After the definition of the feature set, they should be combined into a score for each node. This is accomplished through a linear combination of all attributes with an optimized weight vector, so that important nodes have higher scores. The weights are optimized through the Simulated Annealing method, as it is designed to be capable of escaping from local minima or maxima. To this extent, we used the algorithm developed by Ludermir et al. (2006) for weight optimization in Neural Networks. To obtain the target class of each node (if it should be considered relevant or not), the extractive sum-

4.3 Machine Learning Methods

As there is a new whole set of features developed (Table 1), they can be used as a training input for some Machine Learning algorithms aiming at clas-

sifying nodes as relevant or not, similarly to the original work of Leskovec et al. (2005). The algorithms explored in this work are the following: SVM (originally used by Leskovec et al. (2005)); Decision Trees and Random Forest, which are straightforward interpretable algorithms; and Multi-layer Perceptron, a simple Neural Network method, which is a popular research area currently, specially through Deep Learning<sup>5</sup>. From the selected nodes, the same original rules can be used upon them to

---

<sup>5</sup>We, however, do not explore Deep Learning methods, as they usually require high quantities of data, which we do not have available.
create the final summary graph.

We also explored another machine learning based approach in order to overcome the limitations of the set of rules used, as they prioritize the first sentences of the corpus, which may not be ideal in a multi-document setting. Therefore, one can use the concept of Levi Graphs to also include the relations into the classification problem. Levi Graphs are AMR representations within which the relations (edges) are turned into nodes connected to each original extreme of the edge (Beck et al., 2018). In this way, the relations can also be represented as a feature vector and, consequently, they can be classified directly by the algorithms, dismissing the use of rules for this purpose.

As the classification of edges can lead to disconnected graphs, which would be against the representation guidelines, the largest connected component is selected as the final summary graph.

5 Experiments Setup

As a source of opinions, we used the OpiSums-PT corpus6 (Condori et al., 2015), comprising the opinions from ReLi (Freitas et al., 2014) (concerning 13 books) and also comments about 4 electronic products, obtained from the Buscape e-commerce website7. This corpus also comprehends 10 summaries for each product, 5 extractive and 5 abstractive, created by 14 human specialists. Thus, the corpus contains 171 opinionative documents with a total of 1,502 sentences.

Following the AMR guidelines for the Portuguese language, 404 sentences from the corpus were manually annotated8. Two products of the OpiSums-PT corpus have been fully annotated into AMR to this date. Thus, in this work, they are used as a gold standard test set. In order to compare how the quality of the graphs used with each method interfere in the results, we used an automatic AMR parser (Anchiêta and Pardo, 2018a) to annotate two similar products9, resulting in a total of 4 products in the test set.

We also made use of the parser in order to create an artificial training corpus for the proposed supervised approaches (via score optimization or Machine Learning) from the 13 remaining products of the OpiSums-PT, resulting in 65 examples (pairs of opinions graphs and their corresponding summary graph), with a total of 3,290 AMR sentences, from which 388 are considered relevant to compose the summaries.

Another important resource used is the B2W-Reviews01 corpus10 (Real et al., 2019), which was used, in conjunction with the ReLi (Freitas et al., 2014) corpus (excluding the two products used for the testing) to calculate the Document Frequency term in the TF-IDF counts.

For evaluation, we adopted two metrics from the AMR research community: Smatch (Cai and Knight, 2013) and SEMA (Anchiêta et al., 2019), which are used to compare two AMR graphs (the automatic summary graph and its corresponding gold standard manually annotated graph). As the OpiSums-PT corpus provides 5 summaries for each product, all of them have been used to evaluate the summarization output, however, due to lack of space, we report only the average of these values.

We also would like to call attention to the fact that the Simulated Annealing optimization is sensitive to its random initialization, so it was evaluated by running the same experiment 10 times with different starting weights. The values reported in this paper are the average upon all experiments.

6 Results

The results for every experiment executed are shown in Table 2. For fairness, we compare our methods to other AMR-based summarization approaches, since there is no robust Natural Language Generation tool from AMR to text in Portuguese.

As can be seen, the Random Forest algorithm using the Machine Learning method without Levi graphs, proposed in this work, had the best results among the manual annotated comments, resulting in a Smatch improvement of 15% from the best literature method (Liao et al., 2018). Meanwhile, the Integer Linear Programming based ones (Liu et al., 2015; Liao et al., 2018) were the best for the parsed sentences, indicating that their method is more robust with regards to the quality of the input graphs. The quality of the graphs is, how-

</table>

We do, however, highlight that this does mean that the attributes set is not fit to the problem, since it worked well with the Random Forest algorithm. Thus, the research of other types of weight optimization techniques, such as Genetic Algorithms as used in the work by Khan et al. (2018), may lead to better results. It is also expected that the inclusion of other linguistic features may improve the outcome (Leskovec et al., 2005).

From the optimized weights, however, we can see how important each of the developed features are. This is accomplished by calculating the correlation of the absolute value for the weights with the evaluation metrics used. This result is shown in Figure 2, in which the more intense the green color is, the more important its corresponding feature is.

As can be seen in the heatmap, the most important features to be noticed are the average neighbor degree, the eigenvector centrality and the depth, with some attention to the clustering coefficient feature. On the other hand, the most detrimental features are those which are assigned to deeper shades of pink. There are not much features which can be considered effectively harmful to the quality of the summaries – i.e. there are no features which have such a high negative correlation to the evaluation metrics – but it can be observed that both the TF-IDF and the Hubs features do have a stronger negative correlation.

The lighter colors are related to the features that
may not have had an impact over the output quality. The sentiment analysis features (sentiment and aspect, commonly used in Opinion Summarization approaches) do not appear to have a role of importance during the summarization process, even though we are dealing with opinions.

The feature analysis also highlights our previous observation that the feature set comprises other types of important information. Although there was not much difference (using Smatch or SEMA) between the score optimization method and the original one from Dohare et al. (2018), the results were obtained taking into account different features (e.g., eigenvector centrality vs. TF-IDF). This indicates that there is indeed room for improvement by combining these forms of knowledge.

7 Conclusion

The incorporation of semantic knowledge via explicit representations into the summarization process is a fruitful field of research. In this context, this paper focused on the development of methods for opinion summarization that took advantage of the semantics encoded within AMR graphs.

The experiments indicate that our Machine Learning approach, using the Random Forest algorithm, produced better summary graphs compared to other AMR-based summarization techniques. We also confirm the findings of Liu et al. (2015), stating that the quality of the input graphs used is important to ensure the creation of good summaries. An analysis of the feature set also suggests that using sentiment and aspect information does not actually improve the results.

As future work, we recommend the further development of the feature set, since it has been shown to be effective for a Machine Learning approach, including mainly new linguistic features, as originally proposed by Leskovec et al. (2005). We also advocate that exploring other optimization techniques can be an important path of investigation, such as the Genetic Algorithm approach used by Khan et al. (2018).

There is also a significant improvement to be done during the merging of sentence graphs into a single document representation. Currently, only the concept labels are taken into account, however the usage of coreference resolution can be a valuable enhancement towards the creation of a consistent multi-sentence representation (Liao et al., 2018; Dohare et al., 2018; O’Gorman et al., 2018).

Using Collaborative Filtering to Model Argument Selection

Sagar Indurkhya
Massachusetts Institute of Technology, Cambridge MA 02139, USA
indurks@mit.edu &
Virtualitics, Inc

Abstract

This study evaluates whether model-based Collaborative Filtering (CF) algorithms, which have been extensively studied and widely used to build recommender systems, can be used to predict which common nouns a predicate can take as its complement. We find that, when trained on verb-noun co-occurrence data drawn from the Corpus of Contemporary American-English (COCA), two popular model-based CF algorithms, Singular Value Decomposition and Non-negative Matrix Factorization, perform well on this task, each achieving an AUROC of at least 0.89 and surpassing several different baselines. We then show that the embedding-vectors for verbs and nouns learned by the two CF models can be quantized (via application of k-means clustering) with minimal loss of performance on the prediction task while only using a small number of verb and noun clusters (relative to the number of distinct verbs and nouns). Finally we evaluate the alignment between the quantized embedding vectors for verbs and the Levin verb classes, finding that the alignment surpassed several randomized baselines. We conclude by discussing how model-based CF algorithms might be applied to learning restrictions on constituent selection between various lexical categories and how these (learned) models could then be used to augment a (rule-based) constituency grammar.

1 Introduction

In learning a language, a child solves many difficult puzzles using limited input data (Berwick et al., 2011; Piattelli-Palmarini and Berwick, 2012; Lasnik and Lidz, 2017). One such puzzle involves the child deciding whether a given verb can take a particular noun as its complement when the child has never previously observed that verb and that noun co-occur in a sentence. To illustrate this puzzle, let us consider an example - suppose the child learner has heard the following sentences:

(a) “I lied and and said that I would not smash the windshield.”
(b) “The robber was not planning to smash every plate.”
(c) “I want to take this hammer and smash the precious vase!”
(d) “They are going to shatter the windshield!”
(e) “The boy who was busy staring at his phone will trip over and shatter his mother’s favorite plate.”
(f) “Did you shatter the blue vase?”
(g) “She knew that Susan would break her expensive new windshield.”
(h) “I saw the man in the red sweater break the delicate plate.”

Now suppose that the child learner has never heard a sentence in which the verb “break” takes the noun “vase” as its complement. How should the child decide whether the following production is licit?

(i) “He is going to trip over and break the vase!”

One strategy that the child might employ is as follows. First the child observes that the verbs “smash” and “shatter” behave similarly by noting that both verbs can select any of the three nouns “windshield”, “plate” and “vase” as a complement (see sentences (a-c) for “smash” and sentences (d-f) for “shatter”). Then the child observes that the verb “break” appears to be similar to the verbs “smash” and “shatter” by noting that the three verbs can select “windshield” and “plate” as complements (see sentences (a, d, g) for “windshield” and sentences (b, e, h) for “plate”). On the basis of these observations, the child may decide that if the verb “break” really is similar (semantically) to “smash” and “shatter”, then “break” should also be able to select “vase” as a complement, just as “smash” and “shatter” can. Likewise, the child observes...
that the nouns “windshield” and “plate” behave similarly, as they can both be taken as complements by the three verbs “smash”, “shatter” and “break”, and that the noun “vase” appears similar to “windshield” and “plate” in so far as the three nouns can be taken as the complement by the two verbs “smash” and “shatter”. This is a second line of observations that the child may use to support their conclusion that sentence (i) is a licit production. The strategy outlined above is a simplified illustration of how a Collaborative Filtering (CF) algorithm (reviewed in §2), which uses evidence of how related verbs and related nouns behave, can be used to infer whether a given verb can take a given noun as a complement.

The goal of the present study is to evaluate whether CF algorithms, a widely used method in artificial intelligence for developing recommender systems (Cacheda et al., 2011; Jalili et al., 2018), can be used to accurately model argument selection based on co-occurrence data obtained from a large English corpus (see §3 for details). The results of the experiments presented in this study (see §4) suggest that model-based CF algorithms perform well on the task of recommending which nouns a given verb can or cannot select as a complement, achieving AUROC of between 0.89 and 0.90 and surpassing a number of different baselines; notably, we found during model selection that the number of latent factors (and thus the size of the embedding vectors learned by these CF algorithms) was relatively small (at most 6 latent factors) as compared to the number of distinct verbs and nouns appearing in the analyzed co-occurrence data. Furthermore, we found that when we used k-means clustering to quantize the (per-verb and per-noun) embedding vectors learned by these CF algorithms, using the cluster of a particular verb or noun as a proxy for the verb or noun itself (as opposed to a distinct embedding vector per verb or per noun) yielded minimal loss of performance (< 1%) even when we used a relatively small number of verb and noun clusters. (See §5 for details) Finally, our results suggest that model-based CF algorithms should be considered for use in modeling the inferences a language learner makes when considering problems of argument selection (see §6 for discussion).

2 A Review of Collaborative Filtering

Given a (finite) set of users, a (finite) set of items, and information about the ratings assigned by users to items (encoded in a user-item rating matrix), the task of a recommender system is to predict whether a given user would select a given item, or what rating the user would assign to the given item - these predictions can then be used to generate a list of recommended items for the given user (Bobadilla et al., 2013). This study takes the users to be predicates (i.e. lexical verbs) and the items to be the arguments (i.e. common nouns) that a predicate may select as its complement (i.e. object).

Content-based recommendation algorithms exploit similarities between the features associated with each item - e.g. a content-based recommendation algorithm would predict which arguments a given predicate can select by evaluating the semantic and syntactic features associated with the argument (Balabanović and Shoham, 1997; Lops et al., 2011). In the case that we do not have access to features associated with the items, we may employ Collaborative Filtering (CF) recommendation algorithms, which consider both similarities between the users and/or similarities between the items.\footnote{See (Herlocker et al., 2004) and (Su and Khoshgoftaar, 2009) for surveys that review Collaborative Filtering algorithms; see (Burke, 2002, 2007) for a review of hybrid recommendation algorithms that combine aspects of content-based and CF algorithms.} CF algorithms are traditionally divided into two groups, memory-based CF algorithms and model-based CF algorithms, which we will now describe.

Memory-based CF algorithms assume that similar users select similar items and assign similar ratings, with two users considered to be similar if they tend to assign similar ratings to items. Memory-based CF algorithms work by identifying a set of users who are similar to the target user – e.g. via the k-Nearest-Neighbor (KNN) algorithm, using the Pearson correlation coefficient as a similarity measure – and then predicting the rating the target user would assign to a given item by considering the ratings assigned by similar users, respectively weighted by the degree-of-similarity of each user to the target user (Schafer et al., 2007).\footnote{Memory-based CF algorithms can work to identify similar users, referred to as user-based collaborative filtering, or alternatively, work to identify similar items, which is referred to as item-based collaborative filtering (Sarwar et al., 2001).}

Although Memory-based CF algorithms are widely used in practice, they face difficulty with respect to: (a) scaling as the sets of users and items grow, and (b) dealing with a sparse user-item interaction matrix (Adomavicius and Tuzhilin, 2005).
Model-based CF algorithms, in which a predictive model is learned, address the aforementioned difficulties of Memory-based models. In particular, latent factor models such as Singular Value Decomposition (SVD) and Non-negative Matrix Factorization (NMF) employ dimensionality-reduction in which user and item profiles (i.e. the rows and columns of the user-item rating matrix) are embedded in a lower-dimensional space in which latent relationships between users and items become more explicit (Hofmann, 2004; Koren et al., 2009; Lü et al., 2012). In this way, latent factor models address two weaknesses of memory-based CF algorithms, scalability and sparsity, and for this reason the present study employs (latent factor) model-based CF algorithms.

3 Deriving a Verb-Noun Rating Matrix from Corpus Data

This study employs an English corpus, the Corpus of Contemporary American English. The COCA is a 385 million word corpus of (late 20th century and early 21st century) English derived from several domains including spoken language, fiction, magazines, newspapers, and academic articles (Davies, 2009, 2010).

The corpus was preprocessed as follows. First, we tokenized and segmented the corpus text into sentences. We then annotated the tokens in each sentence with Part-of-Speech (POS) tags. Sentences without at least one verb and one common noun were then discarded. Finally we lemmatized the tokens in each sentence using the TextBlob python library. After preprocessing the COCA corpus, the text consisted of 75584272 words (not counting punctuation markers or numbers) segmented into 10087753 sentences, with 34329 distinct verb lemmas (derived from 60963 distinct lexical verbs) and 89541 distinct noun lemmas (derived from 10957 distinct common nouns).

Next, we derived a verb-noun co-occurrence matrix from the processed corpus as follows. The set of distinct (lexical) verb lemmas and the set of distinct (common) noun lemmas were indexed (using lexicographic ordering) as \( \{v_1, v_2, v_3, \ldots, v_k\} \) and \( \{n_1, n_2, \ldots, n_l\} \) respectively. Then the entry at row \( i \) and column \( j \) in the verb-noun co-occurrence matrix has value equal to the number of sentences in the (processed) corpus in which the (lemmatized) verb \( v_i \) and the (lemmatized) noun \( n_j \) co-occur, subject to the following constraints:

1. no other noun or verb appears between \( v_i \) and \( n_j \);
2. the verb \( v_i \) must appear in the WordNet\(^4\) verb database (Fellbaum, 1998);
3. the noun \( n_j \) must appear in the WordNet noun database (Miller, 1990, 1998);
4. for a sentence to be counted: (a) the verb \( v_i \) and the noun \( n_j \) must be the last verb and the last noun (respectively) in the sentence, with the verb preceding the noun; (b) neither a pronoun, a punctuation marker (e.g. comma, quotation mark, parenthesis) nor any of the tokens \{ who, what, that, by \} may appear between the verb and the noun.

To compensate for noise in the data, we required that a (verb, noun) pair must appear at least twice to be considered; thus, any entry in the co-occurrence matrix that has a value less than 2 was set to 0. Given our goal of predicting novel (verb, noun) pairings (i.e. where the verb serving as predicate may select the noun as an argument in complement position), we restricted our study to verbs and nouns for which there was evidence (in the corpus data) of co-occurrence with different nouns and verbs respectively. To this end, we removed rows corresponding to verbs that do not co-occur with at least two distinct nouns, and we removed rows corresponding to nouns that do not co-occur with at least two distinct verbs. After this process of reducing the verb-noun co-occurrence matrix, there remained 4172 rows, each corresponding to a distinct predicate lemma, and 12601 columns, each corresponding to a distinct argument column; the verb-noun rating matrix has a total of 716861 non-zero entries. In this way, we computed the verb-noun co-occurrence matrix from the (processed) COCA corpora.\(^5\)

Finally, we constructed the verb-noun rating matrix, which serves as the input to the model-based CF algorithms.\(^6\) We derived a distribution of verb occurrences and a distribution of noun occurrences, and from these two distributions we computed a joint distribution. (See Figure 1) We then used this joint distribution to compute the expected

---

\(^3\)We used the POS-tags employed in annotating the PennTreebank.

\(^4\)See (Miller et al., 1990; Miller, 1995; Miller and Fellbaum, 2007) for reference on the WordNet database.

\(^5\)The verb-noun co-occurrence matrix is stored as a list of three-tuples of (verb, noun, counts) for all (verb, noun) pairs for which counts is non-zero.

\(^6\)This matrix corresponds to the user-item rating matrix in the terminology of collaborative filtering algorithms.
number of counts for each (verb, noun) pairing. We assigned a rating to each (verb, noun) pairing for which there were a non-zero entry in the co-occurrence matrix. Whether a (predicate, argument) pairing was rated high or low corresponded to whether that predicate co-occurred with that argument more or less often than would be expected by chance. The ratings were thus assigned as follows: (i) a high rating, which has numerical value 2, was assigned if the value in the co-occurrence matrix was greater than the expected number of counts; (ii) a low rating, which has numerical value 1, was assigned otherwise.\footnote{7}

4 Experiment

The experiment detailed in this section addresses the question of whether model-based CF algorithms can be used to accurately predict which arguments (i.e. common nouns) a predicate (i.e. a lexical verb) may select.\footnote{8} We evaluated two different latent factor models, SVD and NMF.\footnote{9}

4.1 Methodology

To train a model-based CF algorithm, we employed nested $k$-fold cross-validation with shuffling, with the outer loop used to evaluate trained models, and the inner loop used for model selection (hyperparameter tuning) and model fitting (i.e. training). The outer loop consists of a 5-fold cross-validation loop, with 20\% of the data (i.e. entries in the verb-noun rating matrix) held out as a test data set, and the remaining data used for training and validation. The inner loop consist of a 5-fold cross-validation loop, with 20\% of the data held out as a validation set, and the remaining data used for training. Model selection for both SVD and NMF consisted of opti-
mizing the hyperparameter for the number of latent factors, \( n_f \in [4, 21] \).\textsuperscript{10} Models were evaluated for selection by computing the mean average error (MAE), a commonly used metric used for evaluating model-based CF algorithms. The output of a trained model thus consists of: (i) a mapping between predicates and embedding vectors of length \( n_f + 1 \); (ii) a mapping between arguments and embedding vectors of length \( n_f + 1 \); (iii) a matrix with \( n_f + 1 \) and \( n_f + 1 \) columns.

4.2 Results

We computed four baselines that, given a (predicate, argument) pairing \((p, a)\) in the test set, make the following predictions:

- The \textit{pred.med} and \textit{pred.avg} baselines predict the median and mean values (respectively) of entries with predicate \( p \) (in the training set).
- The \textit{arg.med} and \textit{arg.avg} baselines predicts the median and mean values (respectively) of entries with argument \( a \) (in the training set).

