and decoder in the explanation in this section. Let \( \tilde{x} \) be the target side sentence representations of source sentence \( X \). With RRM, inspired by Kiyono et al. (2018) and Luong et al. (2015a), we consider \( \tilde{x} \) as the correct representation of \( X \) and try to reconstruct \( \tilde{x} \) in the target side. We use \( \tilde{q} \) to represent the reconstructed \( \tilde{x} \). Then the seq2seq model predicts not only the target side sequence \( Y \) but also \( \tilde{x} \). The prediction is written as follows:

\[
p(Y, \tilde{x}|X) = p(\tilde{x}|Y, X)p(Y|X).
\]

(2)

The conditional probability \( p(\tilde{x}|Y, X) \) has the role of preventing either over- or under-generation of \( Y \) by predicting the source side context until the decoding step ends. \( p(\tilde{x}|Y, X) \) can be simplified as \( p(\tilde{x}|X) \) if \( \tilde{q} \) does not depend on \( Y \). Since \( p(Y|X) \) is predicted by the seq2seq model as shown in Eq. (1), we give details of \( p(\tilde{x}|Y, X) \) in the next section.

3.2 Prediction of Source Side Context

Instead of using count-based discrete representations as in Kiyono et al. (2018), we incorporate continuous representations for both source and target sides to capture deeper semantic relations (Mikolov et al., 2013). We assume \( p(\tilde{x}|Y, X) \) is proportional to the similarity between the representations of the source sentence \( X \) before and after being encoded and decoded:

\[
p(\tilde{x}|Y, X) \propto \exp(\alpha(\cos(\tilde{x}, \tilde{q}))),
\]

(3)

where \( \alpha \) is a scaling factor.

Next, we explain the representations of the source sentence \( X \) in the source and target sides. Letting \( V_s \) be the source vocabulary, we define the indicator vector for the presence of source tokens as \( x_i \in \{0, 1\}^{\mid V_s \mid} \). The source side representation \( \tilde{x} \) of the source sentence is defined as follows:

\[
\tilde{x} = \sum_i E_{src} x_i,
\]

(4)

where \( E_{src} \in R^{H \times \mid V_s \mid} \) is a word embedding matrix for the source vocabulary, and \( H \) is the embedding size.

Similarly, we define the target side representation \( \tilde{q} \) of the source sentence as follows:

\[
\tilde{q} = \sum_j E_{src} q_j,
\]

(5)

where \( q_j \in R^{\mid V_s \mid} \) represents the probability distribution over the source vocabulary \( V_s \) at the \( j \)-th decoding step, which is calculated as follows:

\[
q_j = SoftMax(W_q \tilde{z}_j + b_q),
\]

(6)

where \( \tilde{z}_j \) is the final hidden state from the decoder, \( W_q \) is a weight matrix, and \( b_q \) is a bias term. Note that this softmax layer is only used in the training step.

3.3 Objective Function

By considering the negative log-likelihood of Eq. (2), we can induce our objective function \( G_t \) as follows:

\[
G_t = \sum_{(X,Y) \in D} \{ -\log p(Y|X) - \alpha(\cos(\tilde{x}, \tilde{q})) \},
\]

(7)

where \( D \) is a parallel training corpus.

4 Experiments

4.1 Experimental Settings

We first used the IWSLT 2014 German-to-English translation task to evaluate our method. The dataset is split into 160k/7k/7k sentences for training, validation, and test. Since Cho et al. (2014) reported that seq2seq models tend to produce few unknown tokens and yield high BLEU scores for short sentences in the neural machine translation task, we supposed longer sentences are vulnerable to be
over-translation, and our proposal would perform better for longer sentences. Therefore, we divided the test data into 3 parts: Short, Medium, and Long. In Short with 4927 pairs, the source contains no more than 25 byte pair encoding (BPE) (Sennrich et al., 2016) tokens. In Medium with 1524 pairs, the source contains 26 to 50 BPE tokens. In Long with 299 pairs, the source contains more than 50 BPE tokens.

We used PERSONA-CHAT for response generation as another dataset. This is the official dataset of The Conversational Intelligence Challenge 2 (ConvAI2) for testing chatbots. It contains 164k/15k/15k utterances (corresponding to 10k/1k/1k dialogs) for training, validation, and test. It also contains corresponding persona information for each dialog.

We used the model of Fonollosa et al. (2019) as a baseline for the machine translation task. And we regarded the best performing model (Wolf et al., 2019) in ConvAI2 as our baseline for the response generation task. Wolf et al. (2019) adopted a Generative Pretrained Transformer (Radford et al.) based encoder and a 12-layer Transformer decoder, and concatenated the persona information, up to two turns of history utterances, and the query (the utterance) together as an input sequence. To investigate the effectiveness of our proposed module, we compared the experimental results between the models with and without RRM on top of the baseline models.

For evaluation metrics, we used tokenized BLEU (Papineni et al., 2002), Meteor (Denkowski and Lavie, 2014), and Repeat (Kiyono et al., 2018) for the machine translation task. Repeat is defined as follows. Following the definition by Kiyono et al. (2018), we think that a model causes a repetition if it outputs the same token more than once. For each pair of a generated translation and its corresponding reference in the dataset, while we considered some tokens might occur more than once in the reference, Repeat was computed by subtracting the frequency of tokens in the reference from the frequency of tokens that occur more than once in the generated translation.

For the response generation task, we used the official evaluation metrics, F1 and Perplexity. Note that the official method, offered by ParlAI (Miller et al., 2017), ignores words \{a, an, the\} and punctuation when computing F1. To compute Perplexity, Wolf et al. (2019) indirectly predicted the word probability on the basis of the ratio of probabilities of subwords since they utilized a BPE vocabulary.

Different from the machine translation task, the response generation task has no fixed answer. Therefore, in this task, we ignored the reference sequence when we computed Repeat. For each generated sequence, Repeat was computed by subtracting 1 from the frequency of tokens that occur more than once in the generated sequence. While ignoring the words \{a, an, the\} and punctuation, we calculated Repeat scores under an n-gram setting at sentence-level and dialog-level. At the sentence-level, we calculated Repeat only with each generated response. At the dialog-level, we calculated Repeat with the concatenation of a sequence of the generated responses in a dialog.

For the machine translation task, we followed the experimental settings of Fonollosa et al. (2019),

---

\[^{1}\text{http://convai.io/}\]
and tuned the scaling factor $\alpha$ in Eq. (7) with Repeat as the evaluation metric on the validation dataset. For the response generation task, we carried on the experimental settings of Wolf et al. (2019), and tuned the scaling factor $\alpha$ with Repeat (Sentence-Level) under 1-gram as the evaluation metric on the validation dataset. See Appendix A for a complete list of hyperparameter settings.

### 4.2 German-to-English Results

Table 1 shows the experimental results for the German-to-English translation task. The results suggest that combining RRM with the model of Fonollosa et al. (2019) helps to improve Repeat, BLEU, and Meteor scores.

Next, we compared the experimental results for Short, Medium, and Long to investigate the effectiveness of RRM at different source sentence lengths. Table 2 summarizes the experimental results. Similar to the results from Cho et al. (2014), both models tended to have lower BLEU scores and more repetitions for longer sentences. RRM performed relatively well for longer sentences. It reduced more repetitions and improved more BLEU on top of Fonollosa et al. (2019) for longer sentences. While RRM ($\alpha = 0.3$) showed no effect in reducing the repetition for short sentences, it assisted the model of Fonollosa et al. (2019) in reducing the Repeat score by 0.335 points and improved BLEU by 0.25 points for long sentences. These results suggest the importance of RRM for long sentences.

In Table 3, we list top and bottom 20 words based on the degree of Repeat reduction by RRM ($\alpha = 0.3$). These results show that RRM tended to reduce repetitions for high frequency words. RRM showed no effect of reducing repetitions for “.” and “&apos;s.” See Appendix B for sample translations.

### 4.3 Response Generation Results

Tables 4 and 5 show the experimental results for the response generation task. Obviously, RRM reduced Repeat (Sentence-Level) by 0.056 (1-gram), and Repeat (Dialog-Level) by 0.471 (1-gram). The results suggest that combining RRM with the model of Wolf et al. (2019) helps to improve F1 and Repeat, while the performance of RRM in reducing perplexity is limited. We suppose that there are two reasons. One is that the probability calculation method offered by Wolf et al. (2019) is an indirect method. The other is that, the response is not fixed for a given source. See Appendix C for a sample dialog.

We conducted extensive experiments to investigate whether RRM has a potential to reduce more repetitions by considering the following conditions. First, beam search is an optimized decoding method which generates less repetitions than greedy decoding, and it may limit the performance of RRM. We investigate whether decoding methods might influence the performance of RRM by comparing beam search with greedy decoding.

Second, Wolf et al. (2019) used the persona information and the history utterances as an input sequence for their model to generate a response that differs from the history and contains a part of the persona information. However, in this task our model shared its vocabulary between source and target sides, and in Eq. (3) we utilized the cosine similarity to force $\mathbf{q}$ to be similar to $\mathbf{\tilde{x}}$, which may make the generated response similar to the input sequence. Therefore, we investigate whether using history utterances in the input sequence during testing might influence the performance of RRM. “w/o

Table 5: Experimental results on the PERSONA-CHAT test dataset. **Bold** indicates the best scores. Results were the average over 3 runs by random seeds. $\alpha$ was fixed to 0.3, that yielded the best with Repeat (Sentence-Level) under 1-gram on the validation dataset.
to producing more repetitions at the sentence-level and hence more repetitions at the dialog-level. We therefore investigated whether using the persona information and the history utterances in Eq. (4) during training influences the performance of RRM. Full indicates the usage of the persona information, the history utterances and the query as a source in Eq. (4) during training, while part indicates the usage of only the query. We also tried the setting divide, which divides the input sequence in Eq. (4) into three parts, $\bar{x}_p, \bar{x}_h, \bar{x}_l$, depending on the persona information, the history utterances and the query, and uses the corresponding $W_{qp}, W_{qh}, W_{ql}$ in Eq. (6) to compute $q_p, \tilde{q}_h, \tilde{q}_l$ respectively. Then, the averaged cosine similarity was calculated between each divided $\bar{x}$ and $\tilde{q}$.

Tables 6 and 7 show the results of our extensive experiments. Clearly, RRM reduced more repetitions and improved F1 scores more when using beam search and the full setting. When the input sequence excluded history utterances during testing, RRM performed worse in F1 scores. Using only the query (part) in Eq. (4) during training reduced more repetitions at the sentence-level than using a full input sequence (full) when the input sequence excluded the history. But under other settings, RRM performed best when full was used. divide setting was the worst among the full, divide and part settings.

It indicates that our third supposition was wrong
and the part setting was unstable. We think the reason of such unstable performance is, when using the part setting, \( \tilde{q} \) and \( \tilde{x} \) in Eq. (3) were respectively generated from the full input sequence and only a part of the input sequence, which makes the information unbalanced.

The above results suggest that, when RRM was utilized, the method for combining multiple information for the input sequence was important. Furthermore, the decoding method would influence the performance of RRM.

5 Related Work

To overcome the repetition problem in neural machine translation, Tu et al. (2016) and Mi et al. (2016) introduced the coverage mechanism into a seq2seq model so that the decoder can pay attention to the encoder information without duplication. See et al. (2017) extended the coverage model by incorporating a pointer-generator network based on Tu et al. (2016). However, it is hard to utilize these coverage methods for multi-head attention based models because multi-head attention is a stack of several attention layers, and each layer is trained to capture its own distribution. Furthermore, the works of Tu et al. (2016) and Mi et al. (2016) are based on one-to-one correspondence generation, which cannot be applied to a “lossy” compression task such as summarization.

Suzuki and Nagata (2017) proposed word-frequency estimation (WFE) which used several linear transformations to map the hidden states of the encoder into the upper-bound occurrence of each target vocabulary and controlled the generation by the estimated occurrence. However, we cannot apply WFE for some generation tasks such as the response generation task, in which the frequency of target tokens is irrelevant to the source sentence. Kiyono et al. (2018) proposed a source-side prediction module (SPM) and assumed that output sentences are always shorter than input sentences (i.e., a summary or a headline of the input). To make sure the lengths of input and output sentences were equal, special \(< \text{pad} >\) tokens were added to the end of the target sentence. While this method helps SPM to estimate the over- or under-generation with the euclidean distance, it limits the application of SPM. Since our approach does not rely on the above assumptions, RRM is more scalable to other downstream tasks, including machine translation and response generation.

6 Conclusion

In this work, we proposed a novel mechanism to suppress repetitions in machine translation and response generation. Our model attempts to estimate the semantic vectors from a source sentence on both sides of an encoder-decoder model, which takes semantic repetitions into consideration and does not rely on any attention features. Therefore, it is potential to apply our proposal to other sequence-to-sequence models, which is an advantage of our approach compared with previous methods.

Experimental results on the IWSLT 2014 German-to-English translation task and the PERSONA-CHAT response generation task demonstrated the effectiveness of our proposal. The results of the extensive experiments in the response generation task showed RRM has the ability to handle a concatenated input sequence.

Because our proposal takes the semantic repetitions into consideration, we believe it might have the ability to reduce the repetitions among semantically similar words. We will verify it as future work.

References

A Hyperparameters

For the machine translation task, we followed the experimental settings of Fonollosa et al. (2019), which used fairseq (Ott et al., 2019) and a 31K-token BPE source and target vocabulary. For the hyperparameters of Transformer, we used 14 layers, an embedding size of 256, a feedforward expansion size of 1024, and 4 attention heads. We used the Adam (Kingma and Ba, 2015) optimizer with a 4k mini-batch size and 85k training steps. The learning rate was linearly warmed from $1 \times 10^{-7}$ to 0.001 in 4k steps and then decayed by a weight of 0.0001 (Loshchilov and Hutter, 2017). In the decoding steps, we used beam search (Wu et al., 2016) with a beam size of 5. We set the scaling factor $\alpha$ to \{1, 0.3, 0.2, 0.05, 0.01\} and selected the best $\alpha$ with Repeat as the evaluation metric on the validation dataset. We pretrained the model of Fonollosa et al. (2019) in advance to extract word embeddings.

For the response generation task, we carried on the experimental settings of Wolf et al. (2019). We utilized a 40k-token BPE source and target vocabulary and trained the model with 2 epochs, a batch size of 32 sequences, and the Adam optimizer. The learning rate was linearly decayed from $6.25 \times 10^{-5}$ to zero. In the decoding step, we adopted beam search, and top 20 sampling (Fan et al., 2018) was utilized before selecting four beams. We set the scaling factor $\alpha$ to \{1, 0.3, 0.2, 0.05, 0.01\}. Since RRM was designed to reduce repetitions at the sentence-level, we selected the best $\alpha$ with Repeat (Sentence-Level) under 1-gram as the evaluation metric on the validation dataset.

B Sample of German-to-English

Table 8 shows sample translations. While the model of Fonollosa et al. (2019) tended to generate repeating phrases, our model reduced such generation.

C Sample of Response Generation

We show a sample dialog in Table 9. Similar to the machine translation task, the model of Wolf et al. (2019) tended to generate repeating phrases, and our model helped to alleviate it. In particular, “i’m a real estate agent” in the second turn is a 5-gram repetition of the one in the first turn at the dialog-level when word “a” is ignored. “they are twins” in the third turn is a 3-gram repetition at both dialog-level and sentence-level because it is generated twice in a response.
the only real choice was who, not when, and not what you did after.

so we take something very complicated, we turn it into sound, a sequence of sound, and we produce something very complicated in the head of others.

it &apos;s a process, and sometimes it works and sometimes it doesn &apos;t. but the idea that we should not allow science to do its job because we &apos;re afraid, is really very deadening, and it &apos; s preventing millions of people from prospering.