The two trained collaborative filtering models and the four baselines each produce, for a given predicate and argument, a continuous value that we interpret as being a high or low rating based on whether is above or particular threshold value or not. We thus evaluated the performance of each model by computing the Area Under the Receiver Operating Characteristic curve (AUROC), which is presented in Figure 2.\textsuperscript{11} Notably, the two CF algorithms, SVD and NMF, achieved an AUROC of 0.90 and 0.89 respectively, and both models outperformed each of the baselines - this suggests that both of these models perform well on the task of predicting which arguments a predicate can take as its complement. See Table 1 for examples of model predictions.

5 Analysis

Having seen that the two model-based CF algorithms performed well on the task of predicting which arguments a predicate is likely to select as its complement, we now turn to considering whether these CF models encode some knowledge of lexical-semantics. Lexical verbs may be said to cluster together into classes, with lexical verbs in the same class sharing similar syntactic and semantic properties (see the verb-classification established in (Levin, 1993)). The model-based CF algorithms that were evaluated in §4 produced distinct embedding vectors for each argument and for each predicate - this section analyzes whether these embedding vectors for verbs and nouns can be clustered into disjoint groups (of embedding vectors for verbs and nouns respectively). We will restrict our attention to the embedding vectors learned by the SVD and NMF models with median performance (with respect to AUROC).

For each of the two trained CF models, we used the \textit{k-means} algorithm (Lloyd, 1982; Forgey, 1965; Jain, 2010) to group the embedding vectors for predicates and arguments into disjoint clusters of predicates and arguments respectively. The \textit{k-means} algorithm was parameterized by the number of clusters the input (embedding) vectors should be grouped into. Let \( k_p \) denote the number of clusters the predicate embedding vectors are grouped into, and let \( k_a \) denote the number of clusters the argument embedding vectors are grouped into. A grouping of the predicates and

Table 1: Examples of arguments that the SVD model with median performance (as measured by AUROC) does or does not recommend for selection as a complement for the listed predicate.

\textsuperscript{10}Both models were trained over 350 epochs. For SVD we used a learning rate of 0.005 and a regularization rate of 0.02; for NMF we used a regularization rate of 0.06.

\textsuperscript{11}See (Fawcett, 2006) for discussion on interpreting the Receiver Operating Characteristic curve.
arguments using particular values of $k_p$ and $k_a$ respectively is referred to as a model-grouping. We ran $k$-means clustering to compute model-groupings using $k_p \in \{10, 15, 20, \ldots, 55\}$ and $k_a \in \{10, 15, 20, \ldots, 100\}$, with clustering run five times for each selection of $k_p$ and $k_a$.

We next evaluated how well a model-grouping could be used to predict whether a given predicate (lexical verb) selects a particular argument (common noun). Given a particular model-grouping with $k_p$ predicate clusters and $k_a$ argument clusters, for a verb-cluster, $\alpha$, and a noun-cluster, $\beta$, let the $c_{\alpha, \beta}$ be the total number of co-occurrence counts for (verb, noun) pairs in $(\alpha, b)$ that have a high rating, and let $d_{\alpha, \beta}$ be the total number of co-occurrence counts for (verb, noun) pairs in $(\alpha, b)$; next, define the average rating $a_{\alpha, \beta}$ to be $\frac{c_{\alpha, \beta}}{d_{\alpha, \beta}}$, and let us suppose that all (verb, noun) pairs in $(\alpha, \beta)$ are assigned the rating $a_{\alpha, \beta}$. We can then recompute the AUROC for this model-grouping on the test data to evaluate the discriminatory power of the model-grouping; we refer to this metric as the clustered-model AUROC.

We identified model-groupings that achieved near-optimal clustered-model AUROC while using as few predicate clusters and argument clusters as possible. We did this as follows. Let the optimal clustered-model AUROC be the maximal clustered-model AUROC achieved by any model-grouping, and let a model-grouping be called sub-optimal if its clustered-model AUROC is less than 99% of the optimal clustered-model AUROC. Then a model-grouping is called near-optimal if (i) its clustered-model AUROC is within 1% of the optimal clustered-model AUROC, and (ii) decreasing either $k_p$ or $k_a$ yields a sub-optimal model-grouping. We computed the clustered-model AUROC for each model-grouping and identified model-groupings that were near-optimal. We found that near optimal performance (i.e. $< 1\%$ loss of maximal clustered-model AUROC) could be achieved using a relatively small number of clusters for verbs and nouns (relative to the dimensions of the verb-noun rating matrix). See Table 2 for statistics of both near-optimal model-groupings as well as model-groupings that obtained the optimal clustered-model AUROC.\footnote{See Figure 4 and Figure 5 in the appendix for the distribution of the clustered-model AUROC for each of the model-groupings, for the (median-performing) SVD and NMF models (respectively).}

We also computed a summary statistic, the weighted average entropy of a clustering, that serves as a measure of how well (on average) the various verb and noun clusters in a model-grouping are able to cluster together similarly behaving verbs and nouns. This statistic was computed as follows. Given a particular model-grouping with $k_p$ verb clusters and $k_a$ noun clusters, for a verb-cluster, $\alpha$, and a noun-cluster, $\beta$, the entropy for this pair of verb and noun clusters is:

$$e_{(\alpha, \beta)} = -\frac{c_{\alpha, \beta}}{d_{\alpha, \beta}} \log \left( \frac{c_{\alpha, \beta}}{d_{\alpha, \beta}} \right)$$

The entropy $e_{(\alpha, \beta)}$ measures how much information is needed (on average) to determine whether a randomly selected (verb, noun) pair in $(\alpha, \beta)$ has a high or low rating; note that since there are only two possible ratings (high and low), $0 \leq e_{(\alpha, \beta)} \leq 1$, and we expect a good (verb, noun) cluster-pair to have an entropy value closer to 0 than to 1, as that signifies that the members of the cluster pair are either majority high-rated or low-rated (verb, noun) pairs, which in turn suggests that these (verb, noun) pairs behave in a similar manner and are thus appropriate to cluster together. We then compute the weighted average entropy (also bounded between 0 and 1) of the model-grouping $(k_p, k_a)$ is computed as:

$$W_{(k_a, k_a)} = \frac{\sum_{\alpha, \beta} c_{\beta} e_{(\alpha, \beta)}}{\sum_{\alpha, \beta} d_{\alpha, \beta}}$$

Table 2: Statistics for model groupings that are near-optimal with respect to AUROC on test data. Here $k_p$ is the number of predicate (verb) clusters, $k_a$ is the number of argument (noun) clusters. The two bolded rows at the bottom are the model groupings that had the maximal AUROC on the test data.

Finally we sought to understand whether the information encoded within the verb embedding-vectors learned by a latent factor model aligns with traditional classification of verbs by their syntactic and semantic properties. To this end, we computed, for both the SVD and NMF models, the Normalized Mutual Information (NMI) between the clusterings of the predicate embedding vectors and the Levin verb classes. The Levin verb classes were restricted to verbs that appear as verbs in WordNet, and (following (Li and Brew, 2008)) we removed verbs that appeared in more than two verb classes. We also compared the NMI between the Levin verb classes against two baselines:

- Baseline A: group the predicates into \(k_p\) clusters of even size, with predicates randomly assigned to the clusters.
- Baseline B: create \(k_p\) clusters and randomly assign each predicate to one of the clusters.

We found the NMF model consistently had a higher NMI score than the SVD model (and thus aligned more closely with the Levin verb classification), and that both the SVD and the NMF model had higher NMI scores than the two baselines (see Figure 3). Note that the Levin verb classes were derived by considering the set of predicate-argument frames that a verb appears in, of which the argument-selection considered in this study (i.e. how a predicate selects an argument that serves as its complement) is a subset; thus, we expected at most a partial alignment between the predicate embedding vectors produced by the model-based CF algorithms and the Levin verb classes.

6 Conclusion

The results of this study suggest that model-based CF algorithms perform well on the task of inferring which (common) nouns a given (lexical) verb serving as a predicate can select as a complement. The two model-based CF algorithms that were evaluated on this task, SVD and NMF, achieved AUROC of 0.90 and 0.89 (respectively), indicating that they have good discriminatory power and surpassing the performance of several baselines. Notably, these two models achieved this level of performance using at most six latent factors, yielding embedding vectors of relatively low dimensionality as compared to the dimensionality of the verb-noun rating matrix from which they were derived. We also found that the embedding vectors yielded by the SVD and NMF models could each be clustered into a small number of disjoint groups with only a minuscule loss of performance (as measured by AUROC). Finally, we observed modest alignment of the verb clusters with the Levin verb classes as compared to several baselines. We believe that the results presented in this study warrant evaluation of whether model-based CF algorithms are suitable for modeling constituent selection, thereby going beyond inferring the arguments a predicate may select as its complement; such a set of CF models for constituent selection could be used to constrain the productivity of the rules that make up a constituent grammar, thereby yielding a system for learning a grammar from noisy corpus data.

Abstract

Recently, domain shift, which affects accuracy due to differences in data between source and target domains, has become a serious issue when using machine learning methods to solve natural language processing tasks. With additional pretraining and fine-tuning using a target domain corpus, pretraining models such as BERT\(^1\) can address this issue. However, the additional pretraining of the BERT model is difficult because it requires significant computing resources.

The efficiently learning an encoder that classifies token replacements accurately (ELECTRA) pretraining model replaces the BERT pretraining method’s masked language modeling with a method called replaced token detection, which improves the computational efficiency and allows the additional pretraining of the model to a practical extent.

Herein, we propose a method for addressing the computational efficiency of pretraining models in domain shift by constructing an ELECTRA pretraining model on a Japanese dataset and additional pretraining this model in a downstream task using a corpus from the target domain.

We constructed a pretraining model for ELECTRA in Japanese and conducted experiments on a document classification task using data from Japanese news articles. Results show that even a model smaller than the pretrained model performs equally well.

1 Introduction

A domain shift problem occurs when using machine learning to solve natural language processing tasks, where the training data (source) domain is differs from the test data (target) domain.

Because downstream tasks fine-tune a model, pretrained models such as BERT (Devlin et al., 2019) can deal with the domain shift problem. To improve accuracy, the additional pretraining of BERT using the target domain corpus and fine-tuning of the additional pretrained models have been used recently. However, the additional pretraining of BERT requires considerable computing resources and therefore cannot be performed easily. Furthermore, a large corpus of the target domain to be used is required, but this corpus is often unavailable in reality.

In this paper, we attempted to address the computational efficiency of pretraining in domain shifting using efficiently learning an encoder that classifies token replacements accurately (ELECTRA) (Clark et al., 2020).

ELECTRA is a pretraining model that uses replaced token detection (RTD) to replace the masked language modeling (MLM) used in BERT. In MLM, the model is trained by estimating the [MASK] and replacing some words in the input sentence with [MASK]. However, only 15% of the words in BERT are replaced by [MASK], which is computationally inefficient: thus, RTD is an improvement on BERT.

RTD provides two models: generative and discriminative, which are based on the idea of generative adversarial network (GAN) (Goodfellow et al., 2014). The discriminator is pretrained by deciding if it replaces each token generated by the generator. RTD is computationally more efficient because it can handle all tokens in training, and the ELECTRA model using RTD performs better than the BERT model of the same size.

In this study, we first built a general small-scale ELECTRA model. Thereafter, we constructed a domain-specific ELECTRA model by additional pretraining it using a small corpus of the target domain. Although the constructed domain-specific ELECTRA model is smaller than BERT-base, we confirmed that it outperforms BERT-base in the
target domain for a document classification task.

2 Method

The corpus used to train pretraining models can be biased (Bai et al., 2020). We can use a pretraining model unique to the domain that the actual system is targeting to increase accuracy in that domain if we construct one. However, most of the current pretraining methods require considerable computational resources to be effective.

In most cases, increasing the amount of computation needed for pretraining, would increase the accuracy of the downstream task; however, when conducting pretraining, considering the accuracy of the downstream task as well as the computational performance is important.

Therefore, herein, we use ELECTRA, that uses RTD, a computationally efficient pretraining method.

ELECTRA models of various sizes evaluated the performance of the downstream tasks considering computational complexity. Experiments on GLUE (Wang et al., 2018), a benchmark for natural language understanding, and SQuAD (Rajpurkar et al., 2016), a benchmark for question answering techniques, were performed. For the same amount of computation, the ELECTRA model outperforms other state-of-the-art natural language processing models. For example, it performs RoBERTa and XLNet with less than 25% of the computational effort.

For further efficiency, ELECTRA-Small, which can be trained in four days on a single GPU, performs better than GPT and requires only 1/30 of the computation.

Building a pretraining model using ELECTRA, which employs RTD, a more computationally efficient pretraining method, and performing additional pretraining on the corpus in the target domain, we can build a model with accuracy comparable to existing pretraining models for document classification tasks with fewer computational resources and less training time; see Figure 1 for an overview.

3 Experiments

3.1 Pretraining Model

We used a program (run_pretraining.py) available on the official GitHub 2, free TPU resources on Google Colaboratory (Colab), and Google Cloud Storage (GCS) to build the ELECTRA model with pretraining in Japanese. We can reduce the training time even more than the GPU using the TPU resources on Colab. Furthermore, TPU on Colab can only input and output data via GCS, so using GCS is necessary.

For the pretraining corpus, we used the full text of Wikipedia in Japanese, which is same as BERT from Tohoku University (Tohoku-BERT). We used Mecab-NEologd for the tokenizer as well as for Tohoku-BERT.

To build the training corpus, preprocess the text, create the vocabulary files, and create the TensorFlow dataset for pretraining, the software on Tohoku-official BERT’s GitHub 3 was used.

3.2 Model Evaluation

The build model was evaluated based on its success on a document classification task in a small domain. We used the Livedoor-news corpus as the evaluation data for fine-tuning. This is a dataset of Japanese news articles from Livedoor-news published by RONDHUIT Inc.

Each document comprises a URL, creation date, a title, and a body text. Here, we labeled the article body numerically according to its category.

We divide the text of an article into training and test data for each of the nine categories, train a model on the training data, perform a nine-value classification task on the test data to predict the article’s category from the text of the article, and assess performance based on the percentage of correct answers.

The numerical labels for each category and number of articles included are shown in Table 1.

3.3 Results

ELECTRA-JP-Small, the model we developed, was pretrained with small size parameters rather than base size parameters, as in Tohoku-BERT. This is because we also consider the computational efficiency of pretraining. In fine-tuning, training is done up to 50 epochs. The trained models are saved for each epoch, and the value with the highest percentage of correct task answers for each model is selected. The results are shown in Table 2.

We perform model comparison experiments using the SentencePiece-based Japanese ELECTRA model (ELECTRA-JP-SentencePiece) released by

Cinnamon AI Inc. as a guide. This model is a pretrained model with the same parameter size as ELECTRA-Small.

The ELECTRA-JP-Small model provides a higher percentage of correct answers than the ELECTRA-JP-SentencePiece model, (Table 2). However, because the model’s parameter size is smaller than the base size, the correct response rate is approximately 4% lower than the Tohoku-BERT model.

3.4 Additional Pretraining

Additional pretraining using this small corpus would enable us to create comparable models; we have been fine-tuning using a domain-specific small corpus and noting the computational efficiency of the ELECTRA models.

Therefore, we experimented to confirm this process. The text of articles from the Livedoor-news corpus, which was used in the previous experiment, was extracted in plain text and used as a single pretraining dataset for the additional pretraining of ELECTRA-JP-Small.

The ELECTRA-JP-Small has already been pretrained for 1 M steps (24 h in training time). We increase the number of steps in this model (ELECTRA-JP-Small-1.25M) by 0.25 M (10 h of training time); see Figure 2 for an overview.

After the additional pretraining, we run the fine-tuning five times on the models, extract the highest correct response rate value from each of the five models, and show the average and highest values in Table 3.

As shown in the table, even with a small parameter size model, we could to confirm that by performing additional pretraining with a small corpus of domain-specific data, we can create an ELECTRA model that outperforms Tohoku-BERT.

3.5 Prediction Time

The ELECTRA model we developed is smaller than the Tohoku-BERT model. This is expected to reduce the training and prediction times during fine-tuning. To confirm this, we measured the training and prediction times for each of the 50 models created during fine-tuning for both ELECTRA-JP-Small and Tohoku-BERT. The results are shown in
3.6 Model Size

Table 4 shows the predictions of the pretraining time up to 1M steps using TPU for different model sizes.

The results in Table 2 are not an exact comparison of model performance because of the performance difference due to the parameter size of the pretraining model. Even with one TPU resource, building an ELECTRA model with the same parameter size as Tohoku-BERT requires approximately a week of training time. As pretraining requires huge computational resources, the larger the model size, the more difficult it becomes to build a pretrained model. The ELECTRA model, which is more parameter efficient for smaller models, the performance was reasonably good even for small size. However, this does not go far enough to override the performance of the different model sizes. To confirm the difference in model performance more accurately, constructing pretraining models of the same size is necessary.

3.7 Effects of Additional Pretraining

From the results in Tables 2 and 3, it is clear that the pretraining model with a small corpus of domain-specific data before the downstream task can im-

</tbody>
</table>

---

Table 4: Pretraining time for models up to 1M steps. The time in the table is the predicted pretraining time for the model up to 1M Steps.

---

Figure 3.

The average training time for each BERT model was approximately 61.7 s, and for each ELECTRA model was approximately 14.4 s. Moreover, each model in BERT took an average of 160.4 s to predict, and in ELECTRA took on average of 33.6 s. Summing up the time taken by each of the 50 models, the training time for BERT was 51 min 25.1 s and the prediction time was 2 h 13 min 39.7 s, whereas the training time for ELECTRA was 11 min 58.7 s and the prediction time was 27 min 59.7 s. From these results, it can be seen that ELECTRA-JP-Small can train the model in approximately 1/4 the length and predict in approximately 1/5 the length than Tohoku-BERT.
prove the model’s accuracy after fine-tuning.

The larger the parameter size of the model, even for BERT and ELECTRA, the more time it takes to pre-train the model, and thus the more difficult it is to perform additional pretraining. However, for small models, the time required for additional pretraining is much shorter than for base-size models. Therefore, additional pretraining of the ELECTRA-Small model with a small corpus of domain-specific models can achieve better performance with less computation.

4 Related Work

4.1 Masked Language Modeling

MLM masks a certain percentage of words in the input sentence (usually approximately 15%). The masked words are replaced with other words or special tokens, such as [MASK], and the model is assigned to predict the masked words. BERT with such a pretraining method outperforms the conventional language model on many of the downstream tasks. However, because the MLM methods is used to predict masked words, only 15% of the masked words in each input sentence are used to train the model. Therefore, pretraining a model using MLM requires considerable computational resources. Additionally, the token [MASK], which represents the mask, exists only during pretraining and does not appear during fine-tuning. This mismatch of [MASK] tokens between pretraining and fine-tuning slightly degrade the performance of MLM pretraining models.

4.2 Replaced Token Detection

ELECTRA employs a new pretraining method called RTD to improve the weaknesses of MLM. It learns a bidirectional model like MLM while learning from all input sentences like a conventional language model.

Based on the idea of GAN, RTD trains the generative model to distinguish between “real” and “fake” input words. Rather than collapsing the input sentence by replacing a word with [MASK], as BERT dose, RTD collapses the input sentence by replacing it with a “fake” word that is false but plausible compared to the original sentence. Thereafter, the discriminative model is trained to take the
collapsed sentence as input and to predict which words have been replaced compared to the original input sentence.

The generator model can be any model that produces token output distributions, but a previous study (Clark et al., 2020) used a small MLM model trained concurrently with the discriminator model, i.e., the BERT model with a small hidden layer scale. Although the relationship between the generator and discriminator is similar to the structure of GAN described above, applying GAN to the text domain is not easy. Therefore, the generator is trained using the maximum likelihood to predict masked words rather than adversarial. If the generator correctly predicts the original word of the masked word, the word is labeled as the original word.

The generator and discriminator share the same input word embeddings, and after pretraining, the generator is removed and only the discriminator is adjusted in the downstream task. Both the two models use the neural transformer architecture.

### 4.3 Analyzing the Efficiency of MLM

MLM is considered inefficient, and to confirm this, Clark et al. (2020) set up and experimented with three models. The performance of ELECTRA is improved by defining the loss for all input tokens instead of only partially. BERT’s performance is slightly impaired by the discrepancy between pretraining and fine-tuning in the [MASK] token. BERT has already been replaced with random tokens as a measure to improve this mismatch; however, even this measure is not sufficient. Consequently, ELECTRA is computationally more efficient than BERT owing to more efficient tokens and less mismatch during fine-tuning (use of MASK symbols). The improvement in ELECTRA can also be attributed to other factors than fast learning. ELECTRA outperforms BERT by a wider margin when the model size is smaller, and it converges perfectly. Although more analysis is needed, ELECTRA is generally considered more parameter efficient than BERT.

Because ELECTRA-JP-Small and Tohoku-BERT model sizes are different, we did not confirm the exact difference in computational efficiency, but if the two Japanese models of the same size are trained together, ELECTRA will likely produce better accuracy.

### 4.4 Unsupervised Domain Adaptation

Models that generate contextualized word embeddings, such as ELMo and BERT, perform well across natural language processing tasks when pretrained on large unlabeled corpora. Although these models use corpora such as Wikipedia or news texts for training, it is unclear whether this approach is effective when the domain and writing style of the target text differ significantly from the pretrained corpus. However, fine-tuning the distributed representation using the text in the target domain improved the performance (Han and Eisenstein, 2019).

In the related research, two texts were tested as target domains: Early Modern English and Twitter. Both are different from the existing pretrained corpora, but the proposed method provides substantial improvements over the BERT model.

We use the computationally efficient ELECTRA model for fine-tuning the target domain instead of BERT to improve the accuracy in downstream tasks and increase the computational speed using a smaller model.

### 4.5 Domain/Task Tuning

Contextualized word embeddings may be ineffective for tagging tasks when the target domain is different from the pretrained corpus. This is especially serious for unsupervised domain adaptation because the labeled data may differ significantly from the target text. To address this problem, a method of the AdaptaBERT model for unsupervised domain adaptation was proposed.

Specifically, the following two approaches have been applied.

**Domain Tuning** Unsupervised tuning of the BERT language model using text from the target domain. For example, BERT trained on Wikipedia can be retrained using Twitter text.

**Task Tuning** A way to tune BERT using teacher data. For example, for named entity recognition, this would be to train the entire model including BERT using CoNLL 2003.

The four experimental settings are defined by the combination of domain and task tunings.

- Frozen BERT
- Task-tuned BERT
- AdaptaBERT
• Fine-tuned BERT

Frozen BERT is a method that uses BERT as a feature extractor without training it. Task-tuned BERT is a method that BERT is trained using supervised data from the source domain. AdaptaBERT is a method in which BERT is tuned using unsupervised data from the target domain and then the model is trained using supervised data from the source domain. The last one, Fine-tuned BERT, is a method to train the entire model including BERT using data from the target domain.

The experiment evaluates part-of-speech tagging in the Penn Parsed Corpus of Early Modern English (PPCEME) and named entity recognition in the Workshop on Noisy User Text (WNUT) 2016.

For part-of-speech tagging, used the Penn Treebank (PTB) corpus of 20th century English as the source domain corpus and PPCEME as the target domain corpus. PTB corpus is for modern English, and the PPCEME corpus is for 15th to 17th century English.

For named entity recognition, used Conference on Natural Language Learning (CoNLL) 2003 as the source domain corpus and WNUT 2016 as the target domain corpus. CoNLL 2003 is for news, and WNUT is for Twitter.

The results of part-of-speech tagging and named entity recognition show that using Domain Tuning to train BERT on a corpus of the target domain improves performance. Even if no large amount of labeled data in the target domain is unavailable, improving performance by simply tuning the pretraining model using unsupervised data from the target domain is practical.

In our experiments, we assume a situation where a large amount of labeled data in the target domain cannot be secured. We are exploring how much Domain Tuning can improve the performance of ELECTRA-Small under this situation.

5 Conclusion

In this paper, focusing on the computational efficiency of the ELECTRA model and its good performance at scale, we constructed a domain-specific pretrained ELECTRA model by additional pretraining it using a small corpus of the target domain.

Although the constructed ELECTRA model is smaller than the Tohoku-BERT model to be compared, it achieved higher performance than Tohoku-BERT in document classification in the target domain.

In future work, we would like to construct a pretraining model of the same size to compare the performance of the two models more rigorously.

Abstract

Named entity recognition (NER) is one of the major tasks in natural language processing. A named entity is often a word or expression that bears a valuable piece of information, which can be effectively employed by some major NLP tasks such as machine translation, question answering, and text summarization. In this paper, we introduce a new model called BERT-PersNER (BERT based Persian Named Entity Recognizer), in which we have applied transfer learning and active learning approaches to NER in Persian, which is regarded as a low-resource language. Like many others, we have used Conditional Random Field for tag decoding in our proposed architecture. BERT-PersNER has outperformed two available studies in Persian NER, in most cases of our experiments using the supervised learning approach on two Persian datasets called Arman and Peyma. Besides, as the very first effort to try active learning in the Persian NER, using only 30% of Arman and 20% of Peyma, we respectively achieved 92.15%, and 92.41% performance of the mentioned supervised learning experiments.

1 Introduction

Named Entity Recognition (NER) is a fundamental Natural Language Processing (NLP) task, in which we try to identify and classify certain entities such as organizations, persons, locations, etc. in a given text. A named entity is often a word or expression in the text that bears a valuable piece of information, which can be effectively used in other high-level NLP tasks such as machine translation, question answering, and text summarization. Unlike English, which is rich in digital resources, there are some natural languages such as Persian, which is regarded to be a low-resource language. However, Persian is an important language because it is spoken by more than 110 million people worldwide.

In this article, we introduce an efficient model for Persian NER. To tackle problems such as the lack of labeled data in Persian, we have used two different learning methods, i.e., transfer learning (Pan and Yang, 2010) and active learning (Settles, 2010). To transfer knowledge in transfer learning, the model-based (parameter) approach (Settles, 2010) has been used to fine-tune BERT (Devlin et al., 2019). Through transfer learning, we can produce a powerful model using limited data that takes much less training time. We also employed active learning in order to perform the fine-tuning task by using only a few informative samples instead of the whole dataset. Through active learning, it is possible to deliver a performance that is very close to that of a supervised learning method.

The structure of this paper is as follows. We review the literature in Sec. 2; BERT is discussed in Sec. 3; Our proposed method is explained in Sec. 4; The results of our experiments are given in Sec. 5 and the article is concluded in Sec. 6.

2 Literature Review

2.1 Named Entity Recognition

The models that have tackled NER through Deep Learning (DL) consist of three main components: 1) input representation, 2) context encoder, and 3) tag decoder (Li et al., 2020). For the first component, Word2Vec (Mikolov et al., 2013) was used in (Lample et al., 2016) and both Word2Vec and GloVe (Pennington et al., 2014) were used in (Poost-
chi et al., 2018). As the second component, in most studies, a bidirectional long short-term memory (BiLSTM) has been used to capture long-distance dependencies (Li et al., 2020; Shahshahani et al., 2019; Lample et al., 2016; Bokaei and Mahmoudi, 2018; Poostchi et al., 2018). In other studies, an architecture named Transformer (Vaswani et al., 2017) was used. In the architecture of Transformer, there is no recurrent structure and it operates based on attention mechanisms, which lead to an increase in parallelization (Vaswani et al., 2017). The Pre-trained BERT model is based on the Transformer architecture and supports more than 100 live languages, including Persian. It has also been applied to NER (Devlin et al., 2019; Taher et al., 2019). As the last component, Conditional Random Field (CRF) (Lafferty et al., 2001) has been mostly used as the referred tag decoder. The main reason for choosing CRF is that, instead of merely looking for the best label (tag) for each word, it jointly uses neighboring tags to determine a sequence of output labels (Li et al., 2020; Lample et al., 2016; Bokaei and Mahmoudi, 2018; Poostchi et al., 2018; Taher et al., 2019).

Table 1: Details of Arman and Peyma datasets (Poostchi et al., 2018; Shahshahani et al., 2019).

2.2 Dataset

One of the datasets that have been used in Persian NER is called Arman, which was first published in 2016. It consists of about 250k tokens and six classes: location, organization, person, facility, product, and event (Poostchi et al., 2018) 1. In 2018, another dataset called Peyma was published in (Shahshahani et al., 2019), which includes 300k tokens and seven classes: location, organization, person, time, data, money, and percent, Table 1 2.

2.3 Active Learning

The active learning strategies are divided into three groups: pool-based sampling, stream-based sampling, and membership query synthesis (Settles, 2010). In the first two, the instances are taken from a pool of data and a stream of data, respectively. However, in the last one, instances are generated. The main advantage of the pool-based sampling is that it provides the possibility of running a comparison among all instances and selecting the most informative samples for training the model. The pool-based sampling method has been applied to English NER in several studies (Shen et al., 2017; Chen et al., 2015).

In (Shen et al., 2017), OntoNotes-5.0 English and Chinese were used for active learning experiments. The authors employed different selection strategies, where in each case, an LSTM-based model was firstly trained with 1% of the original training dataset. Then, in each round, the most informative instances were selected from the remaining 99% for training; and each round was ended when 20,000 words had been added to the training dataset. The training process was repeated at the end of each round based on the accumulated dataset and the parameters of the model were updated through this repetition of training. They showed that by this active learning process, one could achieve 99% performance of supervised learning, using only 30.1% of the Chinese dataset. It was also shown that the same performance could be achieved using only 24.9% of the English dataset.

In (Chen et al., 2015), the NER task was handled for medical texts. The authors used

---

1Arman is available at: https://github.com/HaniehP/PersianNER/blob/master/ArmanPersoNERCorpus.zip
2Peyma is available via a folder named 300K at: http://en.itrc.ac.ir/sites/default/files/pictures/NER.rar
the 2010 i2b2/VA annotated dataset. They randomly split the dataset into two parts: (1) a pool including 80% of the data for being used during the active learning process and (2) a test set including the remaining 20% for assessing the NER model. The authors simulated practical pool-based active learning by getting labels from the mentioned pool instead of interacting with an actual user. It was emphasized that the labels had not been accessed unless the active learning algorithm selected an instance for being added to the training data. They gained F1 score of 80% on the 2010 i2b2/VA dataset, using only 58% of the original training data.

To the best of our knowledge, active learning has not been previously applied to Persian NER and our work is the first examination of this learning method in Persian NER.

3 BERT

As it was mentioned before, the architecture of BERT is based on Transformer. BERT is a pre-trained model, trained on about 3.3 billion unlabeled data. Its input embedding consists of three parts: 1) token embedding, 2) segment embedding, and 3) position embedding (Devlin et al., 2019). For token embedding, WordPiece has been employed. Segment embedding is used to distinguish a pair of input sentences. The goal of position embedding is to determine sentence word order as the words of each sentence are fed to BERT simultaneously and without any specific order (Devlin et al., 2019).

BERT is applicable in both freezing and fine-tuning methods (Pan and Yang, 2010). In freezing, no change is applied to the pre-trained model. Freezing leads to the extraction of constant features from the model so that they can be used as contextualized word embeddings. In contrast, in the fine-tuning method, the parameters of certain layers are fine-tuned based on a down-stream task and labeled data. It was shown that fine-tuning outperforms freezing (Peters et al., 2019). Therefore, we have used fine-tuning in our proposed method. Besides, like several previous studies, we have used CRF for the tag decoding. The detailed account of our proposed method, which we are going to refer to as BERT-PersNER, is given next.

4 Proposed Method

4.1 BERT-PersNER

BERT has been used as the first two sections of our NER architecture (i.e., the input representation and the context encoder sections). BERT generates an intermediate representation for each token. These intermediate representations will be later used to predict the output label sequences. As the tag decoder section of the mentioned NER architecture, we have used CRF for predicting output labels. We have used a number of fully connected neural networks to ensure that the BERT output vector dimension will match with the number of possible tags for each token. The architecture of BERT-PersNER is shown in Figure 1.

Assuming that $x = \{x_1, x_2, \cdots, x_N\}$ shows the observed input tokens of length N, and $y = \{y_1, y_2, \cdots, y_N\}$ represents the corresponding output labels in a linear-chain CRF, $P(y|x)$ is calculated as follows:

$$P(y|x) = \frac{e^{Score(x,y)}}{\sum_{y' \in Y(x)} e^{Score(x,y')}},$$ (1)
where
\[
Score(x, y) = \sum_{i=0}^{N} T_{y_i, y_{i+1}} + \sum_{i=1}^{N} P_{y_i} \quad (2)
\]
In equation 2, the transition matrix \( T \in R^{K+2 \times K+2} \), in which \( K \) is the count of distinguished labels and +2 is added for the beginning and ending labels, represents a transformation from one label to another. The transition matrix is initialized randomly and is updated during training. The fully connected neural network output is in the \( P \) matrix, where \( P_{i,y_i} \) represents the score of label \( y_i \) for \( i^{th} \) input token. \( Y(x) \) is the set of all possible labeled sequences for \( x \). The loss function equals the negative log-likelihood and the best sequence label obtained through the following equation and the Viterbi algorithm:
\[
y^* = \arg\max_{y' \in Y(x)} \log P(y'|x) \quad (3)
\]

4.2 Active Learning in BERT-PersNER

In this work, similar to some earlier researches (Shen et al., 2017; Chen et al., 2015), we have simulated the pool-based sampling method of active learning and, instead of interacting with an actual user for obtaining labels, an annotated dataset has been used. Akin to some earlier works, we randomly divided the original training dataset into two parts: an initial batch named \( L \), which contained 1% of the data, and a pool named \( U \), which included the remaining 99%. Note that the label of no instance in \( U \) was accessed unless that our selection strategy chose that instance for being added to \( L \).

The active learning framework in BERT-PersNER consists of the following four steps:

1. Building the initial model: to begin with, the initial BERT-PersNER model is obtained through performing the training process using the \( L \) batch.

2. Sorting the instances: at this stage, based on a selection strategy, the informativeness of the instances in \( U \) is measured (i.e., done without accessing the labels). Then, 10% of the top-ranked instances, together with their labels, are removed from \( U \) and added to \( L \).

3. Training: the BERT-PersNER model is then trained again on the new \( L \) and the parameters of the model are updated.

4. Iterating: stages 2 and 3 are repeated until that the instances of \( U \) are exhausted.

The selection strategy can be regarded as the most important part of active learning, because the informativeness of each instance is determined by this strategy. In this study, uncertainty sampling (Lewis and Gale, 1994) has been used as our selection strategy. This selection strategy is based on the idea that if the label of those instances on which the model is less certain is known to the system, it will be more beneficial. The following three uncertainty sampling strategies have been implemented in this study:

- Normalized Least Confidence (NLC) (Lewis and Gale, 1994): in this strategy, the certainty of the best label sequence for each input sample is used as a criterion to find the least confident instances. To eliminate the length effect of input sentences, for each instance, a Normalized form of least confidence is calculated through the following equation:
  \[
  \phi^{NLC}(x) = 1 - \frac{1}{N} P(y^*|x; \theta), \quad (4)
  \]
  in which \( x \) is the input sequence, \( y^* \) represents the best label sequence for \( x \), \( N \) is the length of \( x \), \( \theta \) shows the model parameters, and \( P \) is the instance confidence (i.e., based on equation 1).

- Margin (M) (Scheffer et al., 2001): in this strategy, using the following equation, the marginal difference between the first two best label sequences is used as the criterion for finding the least confident instances:
  \[
  \phi^{M}(x) = -(P(y_1^*|x; \theta) - P(y_2^*|x; \theta)), \quad (5)
  \]
  in which the negative sign is added to select the instances with the lowest margin.

- Sequence Entropy (SE) (Settles and Craven, 2008): here, the entropy of all label sequences is used as the criterion to
find the least confident instances through the following equation:

$$
\phi_{SE}(x) = - \sum_{y'} P(y'|x; \theta) \log P(y'|x; \theta)
$$

Since the number of possible label sequences grows exponentially as our input sentence length increases, we have only considered the N-best (with N = 16) label sequences for each instance.

Table 2: F1 scores (in percentage) of running our model on Arman and Peyma.

Word-level evaluation of BERT-PersNER on Arman shows that the best performance of this model is achieved on I-person, and its weakest performance is where it deals with B-event and B-product. On the other hand, in the phase-level evaluation, the model performs best on Person and worst on Event. This is mainly due to the differences between tag counts in Arman; as it is depicted in Table 1, the frequency of Person tags is twice as many as Event tags, and four times as that of Product. Note that although Location is the most frequent tag in Arman, its resemblance to Organization causes that the BERT-PersNER performance on Location to become weaker than its performance on Person.

Word-level evaluation of BERT-PersNER on Peyma shows that its best performance is on I-percent and its worst performance is on B-time. On the other hand, phrase-level evaluation of the model indicates that it works best on Percent and its weakest performance is on Time. This is due to the fact that, although the tag count of Percent in Peyma is not high, the low level of variety between different Percent tags allows the model to learn this class effectively. On the other hand, due to a low tag count of Time and resemblance to Date make BERT-PersNER acts worst on Time.

Figure 2: BERT-PersNER performance on Arman, using different selection strategies

Figure 3: BERT-PersNER performance on Peyma, using different selection strategies

Table 3 shows BERT-PersNER performance against two recent studies (Shahshahani et al., 2019; Bokaei and Mahmoudi, 2018). As it is observed, our proposed model outperforms the baselines on Arman. More precisely, word-level evaluation, BERT-PersNER improved Deep-CRF by 2.73%. Furthermore, in phrase-level evaluation, it enhanced the results of the baseline by 4.01%.

As it is shown in 3, a word-level evaluation of BERT-PersNER performance on Peyma against that of (Shahshahani et al., 2019) did not result in any improvement. However, in a phrase-level evaluation, it has improved the result of baseline by 2.05% of F1 score.

In all our active learning experiments, the evaluation of BERT-PersNER has been performed in word-level. Since a gradual increase of data on its own can improve the model performance, in addition to the previously mentioned selection strategies, we have used a random selection strategy as our baseline. Here, too, a three-fold cross validation has been employed and the final results have been averaged over the three-fold. In each iteration, the chosen selection strategy takes 10% of the remaining unlabeled data from the pool and adds it to the training dataset. That is about 507 and 546 sentences of Arman and Peyma, respectively.

As it can be observed in Figures 2 and 3, reflecting the results of Table 4, NLC has outperformed its counterparts. We think this is due to the fact that it elects the instances based on their very best label sequence, whereas other strategies also take other slightly weaker instances into consideration (e.g., the second best label sequence is used in Margin). As it is shown in Figure 2, on average, the performance of SE, M, and RAND on Arman has been respectively weaker than that of RAND. On Peyma (cf. Figure 3), again, RAND has been the weakest of all; but there has not been any clear superior between SE or M.
As it can also be seen in the mentioned figures, in the earlier stages of active learning, the gradient is much higher than its later stages, which is an indication of selecting much more informative instances in those earlier stages.

Using only 30% of Arman, NLC achieved 92.15% performance of supervised learning. On the other hand, in the case of Peyma, using 20% of data, NLC reached 92.41% performance of the supervised learning approach. Therefore, by using more informative instances, we can reach a performance compatible with that of supervised learning with much less required data. This data saving is particularly critical in the case of low-resource languages such as Persian.

6 Conclusion

We fine-tuned the pre-trained BERT model for the task of Named Entity Recognition in Persian, which is regarded as a low-resource language. We employed both transfer learning and active learning methods to develop a new model called BERT-PersNER for Persian NER. The new model was evaluated on two Persian NER datasets, which are called Arman and Peyma. We first evaluated BERT-PersNER in a supervised approach, which was done on both word- and phrase-level. Our new model outperformed two previous studies in Persian NER by 2.05%, 2.73%, and 4.01% F1 scores, in phrase-level on Peyma, in word-level on Arman, and in phrase-level on Arman, respectively. In the word-level evaluation on Peyma, however, the performance of BERT-PersNER was lower than the best available related work by 0.86% F1 score.

BERT-PersNER was evaluated word-level using the active learning approach with four different selection strategies. As our main contribution, it was shown that using only 30% of Arman, we can achieve 92.15% performance of the supervised learning method. It was also shown that using only 20% of Peyma, we can reach 92.41% performance of the supervised learning case. To the best of our knowledge, the application of active learning in Persian NER is the very first effort in this respect. As our future work, we intend to investigate the impact of other selection strategies on BERT-PersNER. We also plan to evaluate the proposed approach using other newly published pre-trained models.