Table 8: Sample translations for Short, Medium, and Long data. Underline indicates repetitions that contain more than two words, and bold indicates wrong translations. \( \alpha \) was fixed to 0.3, that yielded the best with Repeat on the validation dataset.

Table 9: Sample responses generated by various models. Underline indicates repetitions that contain more than two words, and bold indicates their counterparts. A turn is a pair of a query (an utterance) and its response (either a reference or a generation). In this example, a sequence of the three turns consist of a part of a dialog. When a model tries to output a response to the third query, the first and second turns are the history utterances, and it receives the concatenation of the persona information, the history utterances and the third query as an input. \( \alpha \) was fixed to 0.3, that yielded the best with Repeat (Sentence-Level) under 1-gram on the validation dataset.
Knowledge Distillation with BERT for Image Tag-Based Privacy Prediction

Abstract

Text in the form of tags associated with online images is often informative for predicting private or sensitive content from images. When using privacy prediction systems running on social networking sites that decide whether each uploaded image should get posted or be protected, users may be reluctant to share real images that may reveal their identity, but may share image tags. In such cases, privacy-aware tags become good indicators of image privacy and can be utilized to generate privacy decisions. In this paper, our aim is to learn tag representations for images to improve tag-based image privacy prediction. To achieve this, we explore self-distillation with BERT, in which we utilize knowledge in the form of soft probability distributions (soft labels) from the teacher model to help with the training of the student model. Our approach effectively learns better tag representations with improved performance on private image identification and outperforms state-of-the-art models for this task. Moreover, we utilize the idea of knowledge distillation to improve tag representations in a semi-supervised learning task. Our semi-supervised approach with only 20% of annotated data achieves similar performance compared with its supervised learning counterpart. Last, we provide a comprehensive analysis to get a better understanding of our approach.

1 Introduction

With the rapid growth of the number of users on online social networking sites, image privacy has become a major concern (Ahern et al., 2007; Squicciarini et al., 2017). Users may accidentally disclose their sensitive information such as locations, habits or personal relationships from images that they post to their social networking sites (Squicciarini et al., 2017), which could be used in the detriment of the users (Tonge and Caragea, 2020). Zerr et al. (2012a) defines private images as ones that belong to the private sphere (e.g., portraits, family, home) or capture sensitive contents that can not be shared with everyone on the Internet. The remaining images are considered to be public. Binary image privacy classifiers are developed (Tonge and Caragea, 2018; Yang et al., 2020; Zerr et al., 2012a) aiming to identify whether images belong to the public class or the private class. However, the access to the image content is not always allowed since users may be reluctant to share the real images (revealing user’s identity through the face, and friends, etc.) for visual content analysis. In such cases, tags attached by users to describe their images are found to be informative about the image contents and are good indicators of the privacy settings and improve the privacy prediction methods (Tonge et al., 2018). Privacy prediction models trained with image tags achieve competitive results compared with vision-based privacy prediction models (Squicciarini et al., 2017). Therefore, our goal is to learn good tag representations for images to further improve the performance of tag-based privacy prediction.

Pre-trained language models have been extensively studied in NLP communities (Howard and Ruder, 2018; Devlin et al., 2019; Peters et al., 2018; Liu et al., 2019). BERT (Devlin et al., 2019) is a pre-trained language model based on a multi-layer bidirectional Transformer, and has shown to be effective for generating universal language representations and attains state-of-the-art performance on many natural language processing tasks (Dai and Callan, 2019; Adhikari et al., 2019). In our work, we fine-tune BERT for the task of tag-based image privacy prediction to generate better tag representations. In addition, we propose to use self knowledge distillation with BERT (Hinton et al., 2015; Clark et al., 2019; Zhang and Sabuncu, 2020) to further improve the performance of tag-based
privacy prediction. Specifically, we first train a BERT (Devlin et al., 2019) teacher model for privacy prediction, and then train a BERT student model using both class labels and the pre-trained teacher model’s output probability distributions. The student model can thus learn from not only the ground truth class information, but also how to assign compatible probabilities according to various input examples. Experimental results show that knowledge distillation effectively improves tag representations and achieves boosted prediction performance.

Moreover, training a classifier often requires a large amount of annotated data. However, the annotation process is very time consuming and requires a significant human effort in many cases (Deng et al., 2009). Thus, we investigate knowledge distillation in a semi-supervised learning approach (Xie et al., 2020). To do this, we first train a BERT teacher model using limited amount of labeled image tags, and use it to annotate a large amount of unlabeled data, which is further used to train another BERT student model for privacy prediction. Experimental results show that our semi-supervised approach with BERT learns good tag representations and achieves comparable performance with its supervised counterpart with only 20% annotated image tags.

Last, we provide a comprehensive analysis for our tag-based privacy prediction. First, we perform a calibration analysis to show that models trained by improved tag representations with knowledge distillation yield better calibration (the alignment between prediction confidence and correctness likelihood (Guo et al., 2017)). Second, neural models are sensitive to small perturbation in the input and a small perturbation on the input may fool a well-trained neural network (Hsieh et al., 2019; Belinkov and Bisk, 2018; Niu et al., 2020). We analyze the robustness of our privacy classification models trained by tag representations learned with knowledge distillation against adversarial attacks. The results show that our approach shows the most robustness against adversarial attacks over compared baselines. Third, we perform a statistical analysis on the correlation between the privacy and sentiment and emotion of image tags.

2 Related Works

Knowledge distillation. Knowledge distillation is originally proposed as a model compression method (Buciluă et al., 2006; Hinton et al., 2015). The standard knowledge distillation scheme transfers knowledge from a larger pre-trained “teacher” model to a smaller “student” model by training the student to mimic the class probability distributions generated by the teacher (Hinton et al., 2015). Recently, other works propose self-distillation (Furlanello et al., 2018; Clark et al., 2019): the teacher and the student have identical architectures, which achieve remarkable improvement on the student over the teacher. Zhang and Sabuncu (2020) experimentally demonstrate that the improvement of knowledge-distillation is correlated to the instance-level regularization on the student’s softmax outputs, meaning that by mimicking teacher’s probability distributions, instead of simply being trained to mimic one-hot class labels, the student are trained to assign compatible confidence (probabilities) according to the corresponding input examples. Meanwhile, one interesting focus of research on knowledge distillation has been on finding new applications. Chen et al. (2020) use the idea of knowledge distillation on BERT for text generation. Kim and Rush (2016) introduce knowledge distillation for sequence modeling. In contrast, we propose to utilize knowledge distillation as a tool to learn better tag representations for online images and to achieve improved performance for tag-based image privacy predictions.

Image privacy prediction. Most machine learning-based image privacy prediction models utilize images to train vision-based classification models to detect image privacy (Tran et al., 2016; Yang et al., 2020; Zerr et al., 2012b; Buschek et al., 2015). There are few works that adopt tags attached to describe images as indicators of image privacy and achieve competitive performance compared with vision-based approaches (Squicciarini et al., 2017). Further developing tag-based image privacy prediction approaches becomes a crucial direction for this task. Tonge and Caragea (2020) introduce TagCNN model based on the sentence classification CNN model (Kim, 2014) for image privacy prediction, where Word2Vec (Mikolov et al., 2013) is applied as the word embedding, and the CNN classifier is trained to predict image privacy. The bag-of-tags(BoT) model is introduced in (Tonge and Caragea, 2020) as another tag-based privacy prediction approach, where tags are embedded into multi-hot vectors similar to the bag-of-words embedding. Then a SVM classifier is trained for privacy detec-
tion. Previous tag-based works are trained using only the class labels. In contrast, we distill knowledge using BERT to utilize both hard class labels and soft probability distributions to improve tag representations and boost the performance of this task.

3 Methods

In this work, we adopt knowledge distillation with BERT to learn better tag representations for tag-based image privacy prediction. The idea behind knowledge distillation is that: soft probability distributions generated by a pre-trained image privacy prediction model carries additional privacy information compared with hard class labels. Specifically, hard labels can only reflect the class information (either private or public) of input image tags, while soft probability distributions can further reveal the confidence of the privacy classification model toward each prediction. A proper usage of such additional information, in combination with hard labels, can help learn better tag representations to boost the performance of tag-based image privacy prediction models. The goal of this work is to distill knowledge using BERT to transfer knowledge (in the form of soft probability distributions) from a strong, pre-trained BERT teacher model to a BERT student model to boost the performance of the latter for tag-based privacy prediction.

3.1 Knowledge Distillation with BERT

We first fine-tune a BERT (Devlin et al., 2019) as the teacher model for tag-based image privacy prediction. Given input image tags (x) for an online image, the teacher model generates a vector of scores, which is normalized to be the probability distribution of the two privacy classes: \( P_T = \text{softmax}(p_{\text{pub}}^T(x), p_{\text{pri}}^T(x)) \). As the first teacher model is trained using hard-labels, we adopt an temperature term \( T \) (Hinton et al., 2015) to ”soften” the probability distribution and avoid generating peaky probabilities: \( P_T = \text{softmax}(p_{T_{\text{pub}}}^T(x), p_{T_{\text{pri}}}^T(x))/T \). The teacher model is then trained using the cross-entropy loss:

\[
L_T = \text{CrossEntropy}(P_T, y) \tag{1}
\]

After that, we perform knowledge distillation from the trained teacher model to the student model. As shown in Figure 1, our goal is to teach the student model BERT_{student} to learn from both soft probabilities (soft labels) generated by the trained teacher model, and the class labels (hard labels). Therefore in the total loss function of the student model, we need to minimize the difference between the student’s predictions with both the ground truth hard label and the teacher’s predictions. BERT_{teacher} generates probability distributions \( P_T \) for input image tags x. The probability distribution generated by the student model BERT_{student} is denoted as \( P_S \). The training loss of the student model is the combination of the loss with the soft label \( P_T (L_{soft}) \) and the loss with the class label y \( (L_{hard}) \), where we use cross-entropy as loss functions. The above process can be denoted as:

\[
L_{soft} = \text{CrossEntropy}(P_S, P_T) \tag{2}
\]

\[
L_{hard} = \text{CrossEntropy}(P_S, y) \tag{3}
\]

\[
L_S = \alpha * L_{soft} + \beta * L_{hard} \tag{4}
\]

where \( \alpha \) and \( \beta \) are hyperparameters.

3.2 Semi-Supervised Learning Approach with BERT

While using more labeled data improves performance, manually annotating privacy of online images is very time consuming and requires human intensive effort. This motivates us to distill knowledge with BERT in a semi-supervised manner, where a BERT teacher model is first trained using a small portion of labeled data. The trained teacher is used to annotate the large portion of unlabeled data. Next, we integrate the data annotated by the trained teacher model and the originally labeled data as the overall training set to train a student model. The trained student model becomes the next teacher model and repeats the process.

We used 50\% of the whole training set \( D \) as the unlabeled set \( U \) and the rest set \( L \) is used to sample different fractions to be used as labeled data. In each experiment we randomly select \( l = L * k' = D * k \), a subset of \( L \), as the selected labeled set, which is used to train first teacher model. \( k = 0.5 * k' \) is a fraction parameter ranging from \([0\%, 50\%]\). Our semi-supervised learning process can be concluded as follows:

1. Train the initial teacher model \( T_0 \) with the selected labeled set \( l \).

2. Use the trained teacher model to annotate the unlabeled set \( U \). Then integrate \( l \) and
the annotated $U$ as the annotated training set: $A = I \cup U$.

3. Train the student model $S$ using $A$.

4. The student model $S$ becomes the new teacher model $T$. Go back to step (2).

4 Experiments and Results

4.1 Experimental Settings

**Dataset.** In this work, we use a dataset of 32,000 examples from PicAlert (Zerr et al., 2012a), which, to our knowledge, is the only publicly available dataset for online image privacy prediction that captures real privacy needs of current social networks’ users. Images and tags of PicAlert are crawled from Flickr and manually annotated by external viewers, who are instructed to mark images as “private” or “public” following the guidance: private images are defined as images belonging to private sphere or ones you do not want to share with everyone, and the rest are public (Zerr et al., 2012a). The dataset is randomly split into train set (22000), validation set (5000) and test set (5000). The public and private images are in the ratio of 3:1 in each set. Each experiment is repeated five times using five train/validation/test splits and averaged as the final result. We delete special characters in user tags and replace tags with occurrences lower than 2 with the keyword “(UNKNOWN)” as they may bring noises to the classification model (Tonge and Caragea, 2020).

**Model Configuration.** All models are implemented based on python 3.6 and Pytorch 1.3.1. For baseline models BoT and TagCNN, we apply the same hyper-parameters and network architectures suggested in (Tonge and Caragea, 2020). For BoT, we create a vector with the dimension of the vocabulary size and set 1 to the position of tags that exist in the image, and 0 otherwise (Tonge and Caragea, 2020). We fine-tune BERT with a learning rate of $2e^{-6}$ and the training batch size of 8. Hyper-parameters of BERT are selected on the validation set. We experiment different values weighting parameter $(\alpha, \beta)$ in Equation 4 and use $(0.7,0.3)$ for BERT$_{KD}$ as it shows the best performance. We also experiment with dynamically increase/decrease $\alpha$ and $\beta$ along with the training process but they do not show better performance.

**Research Questions.** In our work, we aim to validate tag representations learned by distilling knowledge with BERT for tag-based image privacy prediction. We address the following research questions:

1. How does the performance of the BERT-based knowledge distillation approach compared with state-of-the-art models for supervised tag-based image privacy prediction?

2. What is the performance of our semi-supervised learning approach and how does it compare with its supervised learning counterparts?

3. Whether tag representations learned with knowledge distillation yield better calibration (the alignment between prediction confidence and correctness likelihood) of models?

4. Can tag representations learned with knowledge distillation show stronger robustness against some adversarial attacks toward image tags?

5. How does the privacy of images tags correlate with tag emotions?

4.2 Experimental Results

In this section, we discuss the experimental results designed to address the research questions. We measure the performance using the $F_1$-score for each class as well as the weighted average $F_1$-score over both classes (private and public).

4.2.1 Research Question 1

Table 1 shows the performance of the knowledge distillation approach and the state-of-art tag-based image privacy prediction models. To fine-tune BERT, we add a fully connected layer after the [CLS] token of the last BERT layer and fine-tune the whole network. For knowledge distillation, we use BERT as the teacher model to transfer knowledge to another BERT (denoted as BERT$_{KD}$) and TagCNN (denoted as TagCNN$_{KD}$), respectively. We observe that BERT$_{KD}$ outperforms the state-of-the-art models on every compared metric especially on $F_{1\text{private}}$, yielding a large improvement upto 6.8%. We also notice that both knowledge distillation approaches effectively improve the $F_{1\text{private}}$ of corresponding student models. For example, TagCNN$_{KD}$ improves TagCNN by 2.5%. BERT$_{KD}$ boosts $F_{1\text{private}}$ of BERT by 1.7%, which further pushes BERT$_{KD}$ to be the new state-of-the-art model for tag-based image privacy prediction. Such results suggest the effectiveness of our knowledge distillation approach of bringing the knowledge of the soft probability distributions generated by the teacher model to the training process of the student and achieves boosted performance. Note that, TagCNN$_{KD}$ does not outperform its teacher, i.e., BERT. Which suggests that in our task, a more compact student model may not always outperform its teacher. Standard deviation results show that BERT-based approaches are more stable on compared metrics. Knowledge distillation can help generate more stable results.