Cross-lingual Fine-tuning for Abstractive Arabic Text Summarization

Abstract

While abstractive summarization in certain languages, like English, has already reached fairly good results due to the availability of trend-setting resources, like the CNN/Daily Mail dataset, and considerable progress in generative neural models, progress in abstractive summarization for Arabic, the fifth most-spoken language globally, is still in baby shoes. While some resources for extractive summarization have been available for some time, in this paper, we present the first corpus of human-written abstractive news summaries in Arabic, hoping to lay the foundation of this line of research for this important language. The dataset consists of more than 21 thousand items. We used this dataset to train a set of neural abstractive summarization systems for Arabic by fine-tuning pre-trained language models such as multilingual BERT, AraBERT, and multilingual BART-50. As the Arabic dataset is much smaller than e.g. the CNN/Daily Mail dataset, we also applied cross-lingual knowledge transfer to significantly improve the performance of our baseline systems. The setups included two M-BERT-based summarization models originally trained for Hungarian/English and a similar system based on M-BART-50 originally trained for Russian that were further fine-tuned for Arabic. Evaluation of the models was performed in terms of ROUGE, and a manual evaluation of fluency and adequacy of the models was also performed.

1 Introduction

When we talk about text summarization that practically means that using certain algorithms, we teach a machine to subtract information from an extensive text and provide a significantly shorter overview of it. And just like in the case of human beings, like a number of cases in our own school experiences, there are two ways of doing that.

The first way is called extractive summarization (Nallapati et al., 2016; Zhang et al., 2018; Narayan et al., 2018). In this method the idea is to practically highlight, take out certain keywords, phrases, or sentences from the text and put them together. Therefore, the result, the summary will use the exact same words, terms, and sentences as the original, and almost certainly even in the same order. It is practically the same method, when we humans glance through a massive text, like a thick script, or a book in just a few minutes. The machine would, just like our mind, focus on the first few words, paragraph, or page, then pick up the most commonly occurring words, and extract complete sentences with them, without changing anything in the sentence.

The second way is abstractive summarization (See et al., 2017; Paulus et al., 2017; Rush et al., 2015). Once again, this is not something new for our brain. Like in so many of our school studies, when a certain assignment was given to us and then later asked about in school, we probably did not use the same words and phrases of the original reading material, but we had a general idea about it, which we explained in our own plain words. And since our limited capability to remember and the inherent tendency for laziness, our summary was usually short, only an essence reflecting the original passage. Quintessentially that is abstractive summarization. Creative reconstruction of a textual message built on its comprehension.

We chose to focus on the Arabic language because it presents us challenges, which once surpassed can open up new fields of research.

Arabic has many features. One of the advantages of the Arabic language is that besides its huge variety of dialects and spoken versions - which is a naturally occurring phenomenon - its formal written version (Fusha), a practically dead language, is highly standardized and lacks major regional varia-
ety. But it still has a massive amount of primary users - native Arabic speakers - and text providers, also a big amount of secondary users, meaning people who are not native speakers themselves but in their engagements with Arab people, or organizations create new texts. This sort of lingual stability is rare among "big languages". So that would be the good side that we have a fairly standard massive corpus with minimal presence of dialectical variables complicating the learning process. On the other hand, Arabic is a language in which short vowels are not written. Though possible, usually not even marked in texts, therefore it is required for the reader to have extensive knowledge of the language, otherwise, the reader would not comprehend the message of the letters, even if he/she knows them.

For better comprehension let us see an example. In English, a given word, like "wish" is always written and read the same way. It might be understood as a verb, or an identically written noun, so there is a number of variables we can attach to the word but given the surrounding text that is easy to process. With some words, like "read", which can be either past or present, and the application of idioms, this number of variables grows, but not significantly. And the number of words presenting such a feature is also fairly limited, as these are rather highlightable exceptions than rules. In Arabic, however, a three-letter word k-t-b, can automatically present 3 distinct forms, namely "he wrote", "it was written" and "books". With minimal alteration, the number of possible solutions goes up to 20, or so, and that is a base rule with very few exceptions. And here we are still not talking about an agglutinative language, like Hungarian and Turkish, where the suffixes with a big number of variables, but cutting them the core stays fairly the same. With Arabic, we face a massive amount of inherent variables, all to be taken into consideration upon processing. The problem, however, presents an opportunity, as we can exploit this phenomenon to achieve bigger coherence in the text digestion.

Arabic also has another advantage, both scientifically and in the sense of application. It is one of the only 6 U.N. official languages, along with English, French, Spanish, Russian, and Chinese. That means that we have a massive resource of scientific and checked texts, beyond the usual quantity, upon which can be built, and which can be a potential test ground for further development. Meaning that we not only have a large quantity of informal, or semiformal text between native speakers, but we also have a huge reviewed linguistically double-checked text. Given it is a U.N. language, massive amount of texts, which otherwise would have necessarily not concerned the Arab world, are translated into it and linguistically checked by professionals. With the inclusion of the political and economic value of the region, and the amount of politically sensitive and important material to be assessed, the value of a text summarization tool for Arabic cannot be overstated.

The main contributions presented in this paper include a) presenting the first corpus for abstractive Arabic text summarization, b) several neural models to perform abstractive news summarization for Arabic, and c) evaluation of the performance of these models. In addition to leveraging linguistic knowledge embodied in pretrained neural language models (using multilingual BERT, a transformer encoder trained on 104 Wikipedia languages including Arabic, and AraBERT, a monolingual BERT model trained specifically for Arabic), we also apply cross-lingual transfer to improve our results. We use summarization models based on multilingual neural language models (multilingual BERT and multilingual BART-50, a pre-trained sequence-to-sequence model for 50 languages including Arabic) that were originally fine-tuned to do summarization in another language, and further fine-tune them for the Arabic summarization task. We thus also leverage the knowledge of the original models concerning the summarization task they learned from resources in other languages.

The rest of the paper is structured as follows. Section 2 presents related work published on Arabic summarization. Section 3 describes the methodology and the experiments that we have done. Section 4 describes the results of automatic and manual evaluation. The last section concludes the paper.

2 Related Work

The work for Arabic summarization is limited. Most existing systems use the extractive approach. Lakhas (Douzidia and Lapalme, 2004) is considered the first extractive Arabic summarization system that was evaluated and compared with systems processing English input. The system produces a 10-word summary and translates it to English and then it is evaluated using the ROUGE measure.
Another Arabic text summarization approach based on fuzzy logic was proposed by Qassem et al. (2019). This model is based on a new noun extraction method and fuzzy logic. Yet another Arabic text summarization tool, SumSAT, (Lakhdar and Chéragui, 2019) adopts an extractive approach using a hybrid of three techniques: a) contextual exploration which allows access to the semantic content of a text, without the need for deep syntactic analysis; b) identification of indicative expressions offering the possibility of generating a summary in a general topic or a specific domain by selecting sentences that contain specific indicators, and c) the graph method which generates the summary by selecting the most representative phrases of the source text.

The evaluation process differs between these systems, as well as the datasets used for evaluation. Lakhas (the first extractive Arabic summarization system) was evaluated cross-lingually. It generates a summary, translates it to English, and then it evaluates the English summary using the ROUGE-N measure. For that aim 240 documents and their corresponding summaries were produced and used as a dataset. In the case of the SumSAT tool, performance was evaluated in terms of precision and recall of the discursive annotation generated by SumSAT and manual reference annotations (i.e. it was not summaries per se that were evaluated). For the evaluation, they constructed a dataset composed of 25 documents and their corresponding annotation. In contrast with the above, (Al Qassem et al., 2019) evaluated the summaries using ROUGE-N (N=1 and 2) metric and evaluated the summarizer using the Essex Arabic Summaries Corpus (EASC) (El-Haj et al., 2010), which contains 153 Arabic articles and 765 human-generated extractive summaries of those articles created using Mechanical Turk.

An RST-based\(^1\) automatic summarization technique for Arabic texts was presented by (Maaloul et al., 2010) which was implemented through the ARSTResume system. They created a corpus of Arabic texts from a newspaper website, and they claimed that the ARSTResume evaluation showed encouraging results based on 50 texts.

Some recently published work also aims to address abstractive Arabic text summarization. Azmi and Altmami (2018) proposed a four-phase abstractive summarizer for Arabic where the core of the system is an extractive summarizer. The four phases are topic segmentation, headline generation, extractive summarization, and sentence reduction. For evaluation, they conducted two experiments. The first is to evaluate the extractive summarizer. For that they used 32 sample documents from two popular Saudi newspapers. The second is to evaluate the abstractive summarizer. For that they used 150 documents from six different Arabic newspapers. In addition, two linguist experts judged the quality of the abstractive summaries.

Another system (Al-Maleh and Desouki, 2020) was trained to generate headlines based on the first paragraph of Arabic articles, a task that can be classified as a kind of abstractive summarization. The authors used a sequence-to-sequence model implementing the pointer-generator approach including a copy mechanism as presented in See et al. (2017). For training and evaluation, they crawled an Arabic data-set consisting of approximately 300 thousand article headline : introductory paragraph pairs.

An attempt at abstractive Arabic text summarization proper was presented in (Elmadani et al., 2020) applying multilingual-BERT-based (Devlin et al., 2019) models for both abstractive and extractive summarization using the models presented in (Liu and Lapata, 2019) trained and tested on the KALIMAT dataset (El-Haj and Koulali, 2013). A shortcoming of the research is, however, that the 20,291 article summaries in KALIMAT are machine-generated summaries output by the extractive Gen-Summ (=AQBTSS) algorithm (El-Haj et al., 2010). The train/test sets are thus neither human generated nor abstractive. Both studies evaluated the summaries using the ROUGE metric (Lin, 2004).

3 Methodology

This paper reflects on a specific approach of abstractive text summarization applied to Arabic. In terms of model architecture, we focus on approaches based on now-ubiquitous large-scale pre-trained language models (LM), such as BERT (Devlin et al., 2019) and BART (Lewis et al., 2020), which obtained new state-of-the-art results in diverse natural language processing tasks, including text summarization. An important feature of BERT and BART is that both of them have a multilingual model available, M-BERT (Devlin et al., 2019) and M-BART:50 (Tang et al., 2020) that include Arabic among the languages supported. In addition, we
need a big enough training and evaluation dataset consisting of Arabic texts and their abstractive summaries. So, the first step we took was to compile a reliable Arabic abstractive news summary corpus.

3.1 Data Collection

While we could mention two recent papers attempting at something that could be categorized as abstractive summarization in Section 2, one of them dealt with headline generation instead of summarization proper, and the other used a machine-generated extractive summaries dataset for training and evaluation. The main bottleneck hindering progress in Arabic abstractive summarization is thus the lack of a sizable dataset. We first needed to overcome this problem. We needed to build an Arabic abstractive summarization corpus. A great source of such a resource could be the press, like in the case of the trend-setting CNN/Daily Mail dataset (See et al., 2017), as many news articles have a lead, a brief overview of the content spread out in the article, with details only supporting, but not altering the original message. The only problem is that news articles with reliable abstractive leads are difficult to find. It is quite often the case that the lead is just a copy of the first paragraph or contains clickbait content rather than containing a good abstractive summary.

Spending considerable effort on evaluating a wide range of sites from the Arabic versions of CNN, BBC, France 24, DW, Sky News to the most popular fully Arabic sites like al-Mayadeen, al-Âlam, al-Ahrâm, al-Akhbar, and Sada-elbalad, we identified two Arabic news resources that could be the basis of a good Arabic abstractive news summaries dataset: the Arabic version of the Deutsche Welle (DW) news website, which seems to be the one containing the best abstractive summaries and the Files section of Sada-elbalad. The latter resource from Sada-elbalad later turned out to contain many problematic items containing several diverse topics only some of which were mentioned in the summary, we thus dropped this resource.

We downloaded Arabic Deutsche Welle resources from Common Crawl. We only kept articles from the “Main/Top Stories” section, and filtered out all articles where either the main article text or the lead was too short or missing and items where the text is shorter than 4 times the length of the lead. The dataset that we used in the experiments consists of 21508 articles and their corresponding leads.

We performed data processing steps on the raw material (the collected articles) to be ready for subsequent processing. Data processing means a number of steps that naturally all differ significantly from one NLP task to another. While that is a sensitive process on its own, we also face another difficulty making it somewhat challenging to rely on the experiences of the already developed model. That is the peculiar nature of each language and that not much similar work has been done on Arabic, which has its own difficulties both as language and script.

We use Python since it is capable to handle the Arabic language. We also use NLTK platform since it is an appropriate tool for Arabic NLP and can be used for preprocessing text for text summarization task with Arabic. Based on our corpora we needed to perform text tokenization. Table 1 displays the main characteristics of the corpora.

3.2 Experiments

The aim of the main task of our work is practically to fine-tune pre-trained language models for our task which is abstractive Arabic text summarization. For this aim, we fine-tuned multilingual BERT (having Arabic among the languages covered) for abstractive Arabic text summarization using our own corpus.

We also fine-tuned AraBERT (Antoun et al., 2020) for abstractive Arabic text summarization using the same corpus. AraBERT is the result of pre-training a BERT model specifically for the Arabic language.

In addition, we propose a cross-lingual-transfer-based approach to improve our results. Using pre-trained multilingual BERT, we fine-tuned multilingual BERT for abstractive Hungarian text summarization using the HVG corpus (Yang et al., 2021) where the articles and corresponding leads were taken from a daily online newspaper. We further fine-tuned this model for abstractive Arabic text summarization using our own corpus.

We followed the same approach using English training data instead of Hungarian. We used the CNN/DailyMail summaries corpus containing over 300k unique news articles to first train an English summarization system fine-tuning multilin-

gual BERT. Then we further fine-tuned this model for Arabic on our corpus.

We also fine-tuned the multilingual BART-50 model, which supports 50 languages including Arabic, using our own corpus. Following the approach mentioned above, we used a model fine-tuned from M-BART-50 for abstractive Russian text summarization using the Gazeta corpus (Gusev, 2020). We further fine-tuned this model for abstractive Arabic text summarization using our own corpus. Table 2 displays the ROUGE results of Hungarian and English m-BERT fine-tuning, and Russian m-BART-50 fine-tuning.

4 Results

Measuring the performance of a summarization system can be done through either automatic or manual evaluation. We evaluated our experiments using the ROUGE automatic metric and compared them to other abstractive Arabic summarization results. We also evaluated our results manually since the reliability of automatic metrics is often perceived as insufficient.

4.1 Automatic Evaluation

Automatic evaluation metrics are the most widely used tools in the overwhelming majority of the research papers on the subject of summarization. We have evaluated our experiments using ROUGE (Lin, 2004). ROUGE-1 and ROUGE-2 measure overlap of word uni-grams and bi-grams respectively. ROUGE-L measures overlap of the longest common sub-sequence between two texts. When comparing the performance of the models that we trained using our relatively small Arabic corpus, we found that using an abstractive summarization model based on multilingual BERT already fine-tuned for English on the CNN/DailyMail dataset as a starting point to train an Arabic summarization model leads to huge improvements in performance, as shown in Table 3.

Note that although there is a significant difference between the measured performance, the numbers cannot be directly compared, because performance was measured on different test sets. Moreover, as it was mentioned in Section 2, TRANS.ABS was evaluated on KALIMAT, in
which summaries are neither human-generated nor abstractive, so that corpus is not in fact suitable for the evaluation of abstractive summarization systems.

4.2 Manual Evaluation

In spite of the recent rapid progress in the development of summarization models, standard automatic evaluation metrics have not developed for nearly 20 years. In our experiments, ROUGE scores determine that our proposed method ranked significantly better than the existing systems, but the ROUGE scores did not reflect the real quality of the summaries generated. For the sake of a more accurate assessment, we decided to conduct a human evaluation. We manually evaluated the summaries generated by the different models. In order to achieve this, we created a web-based evaluation platform containing 100 random samples. For each of the 100 sample articles, the platform displays the following:

- Article text: the article text.
- Lead: the article corresponding lead.
- mBART-50: results generated from fine-tuning M-BART-50 with our corpus.
- mBART-50-ru-gazeta: results generated from fine-tuning the already fine-tuned M-BART-50 for Russian to Arabic.
- BERT multilingual cased trained from English model: results generated from fine-tuning the already fine-tuned M-BERT for English to Arabic.
- BERT multilingual cased trained from Hungarian model: results generated from fine-tuning the already fine-tuned M-BERT for Hungarian to Arabic.
- AraBERT: result generated from fine-tuning AraBERT with our corpus.

The evaluation process was done by 3 human annotators, who are from different backgrounds and have different views. One (S) is from Syria, which is a Levant country, and Arabic is the annotator’s mother tongue. The second (M) is from Morocco (Northwest Africa), where another dialect is used, and we can’t say that Arabic is their spoken mother tongue. The third (H) is from Hungary, who is not a native speaker, but a professional translator. This variety of annotators, who all have different points of view and different approaches to the Arabic language, raises the evaluation standard and ensures more reliable results. Though the two native speakers are both proficient in Fusha, the minor regional stylistic differences and the difference in whether they rely on it as a primary or secondary language, give a different angle of evaluation. The Hungarian annotator, on the other hand, gives an outer, more “neutral” look to the annotation.

We conducted manual evaluation in two steps. The first step is "Ranking", we asked the annotators to evaluate the output of the models and assign marks to each summary from 1 to 6 as shown in Table 5.

<table>
<thead>
<tr>
<th>Ranking</th>
</tr>
</thead>
<tbody>
<tr>
<td>1: BEST</td>
</tr>
<tr>
<td>2: Very good</td>
</tr>
<tr>
<td>3: Good</td>
</tr>
<tr>
<td>4: Acceptable</td>
</tr>
<tr>
<td>5: Poor</td>
</tr>
<tr>
<td>6: Very poor</td>
</tr>
</tbody>
</table>

Table 5: Ranking scores for manual evaluation.

Given the results of the first step of evaluation, we chose the best model and asked the annotators for the second step of evaluation which is giving quality scores, in the range 1 to 5, concerning adequacy (to what extent the output covers most relevant information in the text) and fluency (Table 6).

The ranking results showed that the AraBERT model is the weakest model, while the model based on multilingual BERT first trained for English summarization and then fine-tuned for Arabic (m-BERT English) is the best-performing model.

The manual evaluation showed that the six mod-

<td>5: flawless Arabic</td>
</tr>
</tbody>
</table>

The models differ considerably, though in several areas they are difficult to compare. Output from the m-BERT English model usually comes very close to the original lead. Clarity and language proficiency is rarely a problem.

The m-BERT-based model first fine-tuned for Hungarian (m-BERT Hungarian) also generates good summaries, but usually in a very different way. The wording, structural order, and grammatical tools have a tendency to differ, but in most cases, the meaning does not change. It is usual for this model to generate somewhat (about 10%) longer summaries, but added content is usually explanatory rather than just simple text addition. In other words, these additions give depth to the summary and structural coherence. However, comparison is difficult due to the significantly different expressions used. In other words, while the English-trained BERT model almost recreates the original lead, the Hungarian-trained one formulates the content in a different way.

Summary generated by the model simply fine-tuned from multilingual BERT without pre-training on summaries in another language correlate with those generated by the English-trained model, but they contain significantly more grammatical and contextual errors. Sometimes the message is just the opposite of that of the original article, sometimes the syntax falls apart. Yet there is a good number of promising summaries. It seems like a promising model still in development. It seems unfinished.

The AraBert-based model is far the weakest. It is clearly insufficient for practical usage. This model has a notorious tendency of distorting or reversing the meaning of the text, coming up with disturbingly wrong interpretations. There is a very high number of huge, sometimes hilarious grammatical mistakes not present in the output of any other model. Most problematic, however, is that this model generates far the longest summaries. Often the size is double of that the original lead or the output of the first model, yet this lengthy text does not add anything relevant to the summary. It simply bloats the summary, but does not add content. It seems like randomly selected and poorly sewn together sentences from the original text itself, but with great alterations of the meaning.

The models based on multilingual BART-50 and the m-BART-50-based model first fine-tuned for Russian have almost equally good results to the m-BERT English model, with remarkable text quality and fluency.

There seems to be little chance for improvement for the AraBert-based model, unlike the others, which are very promising. For some of the summaries it cannot be determined whether they were written by a human editor or are machine-generated. See Figure 1,2. Table 7 shows the Kappa(Cohen, 1960) values of inter-annotator agreement. We used 4 metrics to measure the inter-annotator agreement: Fleiss’s Kappa (Fleiss), Krippendorff’s alpha coefficient (Krippen), Scott’s pi (Scott), Average Pairwise Cohen’s Kappa (Cohen). The values of the inter-annotator agreement for the m-BERT English model are substantial.

**5 Conclusion**

In this paper, we introduced the first corpus for abstractive Arabic text summarization, which we compiled with our own effort. Based on this corpus,
we fine-tuned multilingual-BERT and multilingual-BART-based models for Arabic abstractive summarization. We also proposed a cross-lingual-knowledge-transfer-based approach. We applied this approach to improve summarization quality, further fine-tuning models first fine-tuned from multilingual BERT for Hungarian or English summarization to generate Arabic summaries, and applying the same training scenario to Russian using an M-BART-50-based model. The results of the ROUGE metric and manual evaluation showed that the proposed approach led to significant improvements in performance and achieved state-of-the-art results. In the future, we would like to extend our corpus and perform experiments with other models such as the PEGASUS model.

Acknowledgments
The authors of the paper wish to express the deepest gratitude to Professor Gábor Prószéký for his unrelenting support and to Dr. Dániel Sógor and Youssef Messaoudi for their great work in the manual evaluation process. This research was implemented with partial support provided by the National Excellence Programme 2018-1.2.1-NKP-00008: “Exploring the Mathematical Foundations of Artificial Intelligence”.

Abstract

Modern transformer-based language models are revolutionizing NLP. However, existing studies into language modelling with BERT have been mostly limited to English-language material and do not pay enough attention to the implicit knowledge of language, such as semantic roles, presupposition and negations, that can be acquired by the model during training. Thus, the aim of this study is to examine behavior of the model BERT in the task of masked language modelling and to provide linguistic interpretation to the unexpected effects and errors produced by the model. For this purpose, we used a new Russian-language dataset based on educational texts for learners of Russian and annotated with the help of the National Corpus of the Russian language. In terms of quality metrics (the proportion of words, semantically related to the target word), the multilingual BERT is recognized as the best model. Generally, each model has distinct strengths in relation to a certain linguistic phenomenon. These observations have meaningful implications for research into applied linguistics and pedagogy, contribute to dialogue system development, automatic exercise making, text generation and potentially could improve the quality of existing linguistic technologies.

1 Introduction

As is well-known, 2018 saw a breakthrough in natural language processing (NLP) with the advent of several novel pre-trained language models, including BERT (Devlin et al, 2018). These models are capable of fine-tuning, that is, additional training on a smaller dataset for a specific task. Such models develop a certain degree of understanding natural language and therefore require further studies (Zhang et al, 2019; Wallat et al, 2020). To this end, the so-called probing tasks are commonly used, such as testing the model’s ability to identify semantically coherent sentences in running text. A considerable amount of recent research (Gulordava et al, 2018; Salazar et al, 2019, Sun et al, 2019) was devoted to the general language modelling problem and also to masked language modelling. Other scholars (Devlin, 2018; Gong, 2019; Rogers et al, 2020) explored BERT specifically. However, there is a lack of studies concerning BERT’s behavior on Russian language material. In addition, existing papers discuss the problem without taking into consideration systematic linguistic features.

This paper aims to explore the behavior of the pre-trained BERT language model using the example of the diagnostic task of masked language modeling for the Russian language and give a linguistic interpretation of the cases when the model shows unsatisfactory results. This study will focus on new language data with experiment design based on linguistic theories1. The problem will be discussed in terms of the language modelling concept, cognitive science, theory of language, in particular the language frames theory, semantic roles concept, and also negations processing depending on a context.

2 Related Work

Bengio and co-authors (Bengio et al, 2003) suggest the following definition of a language

1 All datasets and the Jupyter notebook with the experiments are made available as a GitLab repository: https://gitlab.com/lieutkat/linguistic-experiments-with-bert/
model: probability distribution over word sequences. Such models can be the basis for solving a large number of NLP tasks, with the help of fine-tuning the general language models. The pre-trained language model weights already encode a lot of information about natural language. Specifically, a pre-trained model provides features of semantics, syntax, and “verbal knowledge” which may be transferred from general to specific tasks (Roberts et al, 2020; Manning et al, 2020). In the past several years, the BERT model and its modifications have become widely used in the natural language processing community (Liu et al, 2019; Lan et al, 2019). The model can be applied to all general types of tasks: single sentence prediction, sentence pair classification, question answering and sentence tagging. As BERT is inherently an encoder for language information, it often plays the role of a text feature extractor (Rogers et al, 2021).

Some authors (Conneau et al, 2018; Kim et al, 2019) focus on different types of tasks regarding language models, namely probing tasks. These authors suggest options for surface information (e.g., recovering a word from its embedding), syntactic information (e.g., the model sensitivity to word order change), semantic information (e.g., identification of main-clause verb tense). Their basic application is testing the pre-training effect: how pre-trained models encode various language phenomena. Currently, there are lists of linguistic capabilities available that allow to explore the of behavior of language models (Ribeiro et al, 2020). Thereby, the main benefit of probing tasks is the analysis of linguistic knowledge that can be extracted from sentence representations (Hewitt et al, 2019).

Other authors (Devlin et al, 2018; Song et al, 2019) suggested a new probing task for language models that is nowadays known as masked language modelling. The key difference is that the model masks some random words from a sequence and then predicts them again based on the contextual information, both left and right. Ultimately, it was suggested to train with masked language modeling, and then fine-tune for specific tasks (Wu et al, 2019; Salazar, 2019).

Differences in human and machine understanding of language were investigated in another paper (Ettinger, 2020), which inspired our experimental setup. The author uses psycholinguistic tests to find out the sensitivity of the model to such phenomena as hypernymy, semantic roles and negation. The tests revealed weaknesses in the language model and proved that computational models have great potential for natural language understanding.

As was pointed out in the previous section, despite this scholarly interest for BERT, there is a lack of studies with a strong linguistic basis. Additionally, previous studies have tended to focus primarily on English language material. The present study is based on a Russian-language dataset and uses theories from cognitive linguistics and the theory of language.

3 Linguistic Basis

From the linguistic perspective, the work of language models is based on the concept of semantic roles (Fillmore, 1976). Speaking about the subject of action, it can have both an agentive (or active) position, and a non-agentive (or inactive) position (Uskova, 2012). Ch. Fillmore also developed the theory of presupposition, which is important for this study. It is the preliminary knowledge that is responsible for the semantic correctness of the utterance. For example, the sentence Snow is expected in Moscow on February 30th, is incorrect due to the fact that it includes a false presupposition on February 30th.

Meanwhile V.Z. Demyankov identifies several types of presuppositions. In our experiment, we will use pragmatic and logical types. Pragmatic presupposition is the conditions and contexts that must be present in order for the speaker’s intention to be realized correctly. The semantic presupposition characterizes the relationship between a sentence and the proposition it expresses.

Another linguistic aspect that requires our consideration is negation. It is considered a semantic primitive integrated into the grammatical and lexical systems of all languages of the world (Paducheva, 2011). We will explore predicate negation.

Speaking about studies of language models, it is necessary to mention the type of lexical paradigmatic relations, such as hypo-hyperonymic. This type of relations reflects the direction of human thinking to systematize lexical units and non-linguistic structures behind them and bring them to a hierarchical form (Kuznetsova, 1989). This fact can be used to evaluate the performance of the language model in such a way that the resulting metric value is interpretable.

So, after considering some linguistic theories and concepts, we came to the term “behavior of
the language model”. According to the Philosophical Encyclopedia (Ilyichev et al, 1983), behavior is a way of reacting to any influence. In this paper, the behavior of a language model is understood as text data that the model provides as output under certain conditions of its use, namely, when testing or applying to a problem.

4 Datasets and Methods

The final dataset consists of three parts, each containing 50 sentences, which were collected using a linguistic observation method. Each part was designed to test and evaluate a certain aspect of the functioning of the language model, namely: common sense inference, the interpretation of semantic roles, and processing negatives depending on the context. Table 1 shows a sample of the data for semantic role interpretation.

<table>
<thead>
<tr>

<tr>
<td>Местное землячество [MASK] ею. The local Ukrainian community was [MASK] by her.</td>
<td>руководилось led</td>
</tr>
</tbody>
</table>

Table 1. Example of a subcorpus for checking the interpretation of semantic roles.

There were two main resources for collecting data. Firstly, educational texts for teaching Russian as a foreign language for B1+ learners, with the help of which the “content” column was filled. Secondly, the National Corpus of the Russian language (RNC)², in which the expected words for contexts were selected through a semantic search. For instance, the selection of contexts for nouns with time semantics was carried out by entering the following characteristics: r:abstr & (t:time:period | t:time:moment).

In the case of semantic roles, complex or simple common sentences were selected from educational texts, the predicate was replaced with a token mask, and the linguistic unit, which had the role of an agent, took on the role of a patient (or experiencer).

To check common sense inference, we selected two consecutive sentences from the educational texts where one word in the second sentence was manually replaced with a mask. Then, using semantic search in the RNC, we selected a word of a related topic and a word of a more general topic with respect to the expected topic. Next, the subcorpus with negations was compiled as follows: in the RNC, using semantic search, we selected sentences with an adjective at the end, and masked the adjective. Finally, the sentence was copied and transformed into a negative one, and the adjective was replaced by its antonym.

The dataset was examined using a Jupyter notebook in the Python programming language with the help of the libraries tensorflow, pytorch and transformers. To perform a comparison, the BERT DrMatters ³ and BERT DeepPavlov ⁴ models for the Russian language, and the multilingual BERT ⁵ were selected.

- The BERT model (bert-base-multilingual-cased) includes 12 layers, 768 hidden layers, 12 heads of the attention mechanism and 179 million parameters. Trained on Wikipedia texts for 104 languages.
- The RuBERT (or BERT DeepPavlov) model was created by the team of the Moscow Institute of Physics and Technology. It contains 12 layers, 768 hidden layers, 12 heads of the attention mechanism and 180 million parameters. The model was trained on the Russian-language Wikipedia and news.
- BERT DrMatters model is based on the BERT DeepPavlov. There is a lack of information about all the other characteristics.

For the assessment, the RuWordNet model was loaded using the ruwordnet package. We received lists of hyperonyms and hyponyms for the target

---

³ See https://huggingface.co/DrMatters/rubert_cased
⁴ See http://docs.deeppavlov.ai/en/master/features/models/bert.html
⁵ See https://huggingface.co/bert-base-multilingual-cased
word, then checked which of the prediction words are included in this list and counted them. Subsequently, the resulting list of numbers was normalized for convenient processing. The obtained data can be interpreted as the proportion of words in the prediction that are semantically related to the target word (that is, there are hyper-hyperonymic relations between them). Using such a metric, it is possible to understand whether the model is trying to put the correct group of objects in the place of the mask, that is, to test the model's ability to generalize and differentiate.

5 Results

5.1 Quality of Predictions

Table 2 provides information about the quality of the models’ predictions for several types of experiment, the measure is normalized RuWordNet-based. The largest values for each type of experiment are highlighted in gray.

</tbody>
</table>

Table 2. Measures based on RuWordNet for multilingual and Russian models (aff – affirmative context, neg – negative context).

The advantage of the measure based on RuWordNet is the fact that a successful prediction is not only the target word itself, but also many of its hyponyms and hyperonyms. For this reason, the values tend to be quite interpretable. Overall, the multilingual model in experiments with semantic roles and negations is slightly ahead of both Russian ones, which have equal values for each aspect. Moreover, no differences were found between the processing of the two types of contexts in the negation experiment. The results of the linguistic analysis are presented below.

5.2 Linguistic Analysis: Common Sense Inference

In case of multilingual BERT, the influence of the pragmatic presupposition is strong, while the role of the logical presupposition is minimal (see Table 3, example 1). It can be assumed that the model uses the acquired background knowledge about historical facts. At the same time the demonstration of background knowledge dominates the observance of grammatical correctness of the prediction (see Table 3, example 2).

<table>
<thead>
<tr>
<th>sentence</th>
<th>target</th>
<th>model's predictions</th>
</tr>
</thead>
</table>

Table 3. Examples from qualitative analysis, multilingual BERT (common sense).

Both models for the Russian language have problems with the pragmatic presupposition: sometimes it is insufficient to fulfill the predictions. Inaccuracies in the predictions occur under the influence of the logical presupposition when it is more pronounced than the pragmatic one (see Table 4). In the example below, the models incorrectly interpret the logical presupposition and perform a pronominal replacement of the subject (“the boy”).

<table>
<thead>
<tr>
<th>sentence</th>
<th>target</th>
<th>model's predictions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Рост Наполеона был выше среднеевропейского. Историки давно закрепили за французским [MASK] прозвище Маленький Капрай.</td>
<td>полководец</td>
<td>[&quot;Наполеон&quot;, &quot;человек&quot;, &quot;племя&quot;, &quot;орден&quot;, &quot;так&quot;, &quot;имя&quot;, &quot;он&quot;, &quot;этот&quot;]</td>
</tr>
</tbody>
</table>

Table 4. Examples from qualitative analysis, multilingual and Russian models.
The boy took out a case, pulled out a gun and began to hurriedly choosing the right ones.

Table 4. Examples from qualitative analysis, BERT DeepPavlov and BERT DrMatters (common sense).

5.3 Linguistic Analysis: Interpretation of Semantic Roles

In the predictions of the multilingual BERT model, the target words themselves are almost absent, but there are more common synonyms for them (see Table 5, example 1). For the case of the non-agentive position of the subject, the model is practically unable to predict the target word correctly (see Table 2, example 2).

Table 5. Examples from qualitative analysis, multilingual BERT (semantic roles).

As for BERT DeepPavlov and BERT DrMatters, when the subject is in the agentive position, the predictions often include the target word (see Table 6, example 1). Moreover, in the situation of the non-agentive position of the subject, the short length of the sentence negatively affects the predictions (see Table 6, example 2).

Table 6. Examples from qualitative analysis, BERT DeepPavlov and BERT DrMatters (semantic roles).

5.4 Linguistic Analysis: Negations Depending on the Context Type

Multilingual BERT’s predictions contain a lot of noise in the form of subwords, UNK-tokens, and punctuation marks. In the predictions without noise, there are often explicit or implicit negation components (e.g., “no”, “absent”, “lack”). Thus, we can suppose that at a high level of abstraction, the model has acquired information about the nature of the context, but it does not have enough representations to express it (see Table 7).
7 Conclusion and Future Work

This paper has investigated the pre-trained BERT language models with probing tasks. As far as we are aware, this is the first time that BERT was explored by professional linguists based on Russian-language material. As a result of this research, we have listed the frequent mistakes made by the BERT model in the masked language modelling task and conducted their analysis. In contrast to previous studies (Ettinger, 2020), where the focus was on psycholinguistic diagnostics and comparison between machine and human performance, we made our study more linguistically grounded by adding knowledge from theory of language. While conducting the research, we created a unique dataset that represents several cognitive phenomena with special annotations. The dataset is made available to the community. In the future, we plan to expand the dataset and annotations to cover more cognitive and linguistic aspects.

Towards Quantifying Magnitude of Political Bias in News Articles Using a Novel Annotation Schema

Abstract

Media bias is a predominant phenomenon present in most forms of print and electronic media such as news articles, blogs, tweets, etc. Since media plays a pivotal role in shaping public opinion towards political happenings, both political parties and media houses often use such sources as outlets to propagate their own prejudices to the public. There has been some research on detecting political bias in news articles. However, none of it attempts to analyse the nature of bias or quantify the magnitude of the bias in a given text.

This paper presents a political bias annotated corpus viz. PoBiCo-21, which is annotated using a schema specifically designed with 10 labels to capture various techniques used to create political bias in news. We create a ranking of these techniques based on their contribution to bias. After validating the ranking, we propose methods to use it to quantify the magnitude of bias in political news articles.

1 Introduction

An increase in Internet and social media access has made it easier for people to know the happenings from all parts of the world. This improved reach of the media has led to people and organisations utilising such platforms to increase their popularity. With this extensive usage of mass communication, there is an increased risk of misinformation, fake news, twisting of facts, and the spread of controversies. In such cases, it is the responsibility of the media houses to verify the authenticity of the reported information and ensure that it is complete, neutral, and not misleading.

However, we often see instances where some news articles emphasize more on particular viewpoints selectively. In some cases, journalists and media houses either intentionally or subconsciously present biased information aligned with their own political ideologies. This can alter public opinion hugely and impact the decision of the general public. This phenomenon of political bias is very prevalent in democracies, especially during elections, where influencing public opinion can have far-reaching consequences.

Detection of political bias in the news is a complex task when it comes to a multi-party political system like India, where multiple parties operate at both state and national levels\(^1\). There has been limited work to date in this area, as discussed in Section 2. However, in a scenario where most of the political content contains bias in some form, it is not just sufficient to identify the existence of bias.

Therefore, we propose two important contributions through this paper - a fine-grained annotation schema specifically designed for analysing political bias and a new sentiment analysis based approach to quantify the magnitude of political bias in an article. We also present PoBiCo-21, an annotated corpus for political bias, containing 500 news articles along with their headlines annotated for various aspects of political bias using our novel annotation schema as discussed in Section 3. The dataset contains news articles in Telugu\(^2\), which is a low resource Dravidian language spoken primarily in the states of Telangana and Andhra Pradesh in India.

2 Related Work

The area of political discourse analysis is closely associated with media studies, political science, anthropology, sentiment analysis, and opinion mining. However, most of the work done is limited to English, primarily due to the high availability of data. For example, Jiang and Argamon (2008) identify

\(^1\)https://bit.ly/3p74aHx
\(^2\)https://en.wikipedia.org/wiki/Telugu_language
subjective sentences in blog posts to understand the political orientation of a given text. Nasab and Dowlatabadi (2015) proposed a rule-based linguistic method to identify bias in a news article based on the semantics of the headline and the article.

Gangula et al. (2019) and Cruz et al. (2020) used attention mechanism on different kinds of document representations to identify bias in an article. Kameswari et al. (2020) proposed a hybrid approach to improve the performance of such ML models by establishing a correlation between presupposition and bias.

Fan et al. (2019) pointed out that restricting to lexical level for detecting bias might not be sufficient and put forward a method of identifying spans of bias by looking at sentences/clauses which are speculative or tangential to the main point being talked about.

Zhou et al. (2011) made use of the comments and opinions of readers in order to classify articles as liberal or conservative. But the limitation to this approach is that it cannot perform well in a political setting where multiple alliances and several parties operate at different levels of the government.

All the work discussed above deals only with the detection of bias, and none of these approaches give us any further insight into the nature or the magnitude of bias in a given text. Our work fills this gap by creating a specialised fine-grained annotation schema for analysing and quantifying the political bias in a given text.

3 Data and Annotation

Our first requirement was a dataset of political news articles containing positive and negative bias along with some unbiased articles. For this purpose, we used the public dataset created by Gangula et al. (2019) as our primary data to begin with. Our aim is to annotate the dataset with different techniques through which bias is generated, and identify the levels of reporting at which it happens. This will be discussed in detail in Section 3.1. We removed the articles which were very short, or had no clear target of bias, either positive or negative. The statistics of our dataset are presented in Table 1.

3.1 Political Bias Techniques

Bias can be incorporated in news articles in several ways. It ranges from selection or gatekeeping bias, which is the selection and filtering of news broadcasted by media houses, since the set of world events is too large to be treated exhaustively. In the case of politics, the scope for subjectivity in selecting information about some specific event, person, or political party often induces bias due to resource constraints, editorial guidelines, ideological affinities, or even the fragmented nature of the information at a journalist’s disposal (Bourgeois et al., 2019).

In this paper, we focus primarily on Presentation Bias which shows how the way of presenting some information can influence the readers directly or indirectly. Since the objective of introducing bias is to persuade the reader towards or against an entity, the methods used to create such bias can also be considered as propaganda. Political Scientist Harold Laswell defines propaganda as “the expression of opinions or actions carried out deliberately to influence the opinions or actions of individuals for predetermined ends and through psychological manipulations”. Herman and Chomsky (2010) came up with a theory on propaganda which views mass media as a group of businesses whose job is to sell readers and audience as a product to other advertising businesses primarily controlled by the government and the corporate sectors.

Based on the strong correlation between propaganda and bias, we used the list of all propaganda

\begin{table}[h]
\centering
\begin{tabular}{|l|c|}
\hline
Polarity of Bias & Number of Articles \\
\hline
Positive & 180 \\
Negative & 220 \\
Unbiased & 100 \\
\hline
Total & 500 \\
\hline
\end{tabular}
\caption{Statistics of our dataset}
\end{table}

3https://en.wikipedia.org/wiki/Sakshi_Telugu

Telugu newspaper owned by the family of the Y.S. Jagan, the leader of YSRCP party and current Chief Minister of Andhra Pradesh. Other possible reasons include the incorporation of subjectivity, or the influence of the personal ideologies of the journalists, editors, and writers of an article, despite the ideal expectation of objective reporting.
techniques compiled from Propaganda and Mass Persuasion: A Historical Encyclopedia, 1500 to the Present by Grandstaff (2006). The list is available on Wikipedia. The original list contains 68 techniques of propaganda. Out of these, many of them were not applicable to political bias. We removed such techniques and clubbed some very similar techniques in the context of political bias to finally create a list of 10 techniques discussed below. It is important to note that these techniques are not mutually exclusive - a given sentence/article may contain multiple techniques together.