4.2.2 Research Question 2

In our semi-supervised learning experiment, we use BERT as the initial teacher model and another BERT as the student model, denoted as BERT$_{KD}$. We consider a baseline that use TagCNN as student model, denoted as TagCNN$_{semi}^{KD}$. Moreover, we also experiment with TagCNN playing the role of both $T_0$ and $S$, denoted as TagCNN$_{base}$. Experiments are performed using different amount of labeled data $L$ (controlled by the percentage parameter $\alpha$). We randomly select $\alpha$ ranging from 0.25% to 100% of labeled data $L$. We repeat the student-teacher rotation 3 times and report the $F_{1\text{private}}$ of the student model in the last iteration. Results are shown in Figure 2, where we observe some trends of $F_{1\text{private}}$. Firstly, BERT$_{semi}^{KD}$ consistently show significant improvements over the two baseline approaches, yielding improvements upto 19.6%. Secondly, BERT$_{semi}^{KD}$ at $\alpha = 20\%$ achieves comparable performance with its supervised learning counterpart BERT$_{KD}$ trained with 100% labeled data, with only a small under-performance of 0.6%. In contrast, TagCNN$_{semi}^{KD}$ and TagCNN$_{semi-base}^{KD}$ always perform much worse than their supervised learning counterparts. This encouraging result illustrates that our semi-supervised knowledge distillation approach with BERT can still be serviceable even

4.2.3 Research Question 3

A well-calibrated classification model should be able to generate the probability of the predicted privacy class label (the confidence) which reflects its correctness likelihood (the accuracy) (Guo et al., 2017). In other words, a well-calibrated model should not only generate accurate predictions of image privacy, but should also “know what it does not know”, meaning that the model does not generate overly confident yet incorrect predictions. This is especially important for the task of tag-based image privacy prediction. For a privacy decision making system, so that if input image tags are misclassified to the wrong privacy class but with lower confidence, the system can pass the input example to the owner of the image to double-check as the privacy prediction model is not confident about its prediction (the privacy classification model “knows what it does not know”).

In this work, we first study the calibration of tag representations learned with TagCNN, TagCNN\textsubscript{KD}, BERT, and BERT\textsubscript{KD}. We then improve the calibration of compared models by performing post-hoc calibration for the predicted probabilities. Specifically, we adopt the temperature scaling (Desai and Durrett, 2020; Guo et al., 2017) to post-process model probabilities, where logits generated by compared models are divided by a temperature scaling term $T'$, which is optimized with respect to the cross-entropy loss on the validation set. Note that temperature scaling does not affect the model’s accuracy. To evaluate the calibration of model predictions, we use the expected calibration error (ECE), which is defined as the weighted average of the difference between accuracy and confidence in $m$ equally-partitioned confidence bins (Guo et al., 2017), where $m$ is commonly selected to be 10. Results are shown in Table 2, where we observe that tag representations learned with knowledge distillation improves model calibration for both TagCNN and BERT: ECE scores are reduced by upto 2.62%, suggesting that soft-labels from the teacher model alleviate the overconfident issue caused by hard labels. Interestingly, we also notice that BERT exhibits higher ECE than TagCNN. This is because BERT has much higher learning capacity than TagCNN. During training, after BERT is trained to correctly classify almost all training samples, the model is able to further increases its confidence towards predictions to achieve lower training loss, while TagCNN can not perform such further optimization due to its limited learning capacity. Thus BERT achieves better prediction accuracy, but result in larger ECE (Guo et al., 2017) compared with TagCNN. We also observe that temperature scaling effectively calibrates both BERT and TagCNN with significantly reduced ECE (Guo et al., 2017).

We also plot the reliability diagrams (Guo et al., 2017; Desai and Durrett, 2020) in Figure 3 to better visualize the alignment between the accuracy and the confidence of compared models. The black dashed diagonal represents the optimal calibration when the accuracy always equals the confidence. We can observe that for both CNN and BERT, tag representations learned with knowledge distillation consistently bring model calibration closer to the optimal line. After temperature-scaling, calibration of all compared models are further optimized.

4.2.4 Research Question 4

We explore the robustness of tag representations learned with knowledge distillation model against two types of adversarial attacks (Hsieh et al., 2019). The goal of a success attack is to fool the model to give the false privacy prediction by replacing one tag in the original input image tags. In this work we consider two types of attacks.
(a) Calibration without temperature scaling.
(b) Calibration results with temperature scaling.

Table 4: Emotion distributions of tags attached to private and public images.

**Random Attack.** This type of attack randomly select one image tag and replace it with another word that is randomly selected from the vocabulary of the dataset.

**Synonym-based Attack** Randomly selecting the word to replace from the vocabulary may change the meaning too much (e.g. replace "good" with "bad") which is not considered as good attacks (Hsieh et al., 2019; Niu et al., 2020). We explore the synonym-based attack: image tags are replaced by one of their synonyms. Particularly, for each image, we start by replacing the first tag with its synonyms. If none of the attacks successfully fool the model, we move to the next tag with the previous tag unchanged. This process is repeated until either the attack succeeds or all tags have been exhausted.

Experimental results addressing research question 3 are shown in Table 3. We evaluate the robustness of TagCNN, BERT, TagCNN$_{KD}$, and BERT$_{KD}$ that have been well-trained for the supervised learning task in Section 4.2.1 against adversarial attacks. As suggested in (Hsieh et al., 2019), we randomly pick 100 examples from the test set that all models correctly predict, based on which we generate adversarial attacks. For random attacks, we repeat the process by $10^3$ times and calculate the average as the final performance. For the synonym-based attack, all synonyms are selected from WordNet. From Table 3 we observe that tag representations with knowledge distillation approach improve the robustness of BERT and TagCNN against the two types of adversarial attacks, especially for the private class. Moreover, we also notice that TagCNN$_{KD}$ does not show stronger robustness than its teacher model BERT, whereas BERT$_{KD}$ outperforms BERT. This result further suggests the advantage of self-distillation on BERT.

### 4.2.5 Research Question 5

We perform analysis to study the correlation between the privacy (private or public) and the emotion of image tags. Precisely, we observe the distributions of tags with various emotions for both the private and the public class to understand whether tags with certain emotions are more often used in private or public images and the underlying reasons behind it. We use the NRC Emotion lexicon (Mohammad and Turney, 2013), a lexicon of 10,000 words, each is associated with one of the eight emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) and two sentiments (negative and positive). In our experiment, we first randomly select the same number of private and public images (7000 for each class), and find common tags that exists in both image tags and NRC lexicon. The distribution of tags with eight emotions in both the private and the public class is shown in Table
Table 5: Examples of private and public images and corresponding tags associated with various emotions. Tags with specific emotions are colored in red.

</tr>
</tbody>
</table>

Table 6: Positive and negative emotion distributions of tags in private and public images.

4, where we observe that tags with emotions of trust, joy, and disgust are more often used to depict private images, while tags with fear and surprise emotions are more often attached to public images. Emotions of sadness, anticipation, and anger do not show obvious bias towards either privacy class.

Next, we look into some examples to better understand the underlying reasons behind such correlations. Examples of online images with tags of various emotions are shown in Table 5. We observe that the tag "innocent" with the emotion of trust is often used to depict images about children, which in many cases are considered as private images. Tags such as "messy" with the disgust emotion is often attached to images with indoor environments, which are ones that more often bias towards the private side. In contrast, tags such as "marvel" and "caution" with emotions of surprise and fear, respectively, are more often used to describe public constructions or signs, and thus are more often used in public images.

Moreover, we also analyze the distribution of tags with positive and negative sentiments for the private and the public class. Results are shown in Table 6, where we observe that tags with positive sentiments takes higher percentage in private images over public images.

5 Conclusion

In this work, we explore learning tag representations with knowledge distillation approach based on BERT for tag-based image privacy prediction. Our approach significantly outperforms the state-of-art models for tag-based image privacy prediction. We also perform a BERT-based semi-supervised learning approach using only a small amount of annotated data, where BERT achieves comparable performance with its supervise counterpart with only 20% of labeled data provided. Moreover, we also perform calibration analysis and show that tag representations learned with knowledge distillation yield better calibration. We also study the robustness of our learned tag representations against some adversarial attacks for image tags. Our results show that our approach show stronger robustness over compared baselines against random and synonym-based attacks. Last, we analyze the correlation between the privacy and the emotion of image tags and use some examples in the PicAlert dataset (Zerr et al., 2012a) to help us understand the underlying reasons.

Our future direction is to integrate deep CNN models for image processing with BERT to develop a multi-modal image privacy prediction model with both images and tags as inputs.

Delexicalized Cross-lingual Dependency Parsing for Xibe

He Zhou and Sandra Kübler
Indiana University
{hzh1, skuebler}@iu.edu

Abstract

Manually annotating a treebank is time-consuming and labor-intensive. We conduct delexicalized cross-lingual dependency parsing experiments, where we train the parser on one language and test on our target language. As our test case, we use Xibe, a severely under-resourced Tungusic language. We assume that choosing a closely related language as the source language will provide better results than more distant relatives. However, it is not clear how to determine those closely related languages. We investigate three different methods: choosing the typologically closest language, using LangRank, and choosing the most similar language based on perplexity.

We train parsing models on the selected languages using UDify and test on different genres of Xibe data. The results show that languages selected based on typology and perplexity scores outperform those predicted by LangRank; Japanese is the optimal source language. In determining the source language, proximity to the target language is more important than large training sizes. Parsing is also influenced by genre differences, but they have little influence as long as the training data is at least as complex as the target.

1 Introduction

For a severely low-resource language, constructing a dependency treebank is labor-intensive and time-consuming, and annotators are difficult to find. Expanding a small treebank via monolingual dependency parsing leads to suboptimal results since we lack enough training data to train a reliable parser. This situation has led to an increasing interest in techniques for supporting low-resource languages by taking advantage of high-resource languages together with methods for cross-lingual transfer (Meechan-Maddon and Nivre, 2019). This is facilitated by the Universal Dependencies (UD) project, which has resulted in a treebank collection covering a wide range of language, with the goal of facilitating multilingual parser development (Nivre et al., 2020). The latest release (v2.7) covers 183 treebanks in 104 languages (Zeman, 2020). In our current work, we carry out preliminary single-source cross-lingual delexicalized dependency parsing experiments for the Xibe language. With this method, we train a parser on the treebank of one source language and parse the target language, with both treebanks delexicalized to abstract away from lexical differences between the two languages.

Choosing the source language is crucial for single-source cross-lingual parsing. The optimal source language needs to be syntactically close to the target language as well as high-resourced. However, it is not obvious how to select this language. We investigate three methods for selecting the source language: We compare LangRank (Lin et al., 2019) and typology, and we investigate whether using perplexity as a similarity metric can approximate typological knowledge. Then we investigate whether the size of the source treebank or a genre mismatch affect the quality of the parser.

The remainder of this paper is organized as follows: Section 2 provides a short overview of Xibe syntax. In Section 3, we describe our research questions in more detail. In Section 4, we briefly summarize methods of cross-lingual transfer. The experimental settings are introduced in Section 5. We then explain the methods for selecting source languages in Section 6, and in Section 7, we discuss our results. We conclude in Section 8.

2 The Xibe Language and Treebank

Xibe is a Tungusic language. There are twelve languages in the Tungusic language family spoken in
Central and Eastern Asia, but the numbers of Tungusic speakers have never been large (Robbeets and Savelyev, 2020). The language of Xibe is the one with a comparatively larger amount of active speakers in the whole language family.

Xibe shares morphological and syntactic features with other transeurasian languages. The transeurasian languages have a very rich system of case marking through the use of affixes (or particles in Japanese and Korean). All transeurasian languages are head final, they use verb-final word order, and attributes, complements, and adjuncts precede their headwords. In Xibe, clausal constituents have a rigid Subject-Object-Verb (SOV) word order, and all phrasal categories are consistently head-final. Like other Tungusic languages, Xibe has agglutinative morphology, which mainly focuses on verbs in that verbs are marked for tense, aspect, mood and voice, as well as convers and participles.

Zhou et al. (2020) describe a Xibe treebank annotated in the Universal Dependencies framework, containing 810 trees. Figure 1 shows an example Xibe dependency tree. The matrix predicate is at the sentence final position with the object and oblique constituent, marked by corresponding case markers, preceding the verb and the present tense suffix -mbi attached to the verb root.

### 3 Research Questions

Our research focuses on cross-lingual dependency parsing using a single target language and concentrates on determining the best method to select the optimal source language. More specifically, we investigate the following questions.

**Question 1** What are the most important factors to consider when choosing the best source language(s)? We investigate three methods: one uses typological knowledge, the second uses LangRank (Lin et al., 2019), a machine learning approach to rank languages based on their relatedness. The third method uses POS n-gram perplexity to determine similarity between languages. Here, our goal is to determine whether perplexity can be used to model typological knowledge.

**Question 2** Ideally, an optimal source language should be closely related to the target language as well as high-resourced, since we need a sizable treebank that can be used for training the parser. However, is a large treebank size more important than syntactic similarity with the target language in delexicalized dependency parsing?

**Question 3** The Xibe treebank includes sentences from two different genres, grammar examples and news whereas most UD treebanks contain multiple written genres. Considering that the performance of the parsing models trained on one domain degrades on sentences drawn from a different domain (McClosky et al., 2010), we assume that this happens in our setting as well. Therefore, we investigate how a parser trained on multiple genres performs on the two target language genres. Is the mixture of genres in the source data robust enough to cover both of our target genres?

### 4 Related Work

Cross-lingual transfer learning has been useful in improving the accuracy of a low-resource target language and has been applied in a multitude of tasks (Lin et al., 2019). The process of cross-lingual transfer learning refers to resources and models from high-resource source languages to low-resource target languages on different levels.

There are four main cross-lingual parsing approaches for dependency parsing: annotation projection (Yarowsky et al., 2001; Hwa et al., 2005), model transfer (Zeman and Resnik, 2008; McDonald et al., 2011), treebank translation (Tiedemann et al., 2014; Tiedemann and Agić, 2016), and multilingual parsing models (Duong et al., 2015b; Ammar et al., 2016; Kondratyuk and Straka, 2019). The annotation projection approach requires parallel treebanks of both source language and target language, and the treebank translation approach requires a machine translation system, while in the
model transfer approach, models trained on source language treebanks are directly applied to parse target languages. A multilingual parsing model is either a model trained on one source language which is refined by taking advantage of similar structures shared with the target language, or a multilingual model using multilingual word clusters and embeddings or language-specific features.

The main challenge for cross-lingual parsing is to reduce the language discrepancies on different levels between the source language and the target language. To reduce the great differences in writing systems and vocabulary, Zeman and Resnik (2008) used delexicalization, based on the hypothesis that the interaction between morphology and syntax in two languages is similar; they applied this approach in parsing Swedish using Danish as the source language. Since this method does not require bilingual parallel data, it is extensively implemented combining with other features. McDonald et al. (2011) implemented the idea of delexicalizing the parsing models and adapting the parsers with a constraint driven learning algorithm that achieved accuracy gains. Søgaard (2011) improved the approach by Zeman and Resnik (2008) by selecting the source sentences that are most similar to the target language. Rosa and Žabokrtský (2015) trained an MSTParser model interpolation as an alternative for multi-source cross-lingual delexicalized dependency parser transfer. The work by Rosa (2015) involved the training of several independent parsers which were applied to the same input sentence. The resulting tree was obtained by finding the maximum spanning tree of a weighted directed graph of the potential parse tree edges from the different parsers.