1. **Cultural/Identity Bias**: This kind of bias includes all sorts of prejudices towards the class and the identity of a politician/party based on several divisions. Some examples are a subtle or direct portrayal of discriminatory attitudes like racism, casteism, ageism, sexism, etc., which could either be used positively or negatively to create bias.

2. **Amplification**: This is a term used to refer to the introduction of bias by overly hyping or exaggerating information about events/people/parties in order to present a skewed impression to the readers. It is often identified by the use of loaded language in political news. It can cause misrepresentation of the truth of an event or alter the reader’s image of a politician/party/political event.

3. **Personal Targeting**: This technique is said be used when an individual is attacked/glorified for his personal traits instead of their political contributions. This is often done as an attempt to divert attention from other issues, or sometimes even as a way to show agreement/disagreement towards some policies or situations.

   Ad Hominem or Personal attack is a technique of attacking some individuals or their political parties instead of attacking their arguments and policies. This can include name calling, stereotyping, labelling and scapegoating. The opposite of Personal attack is Personal praise, where a person’s qualities and virtues are glorified instead of their work/policy/contribution. It is very common to see politicians engaging in personal attacks towards the leaders of other parties, and highly praising their own party leaders.

4. **Repetition**: Ad Nauseam or Repetition is a way of introducing bias by repeating an idea, question, or a slogan in an attempt to sub-consciously establish that as the truth for the reader.

5. **Appeal to Audience**: This is a technique where the audience is persuaded or won over by appealing to various aspects of their lives such as their fears, beliefs and interests. This technique most commonly occurs in the following ways:
   - **Appeal to fear**: This happens when media or a politician seeks to build support of the audience by instilling panic and fear in them, usually about the outcome of not following the suggested course of action.
   - **Appeal to beliefs and prejudices**: This happens when media or a politician seeks to build a connection with the audience by bringing up shared beliefs and prejudices, and using them to influence the opinion of the audience. This often happens when politicians want to alienate or create a distance between the audience and any other party, by portraying it as an “outside entity” which does not fit in their shared beliefs and opinions.
   - **Appeal to shared identity**: This happens when media or a politician appears to be a “part” of some aspect of the identity of the intended audience, and highlights the image of them as a part of that shared identity.
     Unlike beliefs, these aspects of identities are more concrete. For example, a politician dressing up like a farmer and sowing some crops while campaigning and appealing to farmers.
   - **Appeal by making promises**: This includes trying to persuade a specific set of audience by making promises which benefit them.

6. **Bandwagon**: This is a technique where the audience is persuaded to follow a particular path by presenting it as the most favourable
path which all others are taking. This is done by assuring good results, such as guaranteed victory in the elections.

7. **Black and White Fallacy/Rhetorical Questions**: Black and White fallacy involves presenting the audience with only two choices, while clearly showing only one of them as the most suitable choice. In case of political news, this is also seen in the form of rhetoric yes/no questions, where only one of the answers seems logically correct in that particular context.

Another similar way of using questions to persuade someone is called Hypophora, where the audience is presented with a question, and the speakers themselves give a seemingly correct answer along with an explanation, without giving the audience much time to contemplate. This is done to subconsciously make the audience accept the proposed answer as the correct one without questioning it further.

8. **Intentional Vagueness**: Intentionally presenting the audience with vague information, unstated assumptions or unsupported claims falls under this category. This is often done to make the audience draw certain expected conclusions, which would have been difficult if they knew the whole scenario clearly.

For example, there has been study conducted by Kameswari et al. (2020) which shows how introducing vagueness in the form of presupposition contributes to bias in an article.

9. **Oversimplification**: The idea behind this technique is to oversimplify the implications of following/not following a course of action and showing that it leads to some non-acceptable outcome.

This is similar to a philosophical argument called Reductio ad absurdum, where one attempts to establish a claim by showing that the opposite scenario would lead to absurdity or contradiction.

These ways are often used to persuade the audience to support a presented idea, person or a political party without directly asking them to do so.

10. **Whataboutism**: This is a logical fallacy used to discredit an opponent’s claim by deflecting it to something else. This mostly happens in the scenarios where one is questioned about his/her own actions. There have been studies by Islam (2018) and Dykstra et al. (2020) which show how politicians use whataboutism to dodge questions.

For instance, when the former US President Donald Trump was asked about his opinion on whether Virginia should keep a statue of Confederate general Robert E. Lee, he did not give a straightforward answer but resorted to this technique by asking, “What about other statues of famous Americans?”

### 3.2 Annotation Guidelines and Procedure

Each article was already annotated for the polarity of the bias (-1 for negative, 1 for positive and 0 for unbiased) in the corpus we created from the corpus of Gangula et al. (2019). We additionally had the information of the newspaper each article was taken from. There were 3 newspapers from which the articles were taken - Eenadu, Andhrrajyothy and Sakshi.

![Figure 1: Guidelines for Fine Grained Annotation](https://time.com/4941771/donald-trump-whataboutism-rhetoric/)

Each article was annotated for the presence of the 10 techniques described in Section 3.1. Instead of binary annotation (0 or 1 for the presence or absence of a technique), we decided to annotate at a more fine grained level. This was done to capture whether a particular technique was directly quoted, or introduced indirectly while reporting. This kind of indirect incorporation of bias by media while reporting is known as **Spin**, which was found to
be a frequently occurring phenomena employed to twist the facts and influence public opinion (Mullainathan and Shleifer (2002), Burke (2008)).

For each technique, the annotator had to label 0 if it was not present anywhere in the article, 1 if it was quoted directly in any part of the article, 2 if it was indirectly incorporated in the article, and 3 if it was indirectly incorporated and present in the headline of the article. These guidelines are shown in a hierarchical decision tree format for clear understanding in Figure 1. Each article was annotated by 2 annotators, and the inter-annotator agreement was found to be 0.715.

3.3 Statistics

The statistics of the dataset are presented in Table 2. We observe that the direct occurrences are higher than indirect and headline occurrences for most of the techniques. Personal targeting is the most frequently used technique followed by amplification and intentional vagueness. Oversimplification and repetition are the least frequent techniques in the dataset.

4 Sentiment Based Ranking

Our first step towards quantifying the magnitude or severity of the political bias in an article is to create a ranking of the techniques mentioned in 3.1 based on how much they contribute to creation of bias in a text. This was inspired by Graham’s Hierarchy of Disagreement which classifies disagreement, particularly on online platforms, into 7 levels as shown in Figure 2.

The least level of disagreement was Name calling, where a person just says repulsive things about another person or group of people. On the other end, the highest level of disagreement was Refuting the central point of an argument.

We claim that the sentiment of an article can be a useful indicator of the severity of political bias, since an unbiased article contains only objective information devoid of positive or negative sentiment. Based on this claim, we calculate the sentiment of each news article as the average of its sentence-level sentiment values (-1, 0, 1).

4.1 Model

For the purpose of sentiment analysis in Telugu, we use IndicBERT (Kakwani et al., Kunchukuttan et al.) which is a multilingual NLU model pretrained on 12 Indian languages and evaluated on IndicGLUE. The model used is ALBERT (Lan et al., 2019), a light-weight, compact version of BERT with fewer parameters. After generating embeddings for each sentence using the model, we follow the same approach as Kunchukuttan et al. (2020) and use a KNN classifier with k=4 for sentiment classification task. This performed with an accuracy of 0.52 and F1 score of 0.54 on ACTSA News dataset (Mukku and Mamidi, 2017), which

Table 3: Average values of the sentiment scores of articles containing each technique in descending order.

4.2 Results

Using the sentiment values for each article in the annotated dataset, we try to compute the average sentiment value corresponding to each political bias technique. Since our primary interest is to see how much a technique can shift the article from neutrality, we consider only the magnitudes of the sentiment values of each articles. We collect all the articles which contain a particular technique, and calculate the sentiment score of the technique as the average of all the absolute values of the article sentiments.

According to initial claim, the higher the sentiment value of a technique, the higher is its contribution towards creating political bias in an article. The sentiment value for each technique is shown in Table 3. Personal Targeting has the highest value, which can be supported by the fact that attacking or praising an individual/party instead of focusing on policies/actions is the most direct way of introducing bias. It can also be observed from Table 2 that Personal Targeting was observed in around 84% of the articles in our dataset, making it the most common and frequently used technique in Political bias. Figure 3 shows the sentiment ranking of the techniques in a graph.

5 Schema Validation

To test the reliability of the schema proposed in Section 4.2, we tested it on a bias magnitude comparison task against the human annotation results. For this purpose, we created a test dataset consisting of 100 article pairs. For each pair, the task was to identify the more biased article of the two. All the articles were taken from the political news domain. For human annotation, we had the annotation done by two annotators who had no idea about the schema. We removed the articles on which there was a disagreement between the two annotators. We were left with 92 articles.

Then we gave the test pairs to two other annotators who had the list of the 10 techniques along the definition, explanation and examples. Their task was to identify all the techniques present in the two articles given in each article pair. Then they were instructed to give bias scores for each article by adding the scores of all the techniques from Table 3. In a given pair, the article having a higher score was labelled as the one having a higher magnitude of bias.

If both the articles in a pair had same bias score but at least one non-common label, the comparison was to be done based on the non-common label. If two articles had the same score and same labels, we asked the annotators to mark the shorter of the two articles as the more biased one.

We found that 66 out of 92 times, we were able to correctly identify the more biased article using our ranking. This gives us confidence that the ordering of techniques done through our ranking has a strong correlation with the relative contribution of each technique towards political bias in an article.

6 Conclusion and Future Work

This paper explores the creation of a novel annotation schema which captures the nuances of political bias in a fine grained manner. We propose a sentiment analysis based ranking of 10 political bias techniques, and a validation study to show that this ranking corresponds to the relative contribution of each of these techniques towards political bias. We also contribute a fully annotated dataset- PoBiCo-21, containing 500 articles annotated using this schema. The fine grained annotation can also be used for making other interesting observations from political news data such as identifying media houses which often use biased/ misleading headlines, mining frequently co-occurring techniques of political bias, etc.
6.1 Proposed Direction for Future Research

In the future, we can create an end-to-end bias scoring system which takes an article as an input, tokenises it, detects all potential spans of text containing political bias, assigns the relevant political bias techniques to each span, and computes the final score as the summation of each span length multiplied by the relative sentiment scores of the techniques present in that span. This is shown in a step-by-step manner with an example in Figure 4.

Detection of bias spans can be treated as a standard sequence labelling problem. With good amount of labelled data, we can use Neural Transformer architectures like BERT (Devlin et al., 2018), or its variants like RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2019) etc. Once that is done, we can do a one-to-many mapping from spans to the political bias techniques and then compute the final score of the article.

With the help of this system, a reader can not only quantify and compare the magnitude of political bias of several articles, but also identify the techniques which are being used either directly (by the politicians) or indirectly (by the media) to create bias.

Application of Mix-Up Method in Document Classification Task Using BERT

Naoki Kikuta and Hiroyuki Shinnou
Faculty of Engineering, Ibaraki University, Japan
{21nm720n, hiroyuki.shinnou.0828}@vc.ibaraki.ac.jp

Abstract
The mix-up method (Zhang et al., 2017), one of the methods for data augmentation, is known to be easy to implement and highly effective. Although the mix-up method is intended for image identification, it can also be applied to natural language processing. In this paper, we attempt to apply the mix-up method to a document classification task using bidirectional encoder representations from transformers (BERT) (Devlin et al., 2018). Since BERT allows for two-sentence input, we concatenated word sequences from two documents with different labels and used the multi-class output as the supervised data with a one-hot vector. In an experiment using the livedoor news corpus, which is Japanese, we compared the accuracy of document classification using two methods for selecting documents to be concatenated with that of ordinary document classification. As a result, we found that the proposed method is better than the normal classification when the documents with labels shortages are mixed preferentially. This indicates that how to choose documents for mix-up has a significant impact on the results.

1 Introduction
The high cost of constructing training data is always a problem when solving natural language processing (NLP) tasks using machine learning approaches. Several attempts have been made to solve this problem. One of the most recent methods for constructing training data is data augmentation (Shorten and Khoshgoftaar, 2019). Data augmentation methods can be divided into two types: processing and generation. For image identification, even if an image in the training data is flipped or cropped, the image label does not change. This means that the training data can be increased by adding such processed images to the training data. Alternatively, the method for generating artificial data using generative adversarial network can be considered as a type of data augmentation. The mix-up method is one of the methods for generating data augmentation. It is highly effective and can easily be implemented. Although the mix-up method is used for image identification, it can also be used for NLP.

2 Related topic
2.1 Bidirectional encoder representations from transformers (BERT)
BERT is a high-performance, pre-trained model that has been widely used since its creation by Google (2018) (Devlin et al., 2018). It can be used for classification, word prediction and context determination. In this study, we improve the accuracy of the BERT-based document classification task using the mix-up method.

2.2 Mix-up method
Mix-up is a data augmentation method in the field of image proposed by Hongyi Zhang (2017) (Zhang et al., 2017). The data augmentation is performed using Equations 1 and 2 for image data and labels respectively.

\[ x = \lambda x_i + (1 - \lambda) x_j \]  
\[ y = \lambda y_i + (1 - \lambda) y_j \]

x is a vector of image data , y is a one-hot vector of labels, and \( \lambda \) is the mixing ratio.

3 Previous studies using mix-up method for NLP
Hongyu Guo (2019) conducted a study using the mix-up method for NLP (Guo et al., 2019). The data augmentation is performed using Equations 1 and 2 for image data and labels respectively.
4 Proposed method

If we adopt the mix-up method of the previous study for BERT, we will have a problem. In the methods of the previous study (Guo et al., 2019), it is necessary to create feature vectors of the documents before learning the neural network (NN) (Figure 2). However, document classification using BERT obtains the feature vectors of the documents during the NN learning process (Figure 1), which is a different order from the methods used in the previous study. If we were to adopt the method of the previous study, the calculation of feature vectors by BERT would be done outside the learning process. Therefore, high classification accuracy cannot be expected.

In this paper, we propose the following method.

4.1 How to mix data

We don’t use Equation 1 to mix data. Our method is to concatenate the word sequences of the two documents when they are entered into BERT. With this method, it is possible to learn the BERT part to obtain the feature vector of the document (Figure 3). We present the following examples. This time, we used Japanese document as target and Japanese BERT as model. Compared to English, there is no clear separation between words in Japanese. Therefore, when processing Japanese, it is necessary to divide it by tokenizer into words, characters, and other parts by toke. Then, each devided word is assigned an ID. The ID 2 indicates the beginning of the sentence and is not necessary for the following sequence, so it is excluded. Additionally, since the maximum input length for BERT is 512, we limited the first and second halves of the word sequences’ length to 252 each to avoid exceeding this value. If the sentence length exceeded 252, we discarded the remainder.

The first word sequence

[2, 6259, 9, 12396, 14, 3596, 3]

The second word sequence

[2, 11475, 9, 3741, 5, 12098, 75, 3]

Mixed word sentences

[2, 6259, 9, 12396, 14, 3596, 3,
11475, 9, 3741, 5, 12098, 75, 3]

4.2 How to mix labels
First, each label was represented by a one-hot vector consisting of 0 and 1. A vector consisting two 0.5 and seven 0 was created. The mixed labels contain 0.5; it indicates that the two documents are mixed equivalently. We have the following examples.

Label 3  
[0, 0, 0, 1, 0, 0, 0, 0, 0]

Label 6  
[0, 0, 0, 0, 0, 1, 0, 0, 0]

Mixing of labels 3 and 6  
[0, 0, 0, 0.5, 0, 0, 0.5, 0, 0]

5 Experiment

5.1 Conditions

5.1.1 Execution environment
The experiment was conducted using the graphics processing unit environment of Google Colaboratory.

5.1.2 BERT model we used
We used bert-base-japanese-whole-word-masking\(^1\), one of the pre-training BERT models for Japanese. It was developed by Inui and Suzuki Lab of Tohoku university.\(^1\)

\[\text{https://github.com/cl-tohoku/bert-japanese}\]

5.2 Experimental procedure

5.2.1 Preparing data
In this experiment, we extracted 6623 articles (texts) from the livedoor news corpus and sorted them as shown in Table 1.

\[\begin{array}{|c|c|c|c|c|}
\hline
\text{label} & \text{train} & \text{val} & \text{test} & \text{sum} \\
\hline
0 & 87 & 128 & 566 & 781 \\
1 & 87 & 125 & 571 & 783 \\
2 & 86 & 111 & 581 & 778 \\
3 & 51 & 72 & 335 & 458 \\
4 & 87 & 114 & 582 & 783 \\
5 & 84 & 106 & 565 & 755 \\
6 & 87 & 106 & 590 & 783 \\
7 & 90 & 131 & 589 & 810 \\
8 & 77 & 107 & 508 & 692 \\
\hline
\text{sum} & 736 & 1000 & 4887 & 6623 \\
\hline
\end{array}\]

Table 1: Breakdown of data used

5.2.2 Mix-up of training data
For the training data, we used the mix-up method to expand the data. We used the following two methods for selecting the documents to be mixed.

Selection method 1
The first method is to mix the documents of all labels randomly. We randomly sorted 736 documents

\[\text{https://www.rondhuit.com/download.html#ldcc}\]

\(^{1}\text{https://github.com/cl-tohoku/bert-japanese}\]

---

5.1.3 Corpus used
We used the livedoor news corpus\(^2\), which is Japanese to classify documents into the following nine labels.

- label 0: dokujo-tsushin
- label 1: IT lifehack
- label 2: Home Appliances Channel
- label 3: livedoor HOMME
- label 4: MOVIE ENTER
- label 5: Peachy
- label 6: smax
- label 7: Sports Watch
- label 8: topic news

\(^{2}\text{https://www.rondhuit.com/download.html#ldcc}\)
using a random number, and mixed two adjacent documents (and their labels) in order. We generated 735 extended data using this method. As a result, the number of training data was expanded from 736 to 1471. Additionally, each time the program is run, the selected combination changes.

Selection method 2
The second method of selection is to make up for documents with label shortages preferentially. In this experiment (Table 1), the training data lacks documents with label 3. Thus, we select label 3 documents to mix. Specifically, we randomly selected one document from 51 label 3 documents. Then, we randomly selected one document from 685 non-label 3 documents, and repeated the procedure of mixing the two documents. For the order of concatenation, the documents with and without label 3 form the first and second halves, respectively. As a result, the number of training data was expanded from 736 to 1501. Similar to the selection method (1), the combination changes every time the program is run.

5.2.3 The classifier we created
The model of the NN used as the classifier is BERT with an additional nn.Linear layer. We input a sequence of words of length 512 or less into BERT and obtain a feature vector of 768 dimensional documents from final layer as output. Then, we input it to nn.Linear layer Pytorch has and obtain the prediction for each label in nine dimensions as output. The detailed settings are shown below.

Loss function
Cross entropy: When training a classification problem with classes, nn.CrossEntropyLoss is usually used in Pytorch. However, this time, the labels are in one-hot representation and cannot be input directly into nn.CrossEntropyLoss. Therefore, we used LogSoftmax Pytorch has to calculate the loss according to the definition of cross-entropy (Equation 3). Since we used batch in this experiment, the loss is Equation 4 which is the batch average of Equation 3.

\[ E = - \sum_{k} t_k \log y_k \]  

(3)

\[ E = - \frac{1}{B} \sum_{b} \sum_{k} t_k \log y_k \]  

(4)

Here, \( t_k \) is a correct answer, \( y_k \) is a predicted value, and \( B \) is a batch size.

Optimization function
Stochastic gradient descent (SGD): Using the validation data, we set the learning rate to 0.01, considering both classification accuracy and learning efficiency (Figure 4).

Batch size of the training data
The batch size was set to 10, which was the maximum value possible in Google Colaboratory, the execution environment.

Number of epochs
Considering the range of increase in classification accuracy in the validation data (Figure 4), it was determined that the accuracy reached a convergence value after ten epochs of training.

![Figure 4: Percentage of correct answers in the validation data](image-url)
6 Result

For the normal BERT that doesn’t use mixup, the BERT with mix-up of selection method 1, and the BERT with mix-up of selection method 2, we prepared ten models trained with ten epochs of the training data for each of the methods. Then, the accuracy rate for the test data was calculated. Figure 5 show the box plots comparing each model. The comparison of the mean values of accuracy rate is presented in Table 2.

![Figure 5: Result](image)

<table>
<thead>
<tr>
<th></th>
<th>Accuracy rate (mean)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Normal</td>
<td>0.889</td>
</tr>
<tr>
<td>Mix-up selection 1</td>
<td>0.887</td>
</tr>
<tr>
<td>Mix-up selection 2</td>
<td>0.893</td>
</tr>
</tbody>
</table>

Table 2: Comparison of mean

In the order of increasing accuracy, there are mix-up for selection method 2, normal BERT, and mix-up of selection method 1.