In addition to delexicalized methods, cross-lingual lexical representations can also be used in dependency parsing. Täckström et al. (2012) used parallel data to induce cross-lingual word clusters, and added them as features for their delexicalized parser. Xiao and Guo (2014) proposed that the source and target language words with the same meaning share a common embedding. The embeddings are jointly trained with a neural model and are used for dependency parsing. Duong et al. (2015a); Ahmad et al. (2019); He et al. (2019) proposed different methods to develop multilingual word representations and used them for dependency parsing. Also, these approaches utilize zero-shot parsing since the trained parsing models parse a target language without any training target instances (Romera-Paredes and Torr, 2015). It is a suitable method for parsing low-resource languages because knowledge between different languages is transferable and labeled low-resource language data is difficult to obtain.

For Xibe, there are currently no parallel corpora or machine translation systems available, which makes model transfer the most feasible approach. In order to achieve zero-shot single-source cross-lingual parsing, we first train a parsing model on one source language treebank, then parse the target language using this model. As Xibe is written in the traditional Mongolic alphabet, which differs greatly from all the candidate source languages, we must minimize these differences. Therefore, we use treebank delexicalization by replacing lexical items with only part-of-speech tags in both the source and target languages.

5 Experimental Settings

5.1 LangRank and Perplexity Calculation

5.1.1 LangRank

When predicting transfer languages, LangRank requires four types of input: a segmented target language dataset, an unsegmented target language dataset, target language code (in our case sjo) and task label (DEP). We use the 1 131 Xibe sentences (see Section 6.2) as the unsegmented dataset, and we create the segmented dataset with SentencePiece (Kudo and Richardson, 2018)\(^1\). SentencePiece is a language-independent sub-word tokenizer and detokenizer, which creates sub-word models directly from raw sentences, along with tokenization. Such a subword model is required by LangRank. We use the following SentencePiece parameters: We set the final vocabulary size to 8 000 since the Xibe dataset is small. We use the default value for the other two parameters, that is, the amount of characters covered by the model is set to 1.0, and the model type is set to unigram.

5.1.2 Perplexity

We compute perplexity scores based on POS bigrams. We build the bigram language models using NLTK (Bird, 2006) and use Laplace Smoothing to avoid zero probability for unseen bigrams, then calculate perplexity of each Xibe sentence over the

\(^1\)https://github.com/google/sentencepiece
source language model. The final score is averaged over all Xibe sentences per source language model.

5.2 Treebanks

The training data we use come from the Universal Dependencies (UD) project, version 2.7. That is, we retrieve treebanks of the candidate source languages described in Section 6. Since Turkish, Korean, and Japanese have multiple treebanks in UD, we use three Turkish treebanks: tr_gb, tr_imst and tr_boun, and three Japanese treebanks, ja_modern, ja_bccwj and ja_gsd. The perplexity score of ko_kais is 22.77 which is much higher than ko_gsd, we therefore only use ko_gsd (see Table 3). As for the remaining languages, if the language has more than one treebank, we only select the largest. We use the concatenation of train/dev/test splits per source language treebank as our training data. Moreover, the treebanks of candidate source languages differ from one another in size (see Table 4 and Table 5). bxx_bdt, kk_kdt, and ja_modern have only around 1 000 trees, the other treebanks range between around 3 000 and almost 90 000 trees. The size discrepancy is reduced by limiting each language to at most 3 000 trees, sampled randomly where necessary.

Since we use treebanks from the Universal Dependencies project, all treebanks share the same annotation scheme. However, we are aware that there may be differences in terms of annotation quality or the interpretation of language specific characteristics. Such issues are beyond the current project, but need to be addressed in future work.

The test data comes from the Xibe treebank, which generates three test datasets based on genre:
1. grammar: 544 grammar examples
2. news: 266 news sentences
3. mixed: the two genres combined, 810 trees

We delexicalize all the treebanks by replacing their word forms with their POS tags.

5.3 Parser

We use UDify (Kondratyuk and Straka, 2019) for the parsing experiments. UDify is a state-of-the-art multilingual multi-task model capable of accurately predicting universal parts of speech, morphology features, lemmas, and dependency trees simultaneously. It uses the pre-trained multilingual BERT model, which allows it to handle a large number of languages with reasonable performance, without requiring any language-specific components. On top of the BERT model, the parser uses an attention layer and a multi-task learning setup so that each of the linguistic tasks, predicting part-of-speech, morphological features, lemmas, and dependencies are single tasks that are learned jointly.

To determine whether UDify can parse Xibe straightforwardly without removing lexical items, we parse Xibe with the pre-trained UDify model, obtaining a UAS of 24.28% and an LAS of 6.79%. These results provide a strong indication that the vocabulary differences between Xibe and other languages cannot be bridged by the multilingual BERT model. Consequently, we decided to delexicalize our data and use (gold) POS sequences instead.

We train the individual models on the delexicalized treebank of each source language and parse the Xibe texts (also delexicalized) using those models. We use the default parameters, but set the warmup_steps and start_step to 256.

5.4 Evaluation

Evaluation is performed using the Unlabeled Attachment Score (UAS) and Labeled Attachment Score (LAS), as computed by the official evaluation script provided for the CoNLL 2018 shared task.3

6 Source Language Selection Methods

In this section, we describe the three methods for determining the best source languages, and present the languages chosen by these methods.

6.1 Typology Based Selection

The first approach uses linguistic knowledge: As described in Section 2, Xibe is a Tungusic language that shares morphological and syntactic features with other transuralian languages. Therefore, transuralian languages are assumed to be good candidates, including those belonging to Turkic, Mongolic, Tungusic, Koreanic and Japonic language families. To ensure that the candidate source languages have at least one dependency treebank, we limit our experiments to the following languages, which are included in the most re-

6.2 LangRank Based Selection

LangRank (Lin et al., 2019) is an approach for choosing source languages for cross-lingual NLP tasks including machine translation, entity linking, part-of-speech tagging, and dependency parsing. The task of selecting the optimal source languages for an NLP task is formulated as a ranking problem. Given a low-resource target language and a set of candidate source languages, a model is trained to rank the source languages according to the performance achieved when they are used in training to process the target language. Each candidate source language is represented with a set of dataset-dependent and dataset-independent features. The dataset-dependent features include dataset size, type-token ratio, word overlap and subword overlap, and the dataset-independent features include geographic distance, genetic distance, inventory distance, syntactic distance, phonological distance, and feature distance. Based on these features, the system implements gradient boosted decision trees (GBDT; Ke et al. (2017)) to select the best transfer languages for the four NLP tasks.

In our experiment, we use the Xibe treebank sentences (544 grammar examples and 266 news sentences) for prediction. We collect 321 more sentences from news to keep the two genres balanced, since LangRank does not define how much data is needed. Note that we use sentences as input for LangRank, we do not delexicalize the data for this step.

Table 1 lists the top three predicted source languages for each genre. Czech, Norwegian and Spanish rank among the top three when we feed in grammar examples. Finnish, Slovenian and Korean are the top three predictions when only news is used as input. Additionally, Finnish and Slovenian are also top languages when mixed data is used, followed by Slovak.

Lin et al. (2019) mentioned the possibility that LangRank cannot generalize well on certain languages since it is trained only on a few languages for the particular tasks. To obtain more educated guesses for choosing the transfer language, they analyzed the learned models and extracted the most important features for given tasks. In the dependency parsing task, geographic distance, genetic distance and word overlap are features that yield good scores on their own. Table 2 lists the top 3 predictions when only one relevant feature is used. In Table 1 and Table 2, only Czech and Norwegian appear in both results. But the results can be explained more easily. For example, Russia and India are geographically closer to the area where Xibe is spoken, and Xibe has larger word overlap with Chinese as a result of long-term language contact.

6.3 Perplexity Based Selection

Here, we attempt to automatically approximate the typological approach by determining similarity via POS bigrams. We use perplexity as a similarity metric. Basically, we determine the optimal source languages among the languages covered by Universal Dependencies by computing the perplexity between each of the treebanks (see Section 5.2) and Xibe. As vocabularies and orthographies among languages differ greatly, we use POS bigrams instead of words to calculate perplexity. The inherent assumption is that the POS bigrams

</table>

We find that the perplexity scores of the Mongolic and Turkic languages are closest to Xibe (lowest perplexity) among all languages (see Table 3). Comparing these languages with the ones chosen based on typology in Section 6.1, there are considerable overlaps, except for Japanese and Korean. We also examine the perplexity scores for Korean-Xibe and Japanese-Xibe: These scores are higher than those for Turkic and Mongolic languages but lower than most of the other languages.

7 Results and Analysis

In this section, we provide the results for our three research questions.

7.1 How to Choose the Source Language?

Table 4 shows the parsing results for source languages selected by typology. Among the transeurasian languages, Kazakh achieved the highest LAS of 58.69% on grammar examples while Japanese achieved the highest LAS of 38.59% when tested on news and the highest LAS of 44.91% when tested on mixed data. On all three test datasets, Korean had the lowest LAS, with 40.54% on grammar examples, 29.16% on news and 33.41% on mixed genres. Table 5 shows the results for source languages selected by LangRank. Korean scored the highest LAS whereas the lowest was achieved by Spanish with 15.11% on grammar examples, 8.45% on news and 10.94% on mixed genres.

Based on Table 4, we find the most suitable source language to be Japanese. Training on the ja_gsd treebank results in the highest LAS for news and mixed genres, but its LAS for grammar examples is 3.19% lower than when training on Kazakh. This proves that Kazakh is more accurate than Japanese at labeling dependency relations. In terms of news and mixed genres, the gap with Japanese is actually larger, which we will investigate in section 7.3. In addition, Uyghur also performs well, its LAS on mixed genre is only 1.21% lower.

When using perplexity on POS bigrams to choose the source language, we assume that a low perplexity corresponds to a good match. However, when we compare the complexity scores in Table 3 and the parsing results in Tables 4 and 5, the situation is more complex: The Japanese treebank ja_gsd performs best in parsing even though it has a high perplexity score. The Korean treebank ko_gsd has a slightly lower perplexity than the Japanese ja_bccwj, but the Japanese LAS is about 11 points higher than the Korean LAS (on mixed). Similarly, Kazakh, Uyghur, and the Turkish tr_imst have similar perplexities, but the Kazakh and Uyghur LAS are about 10 points higher than the Turkish LAS (on mixed), even though the Kazakh treebank is by far the smallest. This shows that bigram POS perplexity is not an ideal measure of syntactic similarity, even though it performs better than LangRank.

As described in Section 6.2, standard LangRank may not be able to provide the best predictions. Therefore, we also investigate single features that are important for dependency parsing (see Table 2). According to the geographic feature, Hindi has the highest LAS 39.93% (on mixed genre, see Table 6). Similar to Xibe, Hindi has a Subject-Object-Verb (SOV) word order. Hence, we assume that the good performance of Hindi is a result of its syntactic similarity to Xibe rather than its geographic proximity. The genetic feature alone is not a good indicator for source language selection as all three languages achieve LAS around or below 20% (see Table 6). Languages selected via the word-overlap feature have poor results as well. On the mixed genre, Chinese achieves an LAS of 21.03% while Indonesian and English achieve only 13.97% and 13.22% respectively (see Table 6). Since we only used POS tags, we ignore borrowed Chinese words in Xibe sentences, and the higher performance of Chinese shows that Xibe is syntactically closer to Chinese than to English and Indonesian. Nevertheless, the LAS of Chinese is much lower than that of

7.2 Syntactic Similarity vs. Data Size

In the previous section, we have found Japanese to be the optimal source language for Xibe, followed by Uyghur and Kazakh. However, the Kazakh treebank only contains 1,078 trees while the Japanese ja_gsd and Uyghur models are trained with 3,000 trees. We investigate whether the training set size is the main factor in reaching good parsing accuracy. Consequently, we sample 1,000 trees from the Japanese ja_gsd treebank, making the training set size comparable to Kazakh kk_kdt. Parsing results are displayed in Table 7. On all three test datasets, when training with 1,000 trees, the LAS slightly decreases compared to 3,000 trees. Despite this, both LAS and UAS are still higher for the 1,000 Japanese trees than for Kazakh, with the exception of the LAS on the grammar examples. This shows clearly that the training set size is contributing only minimally.

As the Japanese results increase slightly when increasing training data from 1,000 to 3,000 trees, an obvious question is whether we can improve results by increasing the training set size further. Thus, we train parsing models by sampling 6,000 trees from ja_gsd and using all 8,071 trees respectively (see Table 7). However, we only see a minimal increase in LAS (45.03% vs. 44.91%) and a small decrease in UAS (on mixed). Thus we can conclude that larger training data do not necessarily lead to an improvement in performance.

We also had a closer look at Japanese and Korean, which share many linguistic features, despite which Japanese performs better than Korean. On mixed data, Korean obtains an LAS of 33.41%. One possible reason for such a large gap can be found in the differences in annotations between the two languages. As described by Han et al. (2020), in the UD Korean treebanks, a sentence is segmented into eojeols. An eojeol can consist of lexical morphemes and functional morphemes, which means the functional morpheme is agglutinated to the lexical item preceding it. In contrast, the Japanese treebank adopts the Short Unit Word (SUW). This means that functional morphemes are annotated as separate units in the Japanese treebank, and their dependency relations are present. In Xibe, function words are written as any transeurasian language in Table 4, even lower than Korean by 12.38 points.

6.3 Does Genre Matter?

As shown in Section 5.2, the Xibe treebank consists of two different genres (grammar and news) while most of the source treebanks have multiple genres. This design allows us to see how different genres influence parsing results. One prominent difference between Xibe grammar examples and news is that news sentences are much longer and use more complex syntactic structure. Thus, we expect to reach higher accuracy on the grammar examples. This is born out by the results in Tables 4 and 5: Among transeurasian languages in Table 4, Turkish tr_gb has the largest LAS difference between grammar examples and news by 26.48% whereas Uyghur has the smallest by 9.44%. In Table 5, Finnish displays the largest LAS discrepancy between the two genres by 11.45% whereas Spanish has the smallest difference by 6.66%. We find a general tendency that results on grammar are considerably higher than those on news, with sizable differences.

We now have a closer look at the three Turkish treebanks since tr_gb mainly contains grammar examples while the other two contain news and non-fictional data. Comparing performance of the models trained on the three treebanks, when we test with grammar examples, tr_gb outperforms the other two even though it is smaller in size. When testing on news, tr_boun and tr_imst reach similar results: tr_boun reaches an LAS of 37.77% and tr_imst reaches an LAS of 32.77%. However, tr_gb declines by 13.86% in LAS compared to tr_boun. The results indicate that genre does influence parsing. When the training data contains mainly simpler syntactic structures than the test data, the parser cannot analyze the more complex test data adequately.

8 Conclusion

In this research, we have investigated cross-lingual dependency parsing for Xibe. As we do not have parallel data or a machine translation system for this language, we delexicalize treebanks to avoid orthographic and lexical differences. We propose three criteria to select source languages, that is, typology, perplexity, and automatic predictions by the LangRank tool. Then, we train parsing models with UDify and test them with the three sets of
Xibe data. Our results demonstrate that syntactic similarity is considered the most important factor in delexicalized cross-lingual parsing. Japanese is found to be the optimal source language for parsing Xibe. Differences in genre also influence parsing. Parsers trained on simpler sentence structures cannot analyze more complex test data.

In our current work, we use only one source language to parse Xibe. We will determine the best concatenation of source languages for multilingual parsing in the future. Additionally, we will resegment the current units of the Korean treebanks into smaller units and create dependency relations by rules in order to determine if a more similar segmentation will lead to an improvement. Alternatively, we can use lexical information in parsing, such as creating a bilingual dictionary or training Xibe word embeddings.

Abstract

The analytical description of charts is an exciting and important research area with many applications in academia and industry. Yet, this challenging task has received limited attention from the computational linguistics research community. This paper proposes AutoChart, a large dataset for the analytical description of charts, which aims to encourage more research into this important area. Specifically, we offer a novel framework that generates the charts and their analytical description automatically. We conducted extensive human and machine evaluations on the generated charts and descriptions and demonstrate that the generated texts are informative, coherent, and relevant to the corresponding charts.

1 Introduction

Natural language generation (NLG) is one of the core research areas in artificial intelligence (Gatt and Krahmer, 2018). Recent NLG studies have explored data-to-text generation, where exciting applications such as automated news reporting (Leppänen et al., 2017) were developed to generate text from non-linguistic data automatically. In this paper, we explore the chart-to-text generation problem, where analytical textual descriptions are automatically generated for a given graphical chart.

Chart-to-text generation has many exciting academic and commercial applications. For instance, preliminary analyses can be generated on charts to aid users in authoring analytical documents. On the accessibility front, automatically generated chart analyses can also support accessibility since text descriptions can be fed into speech-to-text modules and help visually impaired individuals to understand charts. Chart-to-text generation could also be applied to aid academic writing. Text descriptions of visual elements such as diagrams, charts, and graphs, are among the core academic assignments in linguistics (Molle and Prior, 2008). For example, the IELTS Academic Writing Task 1 (AWT1) is an assessment task that elicits written responses on a visual-verbal relationship. The AWT1 requires test takers to “describe, summarise, or explain the information in a graph, table, chart, or diagram.” Figure 1 shows an example of the AWT1. Chart-to-text generation offers the potential to generate large-scale chart analytical description learning examples for students attempting AWT1.

Despite the many benefits and applications of chart-to-text generation, this NLG task has received limited attention from computational linguistics and NLG researchers. Among the key factors that hinder the development of this research area is the lack of a large chart description dataset that may facilitate chart description studies. Intuitively, one possible solution is to collect and manually anno-
tate a chart description. For instance, we will first 
need to obtain a large dataset of charts and subse-
quently engage human annotators to write the sum-
mary and explanations for these charts. However, 
such a data collection process is time-consuming 
and expensive. Another approach is to perform 
large-scale data-crawling to retrieve charts and cor-
responding human-written summaries from the In-
ternet. However, it is challenging to ensure that text 
summaries correctly describe the chart and have 
provided adequate details to aid readers in under-
standing the chart as the charts are retrieved from 
multiple sources. For instance, in a recent study, 
(Obeid, 2020) had performed a large-scale data 
collection of charts and corresponding text descrip-
tions. However, the descriptions of the chart in the 
dataset contained background knowledge beyond 
the data illustrated in the chart.

In this paper, we aim to address chart analysis 
data scarcity and quality problems by proposing 
a novel framework that generates charts and their corresponding high-quality descriptions automatically. The AutoChart\textsuperscript{1} dataset generated by our proposed framework will pioneer new computational linguistic and NLG research area on chart descriptions. For instance, the availability of a large-scale chart description dataset encourages the creation of supervised machine learning and NLP models to interpret the charts and generate relevant text descriptions automatically.

We summarize our contributions as follows:

- We propose a novel framework to generate charts and their corresponding analytical descriptions automatically.

- Using our novel framework, we constructed AutoChart, which is a large-scale chart description dataset, and make this openly available to encourage future research.

- We conducted extensive human and machine evaluation on the generated charts and descriptions and demonstrate that the generated text is informative, coherent, and relevant to the corresponding charts.

2 Related Work

There are very few data-to-text works that investi-
gate chart recognition and understanding. Many of these existing works focused on extracting data

\textsuperscript{1}Code: https://gitlab.com/bottle\_shop/snlg/chart/autochart

from the various types of visual charts using deep learning computer vision and object recognition techniques (Cliche et al., 2017; Balaji et al., 2018; Liu et al., 2019; Ma et al., 2018; Dai et al., 2018; Battle et al., 2018; Chai et al., 2020). For instance, Balaji et al. (2018) proposed an automated system that extracted data points from bar and pie charts to create textual descriptions. However, the generated textual descriptions listed data values extracted from the figures in a static format without any analytical discussion about the charts’ overall trends or summary. Another line of work have also proposed table-to-text models (Iso et al., 2019; Puduppully et al., 2019), which aims to generate long and good-quality description from structured data formatted in a table. Nevertheless, these table-to-text models are designed for specific domains and structured data, and it is challenging to adopt these methods in the chart-to-text task.

Another related sub-domain of work is the visual-based question and answer (Q&A) task. Kahou et al. (2017) introduced the FigureQA corpus, which consists of over one million question-answer pairs grounded in over 100,000 visual charts. Methani et al. (2020) extended the work in (Kahou et al., 2017) and proposed the PlotQA corpus, which is a larger dataset with 28.9 million question-answer pairs over 224,377 charts from real-world sources and questions based on crowdsourced question templates. While large datasets have been collected for the visual-based Q&A task, these datasets are not applicable to generate analytical chart descriptions as the question-answer pairs are often short and data-specific without any in-depth analysis on the charts.

Closer to our work, Obeid and Hoque (2020) introduced a new large-scale corpus on chart summarization and proposed a transformer-based chart-to-text model. However, the descriptions of the chart in the dataset contained background knowledge beyond the data illustrated in the chart. These "noises" from the beyond-chart-data information may affect the learning of text generation models. Another prominent data source, Statista, has high-quality charts, but corresponding summaries may not be descriptive of the chart.

Our study addresses the limitations of existing chart-to-text datasets. It extends the existing works on chart recognition and data extraction by offering a novel framework to generate charts and their corresponding analytical descriptions auto-
matically. To this end, we construct and contribute AutoChart, a large-scale chart analytical description dataset.

3 AutoChart Dataset Construction

The goal of this study is to construct a dataset of charts with their corresponding analytical descriptions automatically. To this end, we propose a novel framework to construct the AutoChart dataset and illustrate its construction in Figure 2. We begin by collecting statistical data from multiple sources over the web and create the trend generation strategy. The goal of the strategy is to ensure that the generated charts exhibit some form of temporal trends, which ultimately encourages writers to identify these trends analytically. The proposed framework contains two main generation modules: chart generation and analytical description generation.

The statistical data and trend generation strategy guide the automatic generation of charts and their meta-information in the chart generation module. Specifically, we generate four types of charts: scatter plots, line charts, vertical and horizontal bar charts.

In the analytical description generation module, linguistic researchers are first recruited to write the analytical descriptions for a few charts. The human-written descriptions are used as templates for the automatic generation of analytical descriptions. As it is labor-intensive to draft human-written descriptions templates, we expand the number of templates by leveraging open-source algorithms to paraphrase the human-written descriptions. Subsequently, we analyze the linguistic rhetorical moves of the human-written and paraphrased templates. The rhetorical move analysis enables us to categorize the rhetorical function types of sentences presented in the analytical description templates.

Finally, the template sentences annotated with rhetorical moves are strategically sampled and adapted to chart data to generate the analytical description for a given chart.

3.1 Statistical Data Collection

To generate the charts, we first collected statistical data from multiple sources on the web, such as the World Bank Open Data and Nutritional Analysis Data. We crawled data from these sources to extract different variables whose relations could then be plotted (for example, a country’s labor force over time, etc.). There are a total of 346 unique indicator variables (CO2 emission, GDP growth, total population, etc.) with 76 unique entities (cities, states, countries, etc.). The data ranges from 1950 to 2016, though not all indicator variables have data items for all years. The data contains positive integers, floating-point values, and percentages. These values range from 0 to $3.50 \times 10^{15}$.

3.2 Trend Generation Strategy

Besides plotting the actual collected statistical data, we also aim to generate charts with specific trends. This encourages writers or machine learning algorithms to generate descriptions that analyze the patterns observed in the charts. To this end, we formulate a trend generation strategy, where data perturbation is applied to generate various types of trends. Specifically, we applied the following data perturbation:

$$Y = S_0e^{(\mu - \frac{\sigma^2}{2})x + \sigma W}$$  \hspace{1cm} (1)

Here $W$ denotes Brownian motion (Karatzas I.,
1998) that allows some degree of randomness in the trend generation, $S_0$ denotes the given initial value, $\sigma$ denotes the weight of Brownian motion, that is, the volatility rate of the data. $\mu - \frac{\sigma^2}{2}$ is the drift factor of Brownian motion, which indicates the trend of the data. When it is a positive number, the data is on an increasing trend, and when it is a negative number, it is on a decreasing trend. However, a random fluctuation is generated when it is 0. In total, we apply Equation 1 to generate charts with eight different types of trends. This is achieved by incorporating various parameters mentioned above and performing symmetry and rotation operations on the data. Figure 3 shows an example of line charts generated in various trends.

3.3 Chart Generation

We generate four types of charts in our AutoChart dataset: scatter plots, line chart, vertical, and horizontal bar charts. These types of charts are commonly encountered in academic journals, research papers, textbooks, etc.

Python library Matplotlib (Hunter, 2007) is used to generate the charts. To encourage diversity in our chart generation, we developed a script to select parameters randomly to add variation to our charts. Specifically, we randomly select markers from 10 unique shapes for each scatter-plot. We also randomly choose the color of the markers in scatter-plots, lines in line charts, and bars in bar charts from a set of 20 colors. The thickness of the bars and line style of lines are also randomly configured. Note that although we fix the size of the entire visual canvas, the size of legends and y-axis values is different for each chart, resulting in random image sizes. The number of discrete elements of x-axis varies from 2 to 8 and the number of entries in legend box varies from 1 to 2. By using different combinations of indicator variables, entities (years, countries, etc.), and parameters, we created a total of 10,232 charts.

Our script preserves the meta-information of the generated charts in JSON files to enable the development of supervised modules for various sub-tasks. Specifically, the meta-information contains bounding box annotations for the legend boxes, legend names and markers, axes labels, axes ticks, data coordinates, plot title, and image index. The meta-information will be used in the analytical description generation module to generate the charts’ corresponding descriptions. Furthermore, the meta-data could also be used in evaluating the correctness of future chart understanding models.

3.4 Analytical Description Generation

The creation of analytical descriptions for the generated charts is a challenging task. Firstly, as we have created a large number of charts, it is labor-intensive and time-consuming to draft the analytical descriptions for all the charts manually. Therefore, we would need an automated approach to generate the charts’ analytical description. Secondly, the automated solution would need to generate analytical descriptions that are informative, coherent, and relevant to chart context. We propose a template-based approach with linguistics analysis to guide the generation of charts’ analytical descriptions to overcome these challenges.

3.4.1 Templates Generation

We recruited three linguistics researchers to write the descriptions of a small subset of the generated charts to create the analytical description templates. The subset of generated charts is evenly sampled from the various types of trends. The linguistics researchers are instructed to assume the same setting as IELTS AWT1 when writing the analytical descriptions of sampled charts. In total, the linguistics researchers wrote analytical descriptions for 150 charts.

As writing the analytical descriptions templates is a labor-intensive and time-consuming task, we used Quillbot, an online paraphrase API, to paraphrase the sentences in the human-written templates. The paraphrase sentences significantly expanded our analytical description templates. In total, we extracted 213 human-written chart sentences, 661 paraphrased sentences as templates. Finally, both human-written and paraphrased sentences will be used to generate other generated charts’ analytical descriptions automatically.

\footnote{https://quillbot.com/}
3.4.2 Rhetorical Move Analysis

A naive and straightforward way to generate the charts’ analytical descriptions is to randomly sample the sentences from our templates and apply the charts’ meta-data to produce the relevant analytical descriptions. However, such an approach neglects the rhetorical moves in analytical descriptions, which are important linguistic elements in building analytical arguments (Swales, 2004). Inspired by the idea of moves from Swales’ framework of genre analysis, we explored a rhetorical moves framework in analytical description templates. Specifically, we manually annotate each sentence in the template and group them in one of the following five rhetorical moves:

1. **Move 1** [Obligatory]: Overview of the chart. This move is used to explain what the chart is about, the chart’s content, etc. For example, “The chart shows the amount of fast-food consumed in the UK between 1970 and 1990.”.

2. **Move 2** [Optional]: Description of the chart itself. This move mainly focuses on the configuration of or elements in the chart. For example, “All the sampled countries are from Europe: Finland, France, Georgia, Germany, Greece, and Hungary.”.

3. **Move 3** [Obligatory]: Interpretation of the chart information. This part mainly explains the changing trend and simple observation of chart information, etc. For example, “The amount of fish and chips eaten declined slightly”. Nevertheless, it is inadequate to simply describe the trends. Thus, we will add a supplementary **Move 3.1** to report the numeric information from the chart. For example, “In 1970, the consumption was about 300g per week. This fell to 220g per week in 1990.”. We noted that **Move 3.1** could be further divided into descriptions of individual data points and comparisons for trends.

4. **Move 4** [Optional]: Evaluative comments on specific value(s) or comparisons. For example, “The retired and unemployed people enjoyed about 78 to 82 hours per week which is longer than people from other employment statuses.”.

5. **Move 5** [Obligatory]: Conclusions, summaries or implications based on the chart. For example, “In conclusion, although there was a big increase in the consumption of pizza, sales of fish and chips decreased.”.

In particular, for sentences annotated as Move 3 or 4, we further categorize the sentences into the types of charts that they are describing:

- For temporal charts where the x-axis represents time, the sentences focus on the trend of the data and the comparison of different time points. Move 3 and 4 sentences that describe trends are grouped into the eight categories showed in Figure 3. For temporal charts without apparent trends, the sentences will mainly focus on the comparison between data and some special points.

- For categorical charts where the x-axis represents entities, such as cities, food, etc., the Move 3 and 4 sentences will only focus on comparing different categories and describing some special points.

3.4.3 Rhetorical Moves Synthesis for Chart Description

After analyzing and annotating the rhetorical moves of sentences in the human-written and paraphrase templates, we leverage the templates’ sentences and utilize charts’ meta-information to generate the charts’ analytical descriptions. To this end, we designed a script that takes in a generated chart as input and performs the following steps:

1. We first extract the generated chart’s data values and meta-information from its corresponding JSON file. Specifically, we extract the title, x-axis, and y-axis labels, numeric information, the data trend, etc.