7 Consideration

Given the result, we obtained that the selection method of the documents to be mixed has a great influence on the accuracy. In this experiment, it is effective to prioritize mixing documents with labels shortages. We would try different methods and conclude. In this experiment, we used two documents with equivalent values (ratio 0.5 : 0.5). However, we think that it is worthwhile to try a method for varying the length of the concatenated words. Mix-up method is easier to implement than other data augmentation methods in NLP, and its accuracy has been improved. It is expected to become a mainstream method in the future.

8 Conclusion

In this paper, we applied the mix-up method to a document classification task using BERT. Since BERT allows for two-sentence input, two documents with different labels were combined and input. Then, the labels were mixed by creating two 0.5 elements in a one-hot vector. In an experiment using the livedoor news corpus, which is Japanese, we found that the proposed method is better than the normal classification when the documents with labels shortages are mixed preferentially. Therefore, it indicates that the accuracy varies depending on the method of selecting documents to be mixed.

Abstract
Translation Memory (TM) system, a major component of computer-assisted translation (CAT), is widely used to improve human translators’ productivity by making effective use of previously translated resource. We propose a method to achieve high-speed retrieval from a large translation memory by means of similarity evaluation based on vector model, and present the experimental result. Through our experiment using Lucene, an open source information retrieval search engine, we conclude that it is possible to achieve real-time retrieval speed of about tens of microseconds even for a large translation memory with 5 million segment pairs.

1 Introduction
Translation memory technique is a key functionality being widely used in the field of CAT. Translation Memories (TMs) are “structured archives of past translations” which store pairs of corresponding text segments in source and target languages known as “translation units” (Simard, 2020). The size of translation memories and the quality of their contents are major impact factors crucial to the effectiveness of the translation memory system which uses them. Due to the importance of translation memories, there has been done lots of research work for building large TMs on worldwide scale, not just in individual countries (Steinberger et al. 2012).

What plays an important role for TM system is also the similarity evaluation between the input sentence to be translated and the source segment in the TM. The main task of TM system is to get a translation unit whose source segment is the most similar to the input sentence out of TM. There are two possible solutions in performing the task: One solution is to adopt an intelligent TM matching mechanism which is able to correctly calculate the similarity between the input sentence and the source segment in the translation memory. The other solution is to increase the size of TM by collecting translated resources as much as possible. No matter how intelligent the TM matching mechanism is, small-size TM cannot afford rich performance. Of course, the choice of TM matching method is important for improving the effectivity of TM system. But what is no less important than any TM matching method is to use a reasonable size TM. The larger the TM, the higher the possibility to get a translation unit whose source segment is very similar to the input sentence out of the TM. In general, the main value of a TM consists in the number of segments - its size. However, large TMs automatically lead to slow response times. A slow TM might actually slow down a translator, so that fast response time is an essential characteristic of any TM. Many research works have been reported to improve TM matching and retrieval, but the majority of those approaches were just evaluated on relatively small TMs. To our best knowledge, the largest TM tested so far in previous research works is the first five parts of the 2013 DGT-TM (which consisted of 305,324 segment pairs) used in (Weitz 2017) and the 2018 Volume 1 of the DGT-TM (which had 230,000 segment pairs) used in (Ranasinghe et al. 2020).

The main problem we are going to solve in this paper is to provide a TM retrieval mechanism to ensure real-time performance on very large TMs, e.g. with millions of segment pairs. We propose a TM retrieval method based on Vector Model (VM), which is widely used in information retrieval (IR), and implement our proposal using Lucene, an open source IR search engine. The rest of the paper is organized as follows: Section 2 briefly reviews previous research works related to TM matching and retrieval. Section 3 describes TM retrieval
method based on VM, and Section 4 presents experiment result. Finally, Section 5 discusses the result and draws a conclusion.

2 Previous Work on Translation Memory Matching and Retrieval

2.1 Research Work to Improve Translation Memory Matching

The mission of TM matching is to evaluate how similar the source segment in the TM is to the input sentence to be translated. Hence most of research work on TM matching focuses on how to calculate the similarity between the input sentence and the source segment in the TM.

(Planas and Furuse 2000) introduces edit distance based similarity vector whose coordinates refer to the levels of analysis of the segments. Their Multi-level Similar Segment Matching (MSSM) algorithm uses 3 different levels of data (surface words, lemmas, parts of speech (POS)) in a combined and uniform way.

There are studies for improving TM matching by segmenting source sentences. It is less likely for exact matches to be found in most text types, and even less so for complex sentences. MetaMorpho TM (Hodász and Pohl 2005) also divides sentences into smaller chunks. Moreover, it uses a multi-level linguistic features (surface form, lemma, and word class) to determine similarity between two source-language segments, especially for morphologically rich languages like Hungarian. The so-called ‘second generation’ TM system SIMILIS (Planas 2005) performs chunking to split sentences into syntagmas to allow sub-sentence matching. (Timonera and Mitkov 2015) suggests improving translation memory matching by performing clause splitting on the source segment as a pre-processing step for TM match retrieval, since clauses both contain a subject and a verb, hence a “complete thought”, and therefore clause matches are more likely to be in context and to be actually used by the translator.

(Vanallemeersch and Vandegehinst, 2014) also proposes a method which performs matching at level of syntactic trees. The authors notice that tree matching method is “prohibitively slow”. (Pekar and Mitkov 2007) proposes the ‘third-generation translation memory’ which introduces the concept of semantic matching. They employ syntactic and semantic analysis of segments stored in a TM to produce a generalized representation of segments which reduces equivalent lexical, syntactic and lexicosyntactic constructions into a single representation. Then, a retrieval mechanism operating on these generalized representations is used to search for useful previous translations in the TM.

(Chatzitheodorou 2015) presents an approach to match sentences having different words but the same meaning. They use NooJ to create paraphrases of Support Verb Constructions (SVC) of all source translation units to expand the fuzzy matching capabilities when searching in the translation memory.

(Ranasinghe et al. 2020) introduces a TM matching and retrieval method based on Universal Sentence Encoder. They argue that their method is an effective and efficient solution to replace edit distance based algorithms.

2.2 Research Work to Improve Translation Memory Matching

The mission of translation unit retrieval is to filter translation units out of TM which are to be matched against the input sentence. In general, the time consumed for translation unit retrieval is linear to the size of TM. Levenshtein distance, which is widely being used and one of the simplest means for TM matching, can be computed with dynamic programming in $O(mn)$ time, where $m$ is the length of the input sentence, and $n$ the length of the source segment of a translation unit in the translation memory. However, in case of a large TM with more than tens of millions of segment pairs, computing edit distance against the whole TM is too slow for real-time use. This is why the preliminary retrieval is necessary.

(Dandapat et al. 2012) uses an open-source IR engine SMART to retrieve a potential set of candidate sentences (likely to contain the closest match sentence) from the example base. Unigrams extracted from the sentences of the example-base are indexed using the language model and complete sentences are considered as retrievable units. They reported that finding a set of candidate sentences took only 0.3 seconds and 116 seconds, respectively, for 414 and 10,000 example input sentences given 20k and 250k sentence example base on a 3GHz Core 2 Duo machine with 4GB RAM. In order to find the closest matching sentences efficiently, (Dandapat et al. 2012) also proposes a heuristic-based grouping method which divides the example-base into bins based on
sentence length and considers only the segments which have comparable length to the length of the input sentence.

(Wäschle and Riezler 2015) uses MinHash signatures, an efficient way to estimate the similarity of two documents, to efficiently approximate the n-gram overlap of the input sentence and the source segment by representing each sentence as a set of n-grams in that n-gram overlap is a good predictor of TM match quality.

In order to reduce the search space size for Korean-Chinese TM retrieval, (Ryang 2018) builds a structured index using as features the sentence length and the sequence of Korean particles which is included in the sentence.

3 Vector Model-based Similarity Evaluation for Translation Memory Retrieval

3.1 Primary and Secondary Retrieval of Translation Memory

When retrieving from a large TM, it is common and reasonable to use the two-stage approach in which the TM system, firstly, filters candidates likely to be related to the input sentence for TM matching and then finds the most similar segments by fine-grained matching. The filtering is referred to the primary retrieval and the fine-grained finding is referred to the secondary retrieval. (Figure 1)

The primary retrieval is intended to filter translation units whose source segment is likely to be close matched with the input sentence. The secondary retrieval returns as reference translation the target segments of the translation units whose source segment is best matched with the input sentence. The main difference between the primary and secondary retrieval lies in the fact that the secondary retrieval uses a certain similarity threshold, \( \mu \), and the count of the secondary retrieval output should be much smaller than the primary one, because the secondary retrieval output is for human. The primary and secondary retrieval can be formulated respectively as follows:

\[
TM(S_0,K_1) = \arg\max_{\sum_{(S_i,T_i) \in TM} FMS_1(S_0,S_i) = K_1} \sum_{(S_i,T_i) \in TM} FMS_1(S_0,S_i)
\]

\[
TM_\mu(S_0,K_2) = \arg\max_{\sum_{(S_i,T_i) \in TM} FMS_2(S_0,S_i) \geq \mu} \sum_{(S_i,T_i) \in TM} FMS_2(S_0,S_i)
\]

where

- \( FMS_1(S_0,S_i) \): similarity score of the input sentence \( S_0 \) and the source segment \( S_i \), used in the primary retrieval
- \( FMS_2(S_0,S_i) \): similarity score of the input sentence \( S_0 \) and the source segment \( S_i \), used in the secondary retrieval
- \( TM = \{(S_i,T_i)|i=1,\ldots,N\} \): Translation Memory
- \( (S_i,T_i) \): Translation Unit, \( S_i \): Source Segment, \( T_i \): Target Segment
- \( N \): the number of translation units in the translation memory
- \( K_1, K_2 \): the limit count of the primary/secondary retrieval output

One of the essential requirements which the similarity measure should meet for the primary retrieval of TM is to allow partial match. A useful solution to this requirement is to use vector model
by representing as vectors the input sentence and
the source segments in the translation memory. We
adopt vector model based similarity evaluation for
the primary retrieval of TM.

3.2 Primary and Secondary Retrieval of
Translation Memory

For the vector representation of the input sentence
and the source segments in the TM, we use word-
sentence relation matrix which is widely used in IR.
Let $W$ be the set of words occurring in the source
segments.

$$W = \{w_i | i = 1, T\}, T$: The total number of words
occurring in the source segments

Let $V$ be the word-sentence relation matrix. Then $V$ is a $N \times T$ dimensional matrix:

$$V = \begin{pmatrix}
    v_{11} & v_{12} & ... & v_{1T} \\
    v_{21} & v_{22} & ... & v_{2T} \\
    ... & ... & ... & ... \\
    v_{N1} & v_{N2} & ... & v_{NT}
\end{pmatrix}$$

The i-th row of $V$ is a vector representing the
source segment, $S_i$:

$$V_{S_i} = (v_{i1}, v_{i2}, ... , v_{iT})$$

$\nu_{ij}$: The weight indicating how important the word
$w_j \in W$ is for the source segment $S_i$

Let $U_{S_0}$ be the vector of the input sentence $S_0$:

$$U_{S_0} = (u_1, u_2, ... , u_T)$$

$\nu_j$: The weight indicating how important the word
$w_j \in W$ is for the input sentence $S_0$

Given two vectors, $V_{S_i}$ and $U_{S_0}$, the similarity
score of the input sentence $S_0$ and the source
segment $S_i$ used for the primary retrieval can be
defined as follows:

$$FMS_1(S_0, S_i) = \frac{U_{S_0} \cdot V_{S_i}}{\|U_{S_0}\| \|V_{S_i}\|}$$

$U_{S_0} \cdot V_{S_i}$: Dot product of two vectors, $U_{S_0}$ and $V_{S_i}$

$\|U_{S_0}\|$: Euclidean norm of the vector $U_{S_0}$

$\|V_{S_i}\|$: Euclidean norm of the vector $V_{S_i}$

We suggest using TF-IDF weight of the words,
which is commonly used feature for IR. But there
is one problem in using TF-IDF weight for TM
retrieval.

In IR, the length of a query is very short than
documents. However, in case of TM retrieval, the
lengths of the input sentence and the source
segment, two objects to be compared, don’t make
such contrastive difference as in the relationship
between the query and document in IR. It can
rather be assumed that the length of the input
sentence is similar to the source segment in the TM.
Even when the length of the input sentence is short
than the source segment, as in IR, if a word occurs
only once in the input sentence, it is not true that a
source segment, in which that word occurs two or
three times, is more similar to the input sentence
than any other source segment in which that word
occurs once. When a word occurs twice in the
input sentence, it can be assumed that a source
segment, in which that word occurs twice, is more
similar than any other source segment in which that
word occurs once. Based on this consideration, we
define the elements of the vectors $U_{S_0}$ and $V_{S_i}$ as:

$$\nu_{ij} = \min(\text{tf}(w_j, S_0), \text{tf}(w_j, S_i))$$

$$\nu_j = \begin{cases}
    \text{idf}(w_j), & w_j \in S_0 \\
    0 , & w_j \not\in S_0
\end{cases}$$

Consequently, the similarity score of the input
sentence $S_0$ and the source segment $S_i$ becomes:

$$FMS_1(S_0, S_i) = \frac{\sum_{w_j \in S_0} \min\{\text{tf}(w_j, S_0), \text{tf}(w_j, S_i)\} \times \text{idf}(w_j)}{\|U_{S_0}\| \|V_{S_i}\|}$$

In the calculation of the above similarity score
function, the elimination of the term $\|U_{S_0}\|$ from
the denominator doesn’t affect the final result. So
the practical similarity score function can be
written as:

$$FMS_1(S_0, S_i) = \frac{\sum_{w_j \in S_0} \min\{\text{tf}(w_j, S_0), \text{tf}(w_j, S_i)\} \times \text{idf}(w_j)}{\|V_{S_i}\|}$$

3.3 Semantic Similarity for the Primary
Retrieval of TM

There are many previous research works taking
into account semantic similarity for TM matching.
For example, given two sentences, “What is the
actual aim of this practice?” and “What is the real
goal of this mission?”

It is possible to judge that
these two sentences are very similar, based on the
linguistic analysis that the words “actual” and
g“goal” are similar to the words “real” and “aim,”
respectively. When implementing two-stage TM
retrieval which consists of primary and secondary
retrieval for a large TM, it is very important to
ensure that the output of the primary retrieval
might contain the segments likely to be
semantically similar to the input sentence for any
semantic similarity measure to be applied at the secondary retrieval stage. We are going to use linguistic knowledge like synonym for accommodating semantic similarity evaluation in the primary retrieval of TM.

Our solution to evaluate semantic similarity taking into account the synonym knowledge in the primary retrieval of TM, is to change the input sentence \( S_0 \) into a pseudo sentence \( S'_0 \) which includes all the words of \( S_0 \) and also their synonym words, and then calculate the similarity score of the pseudo sentence \( S'_0 \) and the source segments of TM. The pseudo expansion of the input sentence and the similarity score calculation is trivial since the vector representation is based on TF-IDF weights. The similarity score of the pseudo sentence \( S'_0 \) and the source segment \( S_j \) is:

\[
FMS_j(S'_0, S_j) = \frac{\sum_{w_j \in S'_0} \min(tf(w_j, S'_0), tf(w_j, S_j)) \times idf(w_j)}{\|V_{S_j}\|}
\]

where

\[
tf(w_j, S'_0) = \begin{cases} 
\alpha, & w_j \in S_0 \\
0, & w_j \notin S_0 \land w_j \in SYN(w_k) \\
\end{cases}
\]

\[
SYN(S_0) = \bigcup_{w_j \in S'_0} SYN(w_j). SYN(w_k): The set of synonym words of \( w_l \)
\]

In the above expression, \( \alpha \) is a real number between 0 and 1, which is introduced as a weight of the synonym word added into the pseudo input sentence \( S'_0 \).

The knowledge database for synonym are not always available for every language, and even if available, they are qualitatively and quantitatively different from each other. For English, WordNet developed by Princeton University is a useful knowledge database for finding synonym.

As a matter of fact, it is not quite easy to find correctly the synonym of any word in the input sentence. To speed up the primary retrieval on a large TM while avoiding complex linguistic analysis, we establish the following principle for building synonym dictionary which will be used in the similarity evaluation for TM retrieval.

First, for any word \( w_i \) which has only one part-of-speech (POS), its all synonym words will be included in the synonym dictionary \( SYN(W) \).

Second, when the word \( w_i \) has several POSes, only if \( w_i \) doesn’t have verb POS, its synonym words will be included in the synonym dictionary \( SYN(W) \).

Third, if the word \( w_i \) has both general synonym and special synonym, only the general synonym words with more high frequency will be included in the synonym dictionary \( SYN(W) \).

Our principles are based on the linguistic consideration that the synonym of any word can be discussed only when its POS is determined, that there exist two categories of synonym, absolute synonym and relative synonym, and that there are also general synonym and special synonym in terms of use frequency.

We don’t use synonym of multi-POS words with verb POS, because a verb is the core of the statement unit which can determine the meaning of a sentence from a linguistic point of view and linguistic analysis like POS tagging is not applied in the primary retrieval of TM.

According to our analysis on WordNet 3.0\(^1\), it has a total of 117,659 senses with 147,306 words related to each other. Among those words, there are 49,754 words which does not have any synonym at all. Using above-mentioned principles for synonym selection, we selected 36,185 senses with 90,258 words related to each other to build an English synonym dictionary for TM retrieval.

4 Experimental Result

We use Lucene, an open source IR engine in Java, to implement the TM retrieval system using the vector model based similarity evaluation we proposed. As the data structure of a translation unit of TM, the Document class of Lucene is used which has two fields corresponding to the source and target segment of TM, respectively. The version number of Lucene used is 8.5.1. Levenshtein Distance based similarity score is applied for the secondary retrieval of TM. The TM used for the evaluation of the proposed TM retrieval system is an English-to-Korean TM which is made of about 5,000,000 English segments and their automatic Korean translation by English-to-Korean machine translator “Ryonngamsan” 2.0. In the experiment, we use parameter settings for the primary search of TM such that \( K_1 = 100 \), and \( \alpha = 0.5 \). All measurement was carried out on a desktop PC with

---

\(^1\) (http://wordnetcode.princeton.edu/3.0/WNprolog-3.0.tar.gz)
Intel® Core™ i3-3240 CPU @ 3.40GHz and 2GB of RAM. The operating system installed is Windows 7, 64bit.

4.1 Evaluation Method of Retrieval Performance

First of all, the retrieval performance on the English-to-Korean TM using Lucene can be evaluated with the retrieval time on varying size of TM. We randomly selected 1,000 sentences which are not included in the English-to-Korean TM, and then measured the total time consumed for retrieving all those sentences on different size of TM. The time consumed for retrieving was measured 5 times, and the fastest, slowest and averaged time were all recorded. Next, the relevance of retrieval result was automatically tested. Finally, we compare the retrieving performance of our proposal with the retrieving performance when using MongoDB’s full text search API.

4.2 Result

– Relation between the size of TM and the retrieving time

Figure 2 shows the relation between the size of TM and the retrieving time.

As the size of TM increases, so does the retrieving time on the TM.

– Relation between the length of the input sentence and the retrieving time

We also investigate the influence of the length of the input sentence on the retrieving time on TM.

Table 1: Retrieving time according to the size of TM

Figure 2: Retrieving time according to the size of TM

For 1,000 input sentences being tested, the retrieving time for each sentence on the largest TM with 5,000,000 segments was measured and averaged according to the length of those sentences. Figure 3 and Figure 4 show the sentence length-frequency distribution on the test sentences and the average retrieving time according to the sentence length, respectively.

The result shows that the longer the input sentence, the longer its retrieving time of TM.

Figure 3: Sentence frequency according to its length

Figure 4: Average retrieving time according to the sentence length
Relevance of the primary retrieval result of TM

For evaluating the relevance of the primary retrieval result of TM, we checked the ranking result of the primary retrieval when retrieving 1,000 English sentences randomly selected from the largest TM of 5,000,000 segments. According to an automatic checking of the ranking result, the translation unit whose source segment is the input sentence ranked at the first place all the time. This implies that the proposed primary retrieval of TM is relevant for exact match of TM.

The relevance of the primary retrieval result for the sentences which is not included in the TM is impossible to automatically evaluate, and is also related to the secondary retrieval of TM. We did a small manual test but the result was not fully reliable, so we didn’t present the result here.