2. Depending on the type of charts (i.e., temporal or categorical), and the trend(s) in the chart, we sample the sentences from the templates such that the sentences of various rhetorical moves are selected to build a coherent analytical description. Furthermore, to encourage diversity in the generated analytical description, we randomly set the number of rhetorical move sentences to generate. The conditional sampling of template sentences by rhetorical moves ensures that the generated analytical descriptions are structured to be a coherent analytical argument, and the sampling strategy encourages diversity in sentence structures.
3. Once the template sentences are selected, we replace the variables, entities, and values in the sentences with the given generated chart’s meta-information. For example, consider the template sentence “The [y-axis_label] of [x-axis_label] is observed to decline since [x-tick_label]”, we substitute the variables with the generated chart’s meta-information and generate the sentence “The number of visitors of Singapore is observed to decline since 2015.”. The script also analyzes corresponding relationships between data before performing the replacement if there is no related information in meta-data (i.e. the trend, statistical features such as minimum and maximum x-values and y-values, etc.). Such a process chooses templates randomly, and we can repeat the script three times to get multiple analytical chart descriptions for each chart.

Finally, the generated analytical descriptions are paired with the generated charts to form the AutoChart dataset.

4 Dataset Evaluation

In order to conduct a thorough evaluation on the generated analytical descriptions, similar to many NLG tasks, we assess the generated analytical descriptions using both human and automatic metrics (Gatt and Krahmer, 2018).

4.1 Dataset Overview

Table 1 summarizes our constructed AutoChart dataset. In total, we generated 10,232 charts and 23,543 corresponding analytical descriptions. Note that we have generated multiple analytical descriptions for each generated chart, simulating the real-world situation where different human writers may have different analytic descriptions of the same chart. The 150 analytical descriptions written by the linguistics researchers are also included in the dataset. The analytical descriptions have an average of 8 sentences and 140 words. Figure 4 shows an example of a generated chart and analytical description in the AutoChart dataset.

4.2 Human Evaluation

To examine the quality of the generated descriptions in AutoChart, we conducted three human-based evaluation studies. In the first study (S1), we recruited 30 linguistics researchers to write descriptions for 60 charts (20 line charts, 20 bar charts, and 20 scatter plots). The written descriptions from S1 are used in automatic evaluation discussed in the next section and also as the charts in S3. In Study 2 (S2) and Study 3 (S3), we examined the differences between AutoChart generated descriptions and the human-written descriptions from S1, respectively. They are the same otherwise in format and content. We studied S2 and S3 with 600 unique participants (20 line charts, 20 bar charts 20 scatter plots, each evaluated five times = 300 participants × 2 studies) using crowdsourcing on Amazon Mechanical Turk (AMT). Participants were at least 21 years old and were self-reported to be proficient in English. To reduce the potential bias in self-report, we used AMT’s options to select only US-based workers.

Informed consent was first obtained from participants. They then completed a demographics survey before proceeding to the study task. Participants were presented with a chart and its accompanying description, and then asked to rate the description on three dimensions of naturalness, informativeness, and quality (i.e., grammatical correctness) adapted from the study in (Novikova et al., 2018) using a 5-pt Likert scale. To ensure that participants were focused during the task, we asked them to answer a question that pertained to the chart description. We additionally used a reCAPTCHA (rec) to reduce the likelihood of bot responses. Five participants rate each chart, and we compute the median to provide majority voting in ratings.

Results. Comparing the results of S2 and S3, we did not detect significant differences between AutoChart and human-written descriptions for naturalness ($p = 0.056 > 0.05, 1$-tail), informativeness ($p = 0.288$) or quality ($p = 0.227$). From Figure 5, we observe that human descriptions are rated higher on dimensions of naturalness and marginally on quality; with the generated analytical descrip-
From 2013 to 2019, the line graph depicts the number of fast food (hamburger) consumption in Canada and the United States, respectively. In the last seven years, both countries have seen similar increases in consumer numbers. Over the last seven years, the United States has seen a steady increase. In 2018, there was a significant growth in Canada. Based on historical trends, both countries are anticipated to expand their fast food consumption in the coming years.

**Generated:** [Move 1] The line graph displays the number of consumption of fast food (hamburger) in Canada and the USA, respectively, from 2013 through 2019. [Move 2] In this chart, the unit of measurement is Local Currency, as seen on the y-axis. [Move 3] It is obvious that both countries shared similar increasing trends in the number of consumption in the past 6 years. [Move 3.1] For Canada, by 2013 the number of consumption reached nearly 12, while the number continued to increase until 34 in 2019. [Move 3.1] And for the USA, in 2013, the number of consumption was about 26, after that, each year has witnessed some increase. [Move 3] In the past 6 years, the USA had consistently more than Canada. [Move 5] It would be interesting to see what would happen in the next decade in these two countries in terms of current situations.

**Human:** From 2013 to 2019, the line graph depicts the number of fast food (hamburger) consumption in Canada and the United States, respectively. In the last seven years, both countries have seen similar increases in consumer numbers. Over the last seven years, the United States has seen a steady increase. In 2018, there was a significant growth in Canada. Based on historical trends, both countries are anticipated to expand their fast food consumption in the coming years.

**4.3 Automatic Evaluation**

Automatic evaluation of NLG tasks is challenging and an ongoing research area itself. The challenges of evaluating charts’ analytical description automatically are compounded as the generated text are significantly longer than other NLG task such as machine translation. Nevertheless, we leverage existing automatic evaluation metrics commonly used in NLG tasks to evaluate our generated text. Specifically, we perform two automatic assessments on the AutoChart dataset: (i) Quality assessment, which compares the automatic generated analytical descriptions and 60 human-written references written by the linguistics researchers in human evaluation study S1. (ii) Difficulty assessment, where to train existing chart-to-text methods using the AutoChart dataset and compare their generated descriptions against the human-written references.

**4.4 Quality Assessment**

To evaluate the quality of the analytical descriptions in AutoChart, we computed the ROUGE (Papineni et al., 2002), BLEU (Lin, 2004) and BLEURT (Selmam et al., 2020) scores between the human-written references from earlier human-based evaluation study S1 and the automatic generated analytical descriptions for the same 60 charts. We assume that the human-written references are the gold standard, and the generated analytical descriptions in AutoChart should be similar to the gold standard.
Method | BLEU | ROUGE | BLEURT
--- | --- | --- | ---
Balaji et al. (2018) | 20.45 | 22.9 | 13.31
Obeid (2020) | 33.05 | 28.32 | 18.23
Liu et al. (2020) | 10.68 | 19.74 | 5.49

Table 3: Difficulty Assessment Results.

As a baseline comparison, we adopt a simple template-based generative method that generates the charts' analytical descriptions by randomly sampling the sentences from our templates and applying the charts' meta-data to produce the relevant analytical description. The main difference between the baseline and the AutoChart analytical descriptions is the baseline does not consider the rhetorical moves in the description generation.

Table 2 shows the results of quality assessment on the analytical descriptions in AutoChart dataset and baseline. We compute the average scores for various automatic assessment metrics for the different chart types. The overall average scores are also reported. We observe that the AutoChart's analytical descriptions significantly outperformed the baseline generated text, suggesting that the inclusion of rhetorical moves in analytical descriptions are more aligned to the human-written references.

4.5 Difficulty Assessment

Besides evaluating the quality of the AutoChart dataset, we are also interested in investigating the existing chart-to-text methods’ performance in our new dataset. The goal is to assess the difficulty of generation chart analytical descriptions using the existing methods and the AutoChart dataset. Specifically, for this experiment, we first train the two state-of-the-art chart-to-text baselines (Balaji et al., 2018; Obeid, 2020) and an image captioning method (Liu et al., 2020) using the AutoChart dataset. Subsequently, we apply the trained baselines to generate the descriptions for the 60 charts in human evaluation study S1. Finally, we compute the ROUGE, BLEU, and BLEURT scores between the human-written references and the baselines’ generated descriptions of the charts.

Table 3 shows the experiment results. We observe that none of the methods can perform exceeding well in generating chart descriptions that are close to human references. The best performing baselines, (Obeid, 2020), was able to achieve similar results to the simple template-based generative baseline used in the quality assessment experiment. Unsurprisingly, the (Obeid, 2020) is not able to perform well for the chart analytical description generation task as the model did not consider the paragraph structure (i.e., rhetorical moves) in its generation. (Balaji et al., 2018) is designed to generate simple single sentence summaries for charts. Thus, it might not be able to generate informative and detailed analytical descriptions of the charts. The image caption method (Liu et al., 2020) performed badly for the task as it is likely to generate the general captions such as “this is a line chart.”.

The performance of existing baselines highlights the difficulty of the chart analytical description generation task.

5 Discussion and Conclusion

The AutoChart dataset opens up new research opportunities for the computer vision, computational linguistics, and natural language processing research communities. Novel object recognition and deep text generative models can be designed to interpret charts and generate relevant analytical descriptions automatically. The automatic interpretation and generation of analytical chart descriptions have many academic and industrial applications. For instance, generating good-quality analytic chart descriptions can guide students to attempt the IELTS AWT1. The automated analysis of charts is also a valuable function in existing assisted writing tools. The AutoChart dataset can support the development and exploration of the supervised chart-to-text methods.

We opined that this is the start of an emerging research topic, and many future works could be done. As an extension of this work, we aim to investigate and model more sophisticated linguistic techniques to construct better quality analytical descriptions of charts. We will expand the dataset to include more types of charts, e.g., pie charts, box plots, etc. Finally, we will also explore more automatic evaluation methods to assess the quality of the generated analytical descriptions. For example, we can examine and assess the analytical descriptions’ logic, reasoning, and fluency.

To conclude, we have proposed a novel framework that automatically constructs the AutoChart dataset, a large chart analytical description dataset. We conducted extensive human and machine evaluation on the generated charts and descriptions and demonstrate that the generated text is informative, coherent and relevant to the corresponding charts. We hope that the AutoChart can encourage more research in the automatic generation of analytical descriptions of charts.

Abstract

Extracting the most important part of legislation documents has great business value because the texts are usually very long and hard to understand. The aim of this article is to evaluate different algorithms for text summarization on EU legislation documents. The content contains domain-specific words. We collected a text summarization dataset of EU legal documents consisting of 1563 documents, in which the mean length of summaries is 424 words. Experiments were conducted with different algorithms using the new dataset. A simple extractive algorithm was selected as a baseline. Advanced extractive algorithms, which use encoders show better results than baseline. The best result measured by ROUGE scores was achieved by a fine-tuned abstractive T5 model, which was adapted to work with long texts.

1 Introduction

Automatic summarization of legislation documents is a rather challenging task, because they usually are very long and hard to understand. Therefore, any progress on this task might have great value for many businesses.

Most of the existing methods for text summarization are designed for a relatively short text (such as news, web pages, etc.). Most of the available datasets consist of short summaries of articles, news, etc. in which the expected summary is a few sentences long. However, in the case of legal documents both the text and the summary are longer. Dernoncourt et al. (2018) provide a comprehensive overview of the current datasets for summarization, including CNN/Daily Mail (Hermann et al., 2015), Gigaword (Graff and Cieri, 2003), LCSTS (Hu et al., 2015) and others. Noticeably, most of the larger scale summarization datasets consist of relatively short documents.

The paper’s aim is to research the applicability of different algorithms for text summarization on a new dataset, called EU legislation documents. The collected documents were parsed, cleaned and prepared to be used for data summarization training by defining pairs of full text and corresponding summary.

There are two main approaches for text summarization: extractive and abstractive. Extractive summarization means identifying important parts of the text and concatenating them verbatim to produce a summary which is a subset of the sentences from the original text. Abstractive summarization aims to make algorithms that are able to ”understand” the whole text and to generate a new shorter text that conveys the most important information from the original one (Sciforce, 2019).

The algorithm, which was selected as baseline, uses a classical approach for generating extractive summaries - sentence importance evaluation and combining the highly scored sentence to generate the summary (Malik, 2019). In this paper, we report results from different algorithms compared to the baseline algorithm. The compared algorithms include extractive and abstractive PreSumm (Liu and Lapata, 2019), which generates state-of-the-art results for CNN/DailyMail datasets (Hermann et al., 2015), a fine-tuned abstractive T5 model (Raffel et al., 2019), an extractive summarizer which uses BERT (Miller, 2019), an extractive summarizer which uses LEGAL-BERT (Chalkidis, 2015), Gigaword (Graff and Cieri, 2003), LCSTS (Hu et al., 2015) and others. Noticeably, most of the larger scale summarization datasets consist of relatively short documents.
et al., 2020).

2 Related Work

This section presents existing approaches for text summarization. Some are especially related to our work because they focus on long texts and this is the case with the legal documents that we use.

Xiao and Carenini (2019) focus on extracting informative sentences from a given document (without dealing with redundancy), especially when the document is relatively long (e.g., scientific articles). They rely on section information to guide the generation of summaries. Global and local contexts are taken into account when deciding if a sentence should be included in the summary. This approach struggles when there is not a well defined structure of sections which is the case with the legislation documents.

Nakao (2000) presents an algorithm for text summarization using the thematic hierarchy of a text. The proposed algorithm is intended to generate a one-page summary. Based on the ratio of source text size to a given summary size, the algorithm generates a summary with some breaks to indicate thematic changes. This algorithm cannot easily be adapted to summaries with dynamic length.

Another approach is to combine extractive and abstractive models (Wang et al., 2017). In the extraction phase, it creates a graph model to extract key sentences. In the abstraction phase, it uses a recurrent neural network based encoder-decoder, and devises pointer and attention mechanisms to generate summaries.

Vaswani et al. (2017) presented the Transformer architecture, which establishes a new single-model state-of-the-art BLEU score on two machine translation tasks. The architecture consisted of feed forward networks and attention mechanism. The basic architecture of a Transformer is based on the encoder-decoder model and is especially suitable for summarization because it can handle sequential data. Yet, the data does not need to be processed in order (for instance the beginning of the text does not have to be processed before the end). This is very useful for parallel training and reduces the time needed to train the transformers. The encoder takes all the input and encodes it into a vector containing the numerical representation of the text. Then the decoder decodes the vector and produces the summary. The datasets used for training can be big and thus exist pre-trained systems such as BERT (Bidirectional Encoder Representations from Transformers). They have been trained with huge general language datasets and can be fine-tuned to specific language tasks. The following algorithms we experimented with also rely on the Transformer architecture: PreSumm (Liu and Lapata, 2019), LEGAL-BERT (Chalkidis et al., 2020), T5 (Raffel et al., 2019).

Pegasus (Zhang et al., 2019) is a state-of-the-art NLP deep-learning algorithm for abstractive text summarization. It can be used for both extractive and abstractive summarization but the abstractive is more challenging because when the text is long, it should be understood, processed and a new text should be generated.

3 Dataset Collection

In order to create a dataset on which to compare the algorithms, we collected legislation documents. The data was preprocessed and only the relevant information for the task was left.

The dataset consists of short, easy to understand explanations of the main legal acts passed by the EU, intended for a general audience. Most cover the main types of legislation passed by the EU: directives, regulations and decisions. But some cover other documents, such as international agreements. The summaries are grouped into 32 policy fields, and each links to the full, official version of the act. Summaries are not available for legal acts that are considered to be already sufficiently short/clear or aimed exclusively at a specialist audience (Publications Office of the European Union, 2020). The information is provided by the Publications Office of the European Union and is publicly available. It was retrieved on January 12, 2020.

After the data was collected, we analyzed it and cleaned it in order to focus on the problem of text summarization. For the summaries we extracted only the Key points section and for the full documents we removed the references to external documents. There are some summaries that combine more than one full legislation document: 169 summaries are a summary of two documents and 50 summaries are a summary of more than two documents. In these cases, the full documents are concatenated in the mentioned order.

In order to be able to evaluate a wider variety of algorithms and remove potentially incorrect data, the outliers were handled in the following ways:

- 49 summaries with more words than full text
were removed from the dataset.

- 86 summaries, which summarize more than one document and the same document exists for more than one summary were removed from the dataset.

- 18 summaries with word count ratio bigger than 200 were removed. Words ratio has a mean value of 28 and value of 29 at third quantile.

- Nine full documents with more than 75000 words were removed. Full document word count has a mean value of 9615 and value of 11141 at third quantile.

- Three summaries with more than 1500 words were removed. Summaries’ word count has a mean value of 429 and value of 530 at third quantile.

- Two full documents with more than 2000 sentences were removed.

- Three full documents with sentence ratio more than 80 were removed.

- 29 summaries which summarize more than two documents were removed from the dataset.

During the initial collection the dataset contained 1750 records. After the cleaning there are 1563 summaries (10.7% of the dataset was removed). The mean length of the summaries and full texts is 424 and 8990 words respectively (see Fig. 1). The ratio between the number of sentences in summaries and full documents is 0.16.

4 Experiments

The aim of the experiments described in this section is to compare different approaches for text summarization of legislation documents. For this purpose we used the dataset mentioned in the previous section.

4.1 Experiments Design

Different algorithms were experimented on the same dataset. They contain both extractive and abstractive approaches. Some of them do not require training, while others are trained from scratch or fine-tuned on the dataset.

T5 and PreSumm (which is based on BERT) have restrictions for the number of tokens in the input and in the output. In order to be able to handle the data for these algorithms, the full texts and summaries were splitted into chunks: full texts containing 1024 tokens and summaries - 128 tokens. We used the same ROUGE metric to evaluate each summary chunk against each full text chunk. During training each full text chunk is paired with the most applicable summary chunk. During evaluation we generated summaries for all chunks from the full text. They were concatenated and the result...
was evaluated against the original summary.

4.1.1 Extractive Summarization Based on Weighted Frequency Tokens of Sentences (Baseline Algorithm)

The first approach that was used is basic extractive summarization (Malik, 2019). The first step of the algorithm is to split the full text into a list of sentences. After that all special characters and stop words are removed. Then all sentences are tokenized. Next the weighted frequency of occurrences of all words must be calculated. The weighted frequency of each word can be found by dividing its frequency by the frequency of the most occurring word. After that, the words in the original sentences are replaced by their respective weighted frequency. Weighted frequency for the words removed during preprocessing is zero. For each sentence, the sum of weighted frequencies is calculated. Only sentences with more than three words are evaluated in order to avoid the ones that do not contain enough information by themselves. Finally, the sentences are ordered in descending order by the sum of the weighted frequencies. The summary contains the sentences in the beginning of the ordered list. The number of sentences to be selected is based on the ratio between the number of sentences in the training dataset. The algorithm does not require training and is entirely based on the content of the full document.

4.1.2 Fine-tuned PreSumm Encoder

PreSumm is a pre-trained encoder based on BERT for the purpose of text summarization (Liu and Lapata, 2019). This method is entirely based on BERT and provides two implementations: BERT-SUMEXT for extractive summarization and BERT-SUMABS for abstractive summarization.

For both extractive and abstractive settings, the algorithm generates a summary consisting of the sentences which maximize the ROUGE-2 score against the gold summary during training. When generating summaries for a new document, the model is first used to obtain the score for each sentence. These sentences are ranked by their scores from highest to lowest. During sentence selection, Trigram Blocking is used to reduce redundancy (Paulus et al., 2017). Given a summary and candidate sentence, the sentence is skipped if there exists a trigram overlapping between it and the summary. The aim is to minimize the similarity between the sentence being considered and sentences which have been already selected as part of the summary.

4.1.3 Extractive Text Summarization with BERT and K-Means

We used the solution proposed by Miller (2019). It works the following way: the document is tokenized into clean sentences. The tokenized sentences are passed to the BERT model for inference to output embeddings. The embeddings are then clustered with K-Means. The embedded sentences that were closest to the centroid are selected as the candidate summary sentences. The algorithm uses the core BERT implementation. Fig. 2 displays a heatmap of the full text and the words that were selected to be part of the summary.

Table 1: Results for experimented models. Fine-tuned T5 model generated the best results. Baseline F1 score was improved by all other algorithms.

4.1.4 Data-specific Approach for Legal Documents

The Extractive Text Summarization with BERT and K-Means allows its encoding model to be replaced and we experimented by changing it to LEGAL-BERT. (Chalkidis et al., 2020). LEGAL-BERT is a model which is based on BERT and is trained on twelve GB of diverse English legal texts from several fields. This experiment was encouraged by the specific vocabulary which the legislation documents consist of.

4.1.5 T5 Model

T5 (Raffel et al., 2019) is an encoder-decoder model and converts all NLP problems into a text-to-text format. It is trained using teacher forcing. This means that for training it always needs an input sequence and a target sequence. It is pre-trained on an open-source pre-training dataset, called the Colossal Clean Crawled Corpus (C4). The T5 model, pre-trained on C4, achieves state-of-the-art results on many NLP tasks while being flexible enough to be fine-tuned to a variety of important downstream tasks.

4.2 Evaluation Metrics

The most widely used metric for evaluation of text summarization is ROUGE (Recall-Oriented Understudy for Gisting Evaluation). ROUGE is a set of metrics used for evaluating automatic summarization and machine translation software. The metrics compare an automatically produced summary to a reference or a set of references (human produced) summary. ROUGE-N refers to the overlap of n-gram between the system and reference summaries. In particular ROUGE-1, ROUGE-2 and ROUGE-3 were used in the conducted experiments.

4.3 Results

Table 1 shows the results from the experiments. All extractive approaches outperform the baseline algorithm. PreSumm only improved Rouge 1 score from 26.52 (baseline) to 29.25. Extractive Text Summarization with BERT and K-Means yielded the best extractive results - 36.82 Rouge 1 score. When we tried to use the same algorithm but replaced BERT with pre-trained LEGAL-BERT which is fine-tuned on legal texts the results were slightly worse - 36.06 Rouge 1 score. Having in mind that the original summaries are generated in an abstractive way by experts the score of 36.82 can be considered a big success.

Both abstractive algorithms (PreSumm and T5) have limitations on input and output size. Both full texts and summaries were splitted to chunks of sizes 1024 and 128 respectively. During the
Fine-tuned T5-base abstractive model with overridden implementation for handling the long texts by splitting them to chunks showed the best overall results. Here is first paragraph the summary with the highest score (0.65 Rouge-1 F1 score):

Original:

The European order for payment (EOP) procedure applies to all civil and commercial matters in cases where at least one of the parties lives in an EU country different from the one where the application for an order is made. The procedure does not apply to certain issues: revenue, customs or administrative matters, state liability for acts and omissions in the exercise of state authority, matrimonial property regimes, bankruptcy, proceedings relating to the winding-up of insolvent companies or other legal persons, and judicial arrangements, social security, claims arising from non-contractual obligations, unless there was an agreement between the parties or an admission of debt or they relate to liquidated debts arising from joint ownership of property.

Generated:

a European order for payment procedure is established in the EU country where the claimant lives. Its purpose is to ensure that creditors and debtors have equal access to justice throughout the EU. The regulation also establishes an electronic system for determining which courts have jurisdiction to issue an order for payment, as well as a mechanism for the recovery of uncontested pecuniary claims.

Fig. 3 shows the distribution of Rouge 1 F1 scores for all experimented models. The PreSumm abstractive model curve is most similar to normal distribution. We can also observe similar behaviour between baseline extractive curve and PreSumm extractive. The rest have similar shapes and the fine-tuned T5 model achieves the best overall results.

5 Conclusion

We introduced a new dataset about summarization of European legislation documents. We also presented a comparative study of various algorithms for automatic text summarization on this dataset. In our experiments on these tasks, we obtained promising results including huge improvements over baseline. We believe that the new dataset, adopting existing algorithms to domain specific data and the results described in this paper will accelerate research directions on text summarization to expand the variety of domains with domain specific information and different sizes.

Abstract

Moderation of reader comments is a significant problem for online news platforms. Here, we experiment with models for automatic moderation, using a dataset of comments from a popular Croatian newspaper. Our analysis shows that while comments that violate the moderation rules mostly share common linguistic and thematic features, their content varies across the different sections of the newspaper. We therefore make our models topic-aware, incorporating semantic features from a topic model into the classification decision. Our results show that topic information improves the performance of the model, increases its confidence in correct outputs, and helps us understand the model’s outputs.

1 Introduction

Most newspapers publish their articles online, and allow readers to comment on those articles. This can increase user engagement and page views, and provides readers with an important route to public freedom of expression and opinion, with the ability to interact and discuss with others. Comment sections usually provide some degree of anonymity; while improving accessibility, this can also encourage inappropriate behaviour, and publishers therefore usually employ some moderation policy to regulate content and to ensure legal compliance (in some cases, publishers can be held responsible for user-contributed content on their sites).

One possible approach is a ‘moderate then publish’ policy, in which comments must be approved by a moderator before they appear; this requires significant manpower and introduces delays and limitations into the user conversation (for example, the New York Times only allows comments for one day after article publication2). On the other hand, a ‘publish then moderate’ strategy, in which comments are published immediately, and later removed if necessary, is less effective at blocking toxic or illegal content. Combined with the increase in comment volumes in recent years there is increasing interest in automatic moderation methods (see e.g. Pavlopoulos et al., 2017a), either as standalone tools or for integration into human moderators’ practices (Schabus and Skowron, 2018).

Detecting comments that need moderators’ attention is usually approached as a text classification task (see e.g. Pavlopoulos et al., 2017a); but comments can be blocked for a range of reasons (Shekhar et al., 2020). One is the presence of offensive language, a well-studied NLP task (see Section 2 below); however, others include advertising or spam, illegal content, spreading misinformation, trolling and incitement — all distinct categories which might be expected to show distinct features, and perhaps to vary according to the content being commented on. Another aspect that distinguishes the comment moderation task from the usual text classification tasks in NLP is the need for interpretable or explainable models: if classifiers are to be used by human moderators within publishers’ working practices, they must be able to understand the outputs (Švec et al., 2018).

Here, we therefore investigate models which can provide both an aspect of interpretability and the ability to take account of the topics being discussed, by incorporating topic information into the comment classifier. Specifically, we incorporate semantic representations learned by the Embedded Topic Model (ETM) (Dieng et al., 2020) into a classifier pipeline based on Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997). Our model improves performance

__________________________
1Some newspapers allow completely anonymous posting; some require commenters to create an account with a username, but this does not usually reveal their true identity.

2NYT Comment FAQ: https://nyti.ms/2PF02kj
by 4.4% over a text-only approach on the same dataset (Shekhar et al., 2020), and is more confident in the correct decisions it makes. Inspection of the topic distributions reveals how different newspaper sections have different language and topic distributions, including differences in the kind of comments that need moderation.3

2 Related Work

Automated news comment moderation  Most research on this task so far formulates it as a text classification problem: for a given comment, the model must predict whether the comment violates the newspaper’s policy. However, approaches to classification vary. Nobata et al. (2016) use a range of linguistic features, e.g. lexicon and n-grams. Pavlopooulos et al. (2017a) and Švec et al. (2018) use neural networks, specifically RNNs with an attention mechanism. Recently, Tan et al. (2020) and Tran et al. (2020) apply a modified BERT model (Devlin et al., 2019) while Schabus et al. (2017) use a bag-of-words approach.

Some approaches go beyond the comment text itself: Gao and Huang (2017) add information like user ID and article headline into their RNN to make the model context-aware; Pavlopooulos et al. (2017b) incorporate user embeddings; Schabus and Skowron (2018) incorporate the news category metadata of the article. However, no work so far investigates automatic modelling of topics (rather than relying on categorical metadata), or applies this to the comments rather than just their parent articles.

Some steps towards model interpretability and output explanation have also been taken: both Švec et al. (2018) and Pavlopooulos et al. (2017a) use an attention saliency map to highlight possibly problematic words. However, we are not aware of any work using higher-level topic information as a route to understanding model outputs.

Available datasets  Several datasets have been created for the news comment moderation task. Nobata et al. (2016) provide 1.43M comments posted on Yahoo! Finance and News over 1.5 years, in which 7% of the comments are labelled as abusive via a community moderation process. Gao and Huang (2017) contains 1.5k comments from Fox News, annotated with specific hateful/non-hateful labels as a post-hoc task, and having 28% hateful comments. However, both are relatively small, and their labelling methods mean that neither dataset is entirely representative of the moderation process performed by newspapers.

Pavlopooulos et al. (2017a) provides 1.6M comments from Gazzetta, a Greek sports news portal, over c.1.5 years. Here, 34% of comments are labelled as blocked, and the labels are derived from the newspaper’s human moderators and journalists. Schabus et al. (2017) and Schabus and Skowron (2018) provide a dataset from a German-language Austrian newspaper with 1M comments posted over 1 year, out of which 11,773 comments are annotated using seven different rules.

More recently, Shekhar et al. (2020) present a dataset from 24sata, Croatia’s most widely read newspaper. This dataset is significantly larger (10 years, c.20M comments); and moderator labels include not only a label for blocked comments, but also a record of the reason for the decision according to a 9-class moderation policy. However, their experiments show that classifier performance is limited, and transfers poorly across years. Here, we therefore use this dataset (see Section 3), with a view to improving performance and applying a topic-aware model to improve and better understand the robustness in the face of changing topics.

Related tasks  More attention has been given to related tasks, most prominently the detection of offensive language, hate speech, and toxicity (Pelicon et al., 2021). A comprehensive survey of dataset collection is provided by Poletto et al. (2020) and Vidgen and Derczynski (2020).5

Topic Modelling  Topic models capture the latent themes (also known as topics) from a collection of documents through the co-occurrence statistics of the words used in a document. Latent Dirichlet Allocation (LDA) (Blei et al., 2003), a popular method for capturing these topics, is a generative document model where a document is a mixture of topics expressed as a probability distribution over the topics and a topic is a distribution over the words in a vocabulary. The Embedded Topic Model (ETM, Dieng et al., 2020) is an LDA-like topic modelling method that exploits the semantic information captured in word embeddings during topic inference. The advantage of ETM over LDA

3Source code available at https://github.com/ezosa/topic-aware-moderation

4http://24sata.hr/

5http://hatespeechdata.com/ provides a comprehensive list of relevant datasets.
is that it combines the advantages of word embeddings with the document-level dependencies captured by topic modelling and has been shown to produce more coherent topics than regular LDA.

3 Dataset

We use the 24sata comment dataset (Shekhar et al., 2020; Pollak et al., 2021), introduced in Section 2. This contains c.21M comments on 476K articles from the years 2007-2019, written in Croatian. The dataset has details of comments blocked by the 24sata moderators, based on a set of moderation rules—these vary from hate speech to abuse to spam (see Shekhar et al., 2020, for rule description). The dataset also identifies the article under which a comment was posted, together with the section/sub-section of the newspaper the article appeared in. These sections/sub-sections relate to the content of the article: for example, the Sport section contains sports-related news while the Kolumne (Columns) section contains opinion pieces. The largest section, Vijesti (News), is further subdivided as shown in Table 2.

3.1 Data Selection

In this work, we use data from 2018 for training and validation of the topic model and classifiers and data from 2019 for testing. This reflects the realistic scenario where we use data collected from the past to make predictions. For training and validation, we randomly select 50,000 articles out of 65,989 articles from 2018, sampling from the nine most-representative sections/sub-sections (Table 2). Each article comes with c.50 comments on average.

To train the topic model, we sample around 80,000 comments across these articles, with a roughly equal split between blocked and non-blocked comments. This is to encourage a diverse mix of topics from both comment classes. As a preprocessing step we remove comments with less than 10 words from the training data (see Table 1 (lower part)). To train the classifiers, we randomly sample around 80,000 comments such that the sampled set has the same blocking rate as the entire 2018 dataset.

For the test set, we then use all 475,413 comments associated with the 17,953 articles from 2019. Table 1 (upper part) provides the dataset details, with comment moderation blocking rate. For the test set, Table 2 provides details on the section and sub-section of the related articles. These top nine sections account for more than 95% of the comments of the entire test set.

3.2 Content Analysis

To gain some insight into the content of blocked comments, we analyze the linguistic differences between blocked and non-blocked comments and across different sections. First, we compare comment length. As we can see from Table 3, blocked and non-blocked comments have, on average, similar lengths. However, if we further divide blocked comments into two sub-groups — spam and non-spam — we find that on average, spam comments are longer than other comments. We observe a similar pattern across different sections.

Next, we measure lexical diversity using mean-segmental type-token ratio (MSTTR). The MSTTR is computed as the mean of type-token ratio for every 1000 tokens in a dataset to control for dataset size (van Miltenburg et al., 2018). From Table 3, we see that non-blocked comments have higher MSTTR (i.e. higher lexical diversity) than blocked comments (0.62 vs 0.46). However, when we again divide blocked comments into spam and non-spam,
we observe that non-spam blocked comments have a similar MSTTR to non-blocked comments (0.61 vs 0.62), while spam comments have much lower MSTTR (0.35 vs 0.61). This suggests that blocked comments (excluding spam) have as rich a vocabulary as non-blocked. Again, we see a similar pattern across different news sections.

Table 3: Mean-segmental TTR and average length of comments

Now we analyse the usage of topics in our test set. For analysis, we extract the document-topic distribution of a comment in the set and rank the topics according to their weight in this mean distribution. We then take the top 15 topics for analysis because this is the average number of topics in a comment with a non-zero probability in our test set. Note that in this analysis we only use the document-topic

4.1 Topic Model

We use the Embedded Topic Model (ETM, Dieng et al., 2020) as our topic model since it has been shown to outperform regular LDA and other neural topic modelling methods such as NVDM (Miao et al., 2016). We also want to take advantage of ETM’s ability to incorporate the information encoded in pretrained word embeddings trained on vast amounts of data to produce more coherent topics. In the ETM, the topic-term distribution for topic $k$, $\beta_k$, is induced by a matrix of word embeddings $\rho$ and its respective topic embedding $\alpha_k$ which is a point in the word embedding space:

$$\beta_k = \text{softmax}(\rho^T \alpha_k)$$ (1)

The topic embeddings are learned during topic inference while the word embeddings can be pretrained or also learned during topic inference. In this work, we use pretrained embeddings.

The document-topic distribution of a document $d$, $\theta_d$, is drawn from the logistic normal distribution whose mean and variance come from an inference network:

$$\theta_d \sim LN(\mu_d, \sigma_d)$$ (2)

Given a trained ETM, we can infer the document-topic distribution (DTD) of an unseen document. In addition, we can also compute a document-topic embedding (DTE) as the weighted sum of the embeddings of the topics in a document, where the weight corresponds to the probability of the topic in that document:

$$DTE = \sum_{k=0}^{K} \alpha_k \theta_{d,k}$$ (3)

where $\alpha_k$ is the topic embedding of topic $k$, and $\theta_{d,k}$ is the probability of topic $k$ in doc $d$.

4.2 Topic Analysis

Now we analyse the usage of topics in our test set. We trained the ETM for 100 topics on the training set and inferred the topic distributions of the comments in the test set. For analysis, we extract the top topics in a set of comments. To do this, we take the mean of the topic distributions over the comments in the set and rank the topics according to their weight in this mean distribution. We then take the top 15 topics for analysis because this is the average number of topics in a comment with a non-zero probability in our test set. Note that in this analysis we only use the document-topic
distributions and not the document-topic embeddings. To more easily discuss the topics here we provide concise labels for each topic as interpreted by a native speaker. Automatic labelling of topics is a non-trivial task and an area of active research (Bhatia et al., 2016; Alokaili et al., 2020; Popa and Rebedea, 2021).

First, we examine the prevalent topics in the blocked and non-blocked comments, separately. The top topics of non-blocked comments cover a diverse range of subjects from politics to football while the top topics in blocked comments are dominated by spam and offensive language (Figure 1). However, we also see many topics shared between blocked and non-blocked comments.  

7 All 100 topics and labels are available at https://github.com/ezosa/topic-aware-moderation

Next we illustrate how different topics intersect and diverge between blocked and non-blocked comments across sections by looking at the top topics of two thematically-different sections, Lifestyle and Politika (Politics).

Figure 2 shows the top topics of these sections and the intersections between them. In Politics, blocked comments tend toward spam and targeted insults. Non-blocked topics include public safety and finances. However, we also see that more than half of the top topics overlap between blocked and non-blocked. This suggests that, thematically, there isn’t a very clear distinction between blocked and non-blocked comments in the Politics section.

In Lifestyle, blocked topics are dominated by spam and while there are topics on offensive insults, they are not as prevalent as the spam-related ones. The non-blocked topics are about family and relationships and commenters arguing with each other. Compared to Politics, we see a clearer distinction between topics in blocked and non-blocked in this section. In terms of topic overlaps between Lifestyle and Politics, blocked comments in both sections are dedicated to spam and insults while non-blocked comments focus on positive sentiments.

The combination of certain topics also provide an indication of the classification of the comment. For instance, we notice the use of topics about football cards in comments that do not do not discuss the sport (for instance, football cards as a topic is prominent in the blocked Lifestyle comments). It turns out that some commenters use the red and yellow cards from football as metaphors for being banned or having their comments blocked by moderators (12% of comments that use these metaphors are blocked by moderators). On the other hand, comments that use the football cards topics and any of the sports-related topics are likely to be a genuine discussion of football (only 5% of such comments are blocked by moderators). We show some examples of these comments in Table 5.

So clearly there is a distinction between the usage of topics in the non-blocked and blocked comments. We therefore think it is a good idea to propose a model which incorporates topic information into a comment moderation classifier.

5 Topic-aware Classifier

Our aim is to improve comment moderation predictions by combining textual features with document-level semantic information in the form of topics. To this end, we test several model architectures that combine a language model with topic features.

For the comment text representation, we use a...
bidirectional LSTM (BiLSTM, Schuster and Paliwal, 1997). The comment text is given as input to an embedding layer then a BiLSTM layer where the output of the final hidden state is taken as the encoded representation of the comment. For the topic representations, we use the topic distributions (DTD) and topic embeddings (DTE) discussed in Section 4.1.

We propose two fusion mechanisms to combine the text and topic representations: early and late fusion. In early fusion, topic features are concatenated with the output of the embedding layer and then passed to the BiLSTM layer. In EarlyFusion1 (EF1), only DTD is concatenated with the word embeddings; EarlyFusion2 (EF2) uses DTE instead of DTD; and EarlyFusion3 (EF3) uses both DTE and DTD. In late fusion, topic features are concatenated with the output representation of the BiLSTM layer, and passed to the MLP for classification. Again, LateFusion1 (LF1) uses DTD; LateFusion2 (LF2) uses DTE; and LateFusion3 (LF3) uses both. Figure 3 shows the architectures.

Our model is inspired by the Topic Compositional Neural Language Model (TCNLM, Wang et al., 2018) and the Neural Composite Language Model (NCLM, Chaudhary et al., 2020) that incorporate latent document-topic distributions with language models. Both of these models simultaneously learn a topic model and a language model through a joint training approach. The NCLM introduced the use of word embeddings to generate an explanatory topic representation for a document in addition to the document-topic proportions to produce the document-topic embeddings (DTE). Also unlike the TCNLM and NCLM, we use pre-trained topics in our model so as to easily de-couple and analyse the influence of topics in the classifier performance. Another related work is TopicRNN (Dieng et al., 2016), a model that uses topic proportions to re-score the words generated by the language model. The topics generated by this model, however, have been shown to have lower coherences compared to NCLM (Chaudhary et al., 2020).

6 Experimental Setup

Dataset As discussed in Section 3.1, we use the 2018 data as the training and validation sets of our topic-aware classifier and the 2019 data as the test set. Details of the train and validation sets are shown in Table 1 and the test set in Table 2.

Baseline models To assess how topic information improves comment classification, we use as baselines the following models trained only on text or topics:

- **Text only**: a classifier with BiLSTM & MLP layers, similar to Figure 3 but with comment text alone as input.
- **Document-topic distribution (DTD)**: MLP only, document-topic distributions as input.
- **Document-topic embedding (DTE)**: MLP only, document-topic embeddings as input.
- **DTD+E**: MLP only, concatenated document-topic distributions and embeddings.

Hyperparameters We use 300D word2vec embeddings, pretrained on the Croatian Web Corpus (HrWAC, Ljubešić and Erjavec, 2011; Šnajder, 2014), for training the ETM and to initialize the embedding layer of the BiLSTM. The ETM is trained...
for 500 epochs for 100 topics using the default hyperparameters from the original implementation. The BiLSTM is composed of one hidden layer of size 128 with dropout set to 0.5. The MLP classifier is composed of one fully-connected layer, one hidden layer of size 64, a ReLU activation, and a sigmoid for classification with the classification threshold set to 0.5. We use Adam optimizer with $lr = 0.005$. We train all classifiers for 20 epochs with early stopping based on the validation loss.

7 Results

In Table 4, we present the performance of the baselines and proposed models, measured as macro F1-scores. All models that combine text and topic representations perform better than the models that use only text or topics. Of the baseline models, the DTD model performs comparatively better than the DTE and DTD+E models, and surprisingly performs almost as well as the Text-only model; however, we show in Section 8 below that DTD is much less confident in its predictions than the Text-only model. Overall, the best performing model is LF1, which improves the Text-only model’s performance by +4.4% (67.37% vs 62.97%); and improves by a similar amount over Shekhar et al.’s results using mBERT (macro-F1 score 62.07 for year 2019).

Interestingly, we see a wide variation in performance across news sections. We observe that comments in Lifestyle and Tech are the easiest to classify (best F1 over 72.00) while Politika (Politics) is the most difficult (best F1 around 61.61). The main cause appears to be that Lifestyle and Tech have the highest proportion of spam comments: on average, 49.44% of blocked comments in the test set are spam, but for Lifestyle and Tech this number rises to 77.25% and 69.63%, respectively. As for the Politics section, the most likely reason the comments are difficult to classify is that, excluding spam, there is a high degree of overlap in the subjects discussed in the blocked and non-blocked comments (see the topic analysis in Section 4.2).

7.1 Analysis of Classifier Outputs

In general, we observe that blocked comments tend to use similar topics across different sections while non-blocked comments have more diverse topics. Of the nine sections that we analyzed, there are five topics that are prominent in blocked comments in all sections (‘Targeted/personal insults’, ‘Spam4’, ‘Spam7’, ‘Online media’, and, ‘Having a discussion’) and only three topics prominent in non-blocked comments (‘Having a discussion’, ‘Online media’, and, ‘Life and government’). This suggests that blocked comments are more semantically-coherent across sections than non-blocked ones. In contrast, topics in non-blocked comments tend to be more relevant to their respective sections: for instance, family and relationships are not discussed a lot in the Politics section, while Lifestyle commenters do not tend to talk about political issues.

The higher topical coherence then of blocked comments explains why a text classification approach can achieve reasonable performance; but the variation in blocked comment content between some sections explains why adding topic information improves our classification results.

Next, we analyze the confidence of classifiers and examine some of the outputs of the models. To analyze confidence, we gradually increase the classification threshold from 0.5 to 1.0 in increments of 0.05. For every new threshold, we plot the macro-F1 for the different models (Figure 4). We compare the confidence of four models: DTD, Text-only, EF2 (the strongest early fusion model), and LF1 (the overall best-performing model). We find that the most confident model is LF1 and the least confident is DTD. The two fusion classifiers display similar levels of confidence. The Text-only classifier is not as confident as the fusion classifiers but still more confident than DTD. This suggests that adding topic features to text not only improves performance, it also increases classifier confidence.

Figure 4: Confidence of the top performing models.

In Table 5 we give some examples of comments and the classifier decisions of the Text-only classifier and LF1 (our best-performing fusion model) and their top topics (topics with prob > 0.10). The

Table 5: Sample comments and classifier decisions.

first example contains swearing which both models pick up on and classify as blocked although LF1 is more confident in its decision than Text-only. In the second example, both models predict the wrong label but LF1 treats this as a borderline case because it is targeted at the moderators. However since this is only a mild provocation of the moderators, this might be a case where the gold label is incorrect. The topics also pick up on the fact that this comment talks about football cards but only has a tenuous connection to the sport (“getting a red card” is an expression used for “being banned”). In contrast, the third comment also uses the banning sense of “card” but is not directed at anyone, and is thus labeled as 0 (non-blocked), which both models get right. Again the topics indicate that the comment is not really about the sport. The fourth example shows a case where “cards” are mentioned in their standard football sense but also contains a swear word, making the gold label of 0 (non-blocked) questionable. The better performance of LF1 on such examples, compared to Text-only, implies that
LF1 is better aware of the different semantics of “card” (sports-related vs. metaphorical), likely due to added topic information.

The fifth example contains a moderately offensive insult that is not directed at any single group except the 24sata readership in general. One reason why both classifiers do not get this right is that the word jadnici is not strong enough to be considered offensive. Finally the last example is clearly a spam comment that both classifiers correctly classify but for which the gold label is incorrect.

Overall, compared to the Text-only model, we find that LF1 more often than not improves the confidences (and sometimes the classification), especially in cases in which the gold label is clear. This is valuable in practice, as better confidences might lead to better prioritisation of comments for manual moderation, reducing the time required to remove the most problematic ones.

8 Conclusion

In this work, we propose a model to combine document-level semantics in the form of topics with text for comment moderation. Our analysis shows that blocked and non-blocked comments have different linguistic and thematic features, and that topics and language use vary considerably across news sections, including some variation in the comments that should be blocked. We also found that blocked comments tend to be more semantically coherent across sections than non-blocked ones. We therefore see that the use of topics in our model improves performance, and gives more confident outputs, over a model that only uses the comment text. The model also provides topic distributions, interpretable as keywords, as a form of an explanation of its prediction. As future work, we plan to incorporate comment, article, and user metadata into the model.

Acknowledgements

This work has been supported by the European Union Horizon 2020 research and innovation programme under grants 770299 (NewsEye) and 825153 (EMBEDDIA), and by the UK EPSRC under grant EP/S033564/1.

Ethics and Impact Statement

Data The dataset and annotations are provided by the publisher of 24sata.hr, Styria Media Group, for research purposes and deposited in the CLARIN repository. The authors of the comments are anonymised. The researchers used the data as-is and did not modify or add annotations.

Intended Use The models we present here are intended to assist comment moderators in their work. We do not recommend that the model be deployed in the moderation process without a human-in-the-loop.

Potential Misuse The models and the analysis of their performance we provide in this paper could be used by malicious actors to gain an insight into the comment moderation process and find loopholes in the process. However, we think such a risk is unlikely and the impact it might have outweighs the potential benefits of models intended to assist human moderators such as the ones we present here.