Comparison with the retrieving performance of TM using MongoDB

MongoDB, a NoSQL database management system, supports textual data indexing and searching which allows partial matching. For comparison with our proposal, we implemented a TM retrieval module using the full text search API of MongoDB, and evaluated its performance on a desktop PC with Intel® Core™ i7-7700 CPU @ 3.6 GHz and 16 GB of RAM. The version of MongoDB used is 4.4. It took about 18 minutes to insert into the MongoDB collection the English-to-Korean TM of 5 million segment pairs. It also took about 5 minutes to index the source language field and about 1 hour and 38 minutes to retrieve a set of candidate sentences for the same 1,000 English sentences as in the previous experiment. The size of the set of candidate sentences was limited to 10. By automatically checking the relevance of the retrieval result, the translation unit whose source segment is the input sentence ranked at the first place all the time, too. Obviously, the retrieving speed when using Lucene is incomparably superior to when using MongoDB.

5 Conclusion and Future Work

Through a series of experiments on the primary retrieval of English-to-Korean TM using vector model based similarity evaluation, we conclude that:

- The time and space complexity of indexing the TM increases linear to the size of the TM. The indexing time consumed for a large-scale English-to-Korean TM with about 5,000,000 segments is about 5 minutes, and the indexed data size is 1.84 GB with an increase of about 29 % compared to the text file size of the TM.
- The time complexity of the primary retrieval of TM increases linear to the size of the TM and the length of the input length. The fact that the retrieving time of TM is in linear proportion to the size of the TM and the length of the input sentence fully accords with Lucene’s inverted indexing principle and the ranking process of our vector model based similarity evaluation.
- When there is a translation unit whose source segment is the same as the input sentence, the translation unit ranks at the first place in the primary retrieval result of TM. The automatic checking result of the source segments included in the TM shows that Lucene is an effective means for exact match, as well as fuzzy matching.

The effect of the vector model based similarity evaluation for the primary retrieval of TM wholly depends on the correctness of the morphological analysis and the richness of the synonym knowledge. Since the difficulty of the morphological analysis and the availability of the synonym knowledge like WordNet is all different for each language, we plan to do more research work on these aspects. Furthermore, we also plan to evaluate more comprehensively the relevance of the primary retrieval of TM.

Abstract
Authors of text tend to predominantly use a single sense for a lemma that can differ among different authors. This might not be captured with an author-agnostic word sense disambiguation (WSD) model that was trained on multiple authors. Our work finds that WordNet’s first senses, the predominant senses of our dataset’s genre, and the predominant senses of an author can all be different and therefore, author-agnostic models could perform well over the entire dataset, but poorly on individual authors. In this work, we explore methods for personalizing WSD models by tailoring existing state-of-the-art models toward an individual by exploiting the author’s sense distributions. We propose a novel WSD dataset and show that personalizing a WSD system with knowledge of an author’s sense distributions or predominant senses can greatly increase its performance.

1 Introduction
Authors of text tend to predominantly use a single sense for a lemma that can differ among different authors (Gella et al., 2014). This might not be captured with an author-agnostic word sense disambiguation (WSD) model that is trained on multiple authors. Our work finds that WordNet’s first senses, the predominant senses of our dataset’s genre, and the predominant senses of an author can all be different and therefore, author-agnostic models could perform well over the entire dataset, but poorly on individual authors. Ideally, each author would have access to a personalized WSD model, which is a model that was tailored toward that individual. In this work, we explore methods for personalizing WSD models by tailoring existing state-of-the-art models toward an individual by exploiting the author’s sense distributions. We evaluate our models on our proposed dataset which contains 1586 sense-annotated instances for 11 lemmas across 36 authors. Our evaluation includes metrics that focus on the performance of models with respect to the authors that they perform poorly on, which highlights the potential gain for individual authors.

The most similar work to this is presented in Gella et al. (2014), which created a dataset that contains sense-annotated instances of tweets for a list of authors. We differ from them by including more annotated instances from a single author and by using text from blog posts, which do not have a limitation on the length of text, unlike text from tweets. We evaluate different WSD models, including a state-of-the-art model (SensEmBERT) (Scarlini et al., 2020), which we extend with personalization techniques to achieve our best scores. We personalize SensEmBERT with knowledge of an author’s sense distributions or predominant senses, which outperform author-agnostic WSD systems. Our work also shows that the use of author-specific sense distributions outperforms the use of genre-specific senses. In this first work on personalized WSD, we do not automatically learn the sense distributions of an author, but instead, we use the author’s true sense distributions to demonstrate the importance of learning author-level sense distributions when considering personalized WSD.

2 Related Work
Two common frameworks for WSD systems include knowledge-based, which utilizes information contained in a sense inventory, and supervised, which involves training on annotated instances. In this work, we focus on knowledge-based models because they do not require annotated instances and they are able to work well on less frequent lemmas and senses (Scarlini et al., 2020). Many modern knowledge-based methods extend the simplified Lesk method (Kilgarriff and Rosenzweig, 2000), which involves classifying a token with the sense that contains the most overlapping words in its defi-
nition with the context of the word being classified.
WSD methods that involved a Lesk-style approach
are Banerjee and Pedersen (2002), which included
looking at the definition of words that are similar
to the token being classified according to Word-
Net and Basile et al. (2014), which looked at the
definition of similar words but added a vector repre-
sentation of the target token — generated by a topic
model — into their similarity calculations. Topic
modeling is a probabilistic model that views docu-
ments as a distribution over topics and topics as
distribution over types (Blei et al., 2003). Topic
modeling was also applied to WSD in Boyd-Graber
et al. (2007) and Li et al. (2010).

The current knowledge-based model, that
achieves state-of-the-art performance on the uni-
ified WSD evaluation framework (Raganato et al.,
2017), creates an embedding for each sense of a
word by using BERT (Devlin et al., 2019) to embed
both the sentences in Wikipedia articles related to
that sense — determined by words in the sense’s
WordNet synset — and the gloss of the sense (Scar-
lini et al., 2020). The two vectors are then con-
catenated to make the final sense embedding. At
runtime, the context of the target word is embed-
ed using BERT and is compared to the previously
described sense embeddings to determine which
sense is assigned. SensEmBERT works well on rare
lemmas and senses (Scarlini et al., 2020), which is
important to consider for our experiments that
contain author-specific text since authors tend to
favour a single sense for a word (Gella et al., 2014),
which might not be the predominant sense of a do-
main. Therefore, if a model performs poorly on
rare senses according to the sense inventory, then
it might perform poorly on the favoured sense of
the author. Likewise, if an author frequently uses
rare words — according to the sense inventory —
then a model that performs poorly on rare words
would perform poorly for the author. The ability to
perform well on all authors and demographics is a
way to evaluate the fairness of a model (Ethayarajh
and Jurafsky, 2020; Hashimoto et al., 2018). In this
work, we consider the fairness of our models by
focusing on authors that they perform poorly on.

3 Data Statement

In this section, we discuss the properties of our
dataset, while following the proposed schema from
Bender and Friedman (2018).

3.1 Data selection

We collect all text from blogs of the top 50 authors
that contain the most tokens from the corpus that
was originally presented in Schler et al. (2006).
The original corpus consists of English blog posts
from 19,320 authors. There were some authors
who have blog posts that are copied from other
authors and therefore, we do not consider these au-
thors in the top 50. We consider the top 50 authors
to ensure that each author possesses enough text to
allow the ability to study the potential benefits of
using text from the author for personalizing a WSD
model. For selecting lemmas, we first consider all
20 nouns from Gella et al. (2014). We consider the
top 10 authors — authors that have the $10^{th}$ highest
frequency of a lemma — to ensure that there is
text from multiple authors for each lemma to study
the effects of personalization on a per-lemma basis.
From this group of lemmas, we retain all lemmas
that have been used 20 or more times by the author
who has used this lemma the $10^{th}$ most frequently.
We selected the cutoff of 20, because there is not a
large possibility that all instances from an author
will be usable due to them not being a noun or not
representing a sense from our chosen sense inven-
tory. The group of lemmas that we include moving
forward will be referred to as SHORT LIST.

For each lemma in SHORT LIST, we randomly
sample approximately 10 sentences that contain
the lemma from 10 authors and manually assign
the lemma a sense ourselves.¹ We then use this
annotated subset to perform two different analy-
ses that focus on quantifying the diversity of the
senses for a lemma. The first analysis involves
calculating the predominant sense of each lemma
for each author and then finding the most frequent
sense among the author-level predominant senses,
which we call the grand sense. We then calculate
the percent of author-level predominant senses for
a given lemma that are not the grand sense. The
second analysis calculates the number of assigned
senses that are not the grand sense. Both types
of analysis assist in showing which lemmas have
senses that vary among authors and therefore, they
might benefit from a personalized model which is
the main focus of this work. Lemmas that score
low on these metrics could be ideal for models
that predict the predominant sense, but would most
likely not benefit from an author-level model. We
originally wanted the top 10 lemmas that scored

¹We are native English speakers.
Table 1: List of lemmas and their frequency for the author who uses the lemma the 10th most frequently (10th MF). The percent of author-level predominant senses and token senses that are not the grand sense, represented by Predom and Token, respectively (higher values indicate more diversity). The number of WordNet senses for each lemma under the label #Senses is also shown.

</table>

the highest when comparing predominant senses with the grand sense, but we received a tie for the lemmas that scored 9th, 10th, and 11th. We remove all lemmas from SHORT_LIST that scored less than 0.22 on the percent of predominant senses that are not the grand sense, which was the score for the lemmas with the 9th, 10th, and 11th highest values. Table 1 shows our final 11 lemmas with their frequency for the top 10 authors, and their two diversity metrics.

Additional preprocessing was applied to the text from authors and the annotated instances, including the replacing of tokens that contain URL identifiers (www, html, https, etc.) with the token urlLink and the removal of what appear to be artifacts of text encoding, such as \texttt{xx}.

For each of the 11 lemmas in the dataset, we gather the top 10 authors that used that lemma most frequently and gather all sentences from them that contain that lemma tagged as a noun by a part-of-speech tagger (Qi et al., 2020). This results in 36 authors and a total of 1607 instances across all lemmas. We manually scan through all instances ourselves and remove all instances that were incorrectly tagged as nouns.

3.2 Annotation

In this work, we use WordNet (Miller, 1995) as the sense inventory due to its popularity among WSD tasks (Raganato et al., 2017). We show the number of WordNet senses for each lemma in Table 1, which ranges from 7 for degree to 19 for case.

We used Amazon Mechanical Turk — a common crowd-sourcing site — to annotate the instances of each lemma. We divided the instances into groups of 5 — known as HITs — and ensure all 5 instances belong to the same lemma. Each instance in a HIT is presented to the annotator, known as a turker, with a piece of text that contains a single target token written in bold for each text. Each instance contains up to 20 tokens before the target token and 20 tokens after the target token, which can cross sentences but does not cross blog posts. This provides the turker with more context than only looking at a single sentence, which can assist their annotations. The turkers are asked to select the sense that best applies to the target token from a list of the WordNet senses for the lemma of the target token or they can select I cannot assign a sense. There was space available for feedback for each instance, where turkers can write the reason that they cannot assign a sense or provide general feedback.

It is possible that a token can exhibit multiple senses (Erk et al., 2009), but our dataset will only consider one sense as the ground truth for each instance. Therefore, following Chkolvski and Mihalcea (2002) and Pradhan et al. (2007), a turker can only select one sense for any instance. Each HIT was annotated by 10 turkers. An example of the task assigned to turkers is seen in Figure 1.

3.2.1 Annotators

For a turker to be eligible to annotate the HITs, they need to be 19 years of age, speak English as a first language, live in Canada or United States, and have a previous HIT acceptance rate of 98%. We paid the turkers between $0.05 and $0.10 per HIT, which is competitive with other sense annotation tasks (Akkaya et al., 2010; Hong and Baker, 2011; Rumshisky, 2011; Passonneau and Carpenter, 2014). Our work consists of 185 annotators producing a total of 14,607 annotations and 137 instances of feedback.

Some turkers may provide poor annotations and therefore an initial pass over the annotations can help identify these turkers (Gella et al., 2014). Gella et al. (2014) included a gold-standard instance within each HIT and disregarded all annotations from turkers that performed poorly on these gold-standard instances. Instead of providing a gold-standard instance within each HIT, we compare each turker’s annotations against a majority vote. We avoid the use of a gold standard because we did not want to mix text types, i.e., blog posts and WordNet, and because not all senses in WordNet have an example, and those that do have
examples do not always contain the target lemma. We do this by performing an initial pass over the annotations to calculate the majority vote for each instance and then calculate each annotator’s accuracy with the majority vote. Annotations from any turker that scored less than 50% agreement with the majority vote are removed from consideration, leaving 162 turkers in the dataset. We perform a second pass through the dataset and calculate the majority vote for each instance and remove 7 instances, which were assigned I cannot assign a sense as the most frequent label and 2 instances where there was a tie for the most frequent label. We randomly annotated 86 instances and our annotations agreed with the turkers’ majority vote 85% of the time.

3.3 Speech Situation
All text was originally obtained from downloading all accessible blogs from blogger.com on a single day in August of 2004 (Schler et al., 2006). The number of instances per author ranges from 3 to 152 with a mean of 44 and a median of 31 instances per author. The age of the authors range from 17 to 48 years with a mean of 30 and a median of 27. The sex of the authors is disproportionate, with 10 females and 26 males.

3.4 Speaker Demographic
All text in the original corpus was English, although there was non-English text in the blogs, which was removed by Schler et al. (2006).

3.5 Dataset Analysis
The final dataset consists of 11 lemmas and 1586 annotated instances. The dataset consists of multi-sentence instances that were annotated by the turkers. We did this to maintain consistency with the text being annotated by turkers and the text being used by WSD models. Table 2 shows the number of instances per author for each lemma ranges from 93 for charge to 192 for paper with an average of 144. The number of assigned senses ranges from 4 for deal to 13 for field with an average number of 8.5, known as sense ambiguity (Jurgens, 2014). The sense ambiguity is a metric that can be used to measure the difficulty of a WSD dataset. The dataset’s sense ambiguity of 8.5 is among the higher values of the datasets in the collection from Raganato et al. (2017) and the dataset from Gella et al. (2014), which range from 4.9 to 8.9.

Figure 2 shows the sense distributions for four authors with respect to the lemma deal and shows how authors can use the same lemma differently and the potential benefits of tailoring models toward an individual author. Specifically, each author in Figure 2 has a different predominant sense for the lemma deal and only Author.0 shares their predominant sense with the predominant sense across all authors.

4 Methods
In this section, we discuss the WSD methods that we evaluate on the dataset. This includes predominant sense baselines, a state-of-the-art method (SensEmBERT), and our proposed personalized models.

4.1 Baselines
We apply three WSD baselines, which include always predicting the predominant sense for each lemma. The predominant sense is calculated via Mordecaffe/Personalized_WSD_Dataset.

Figure 2: Sense distributions for four authors for the lemma deal. The average distribution across all authors is in black.

WordNet (WORDNET), the predominant sense of the dataset (DATASET_PREDOM), and the predominant sense for each author (AUTHOR_PREDOM).

4.2 SensEmBERT

This method is an unsupervised method that has achieved state-of-the-art results on the English datasets from Raganato et al. (2017) and can outperform supervised WSD models on less frequent lemmas and senses (Scarlini et al., 2020). It uses sense embeddings of a noun by embedding text from Wikipedia articles related to the noun and concatenating it with an embedding of text from the noun’s BabelNet entry. The embedding process of a token is done by averaging BERT embeddings of each considered token. A BERT embedding is calculated by summing the last four layers of BERT after using the target token in context as input.

SensEmBERT assigns a token’s sense by embedding the token with BERT and concatenating this embedding onto itself to double the vector length. Cosine similarity is calculated between this vector and all sense embeddings for all possible senses for the lemma of the target token. The sense that has the highest similarity is assigned as the target token’s sense.

4.3 Personalizing SensEmBERT

We extend SensEmBERT by using text from the author to tailor the model to them by assuming knowledge about the author’s sense distributions. These methods are used to explore the benefits of personalized WSD systems and the potential gains of learning the sense distributions of an author. We discuss these types of methods in this subsection.

4.3.1 SEBERT_PERS

In this method, we exploit the Zipfian distribution that sense frequencies tend to exhibit (Kilgarriff, 2004). Specifically, the weights for each sense that are outputted by SensEmBERT are ranked and the final score for a sense is calculated by the inverse rank of the sense multiplied by the probability of this sense given an author (calculated by the author’s gold standard sense distributions) as seen in Equation 1. The sense that results in the highest score is assigned as the sense of the target token.

$$weight(sense) = \frac{1}{rank} \times p(sense|author)$$ (1)

4.3.2 SEBERT_PERS_PREDOM

The author-level sense distribution of a lemma could be difficult to automatically estimate and it might be easier to estimate the author-level predominant sense. Therefore, we assume knowledge of only the author-level predominant sense of a lemma for this method by using the author’s gold standard predominant sense. Specifically, we assign the sense that was given the most weight according to SensEmBERT if the predominant sense of the author is not among the top k ranked senses. If the predominant sense is in the top k ranked senses, we assign the predominant sense. We refer to this k value as the override rank and it is a hyperparameter that needs to be tuned. We also explore the use of the predominant senses from the dataset and WordNet; we refer to these methods as SEBERT_DATASET_PREDOM and SEBERT_WORDNET_PREDOM, respectively.

5 Experimental Results

In this section, we evaluate our different models. We first explore the tuning of the override rank for PREDOM-based methods. We then evaluate our
models using average accuracy across all authors and for individual authors.

5.1 Tuning SEBERT_PERS_PREDOM
Unfortunately, due to the relatively small size of our dataset, we are unable to use a held-out subset of the data for model tuning. Therefore, we show the performance of the PRE-DOM-based models using different override ranks. Figure 3 shows that SEBERT_PERS_PREDOM and SEBERT_DATASET_PREDOM outperform the SensEmBERT approach for any of the tested override rank values except for SEBERT_DATASET with an override rank of 6. This finding eliminates the need to fine-tune this model, since any value between 2 and 5, inclusively, works reasonably well. Increasing the override rank results in the model that uses WordNet first-senses to perform worse, which suggests that the authors’ predominant senses do not align with WordNet’s first senses. We do not consider SEBERTWORDNET_PREDOM for the remaining experiments due to its poor performance and we use an override rank value of 4 for SEBERT_PERS_PREDOM and SEBERT_DATASET_PREDOM.

5.2 Overall Accuracy
In this subsection, we discuss the results of each method on the entire dataset. We evaluated each model using accuracy across instances, average accuracy across lemmas, and average accuracy across authors. We evaluated using these three metrics to eliminate the issue of having non-uniform distributions of instances in the dataset. For example, the number of instances per author ranges from 3 to 152 and, therefore, we would like to weigh each author equally in the case of accuracy across authors, instead of favouring models that only perform well on authors with more instances in the dataset.

Table 3 shows the scores for each method across the different evaluations. The three predominant sense baselines’ performances scored in the expected order, such that using the predominant sense of the author outperforms using the predominant sense of the dataset, which outperforms using the first sense from WordNet. SensEmBERT outperformed all other baselines. The inclusion of the author’s sense distribution in SEBERT_PERS and their predominant sense in SEBERT_PERS_PREDOM both outperform SensEmBERT. SEBERT_PERS achieves the highest score of 0.738 in terms of average accuracy across all authors, which is an absolute improvement of 0.127 above SensEmBERT. The use of the dataset-level sense distributions in SEBERT_DATASET and predominant senses in SEBERT_DATASET_PREDOM outperform SensEmBERT but does not outperform SEBERT_PERS and SEBERT_PERS_PREDOM, which supports the importance of using author-specific data. Interestingly, SEBERT_DATASET_PREDOM outperforms SEBERT_DATASET for average accuracy across authors. These findings indicate that SensEmBERT can be improved through personalization by incorporating information about author-level sense distributions or predominant senses.

5.3 Author-level Performance
In this subsection, we consider the models’ performances on individual authors and observe the lower bound of each model’s score with respect to the authors. By observing the lower bound of each model’s performance with respect to the authors, we can observe the fairness of the models.

Figure 4 shows the performance of our two personalized models (SEBERT_PERS and SEBERT_PERS_PREDOM) and the SensEmBERT
Figure 4: Author-level performances for the two personalized methods and SensEmBERT.

Figure 5: Performance of methods on the $x$ authors that they achieve the lowest accuracy on. The authors are sorted in ascending order with respect to the accuracy of SensEmBERT. It shows that authors that SensEmBERT performs below average on with respect to accuracy across authors (i.e. 0.611) often receive the largest boost in performance from personalized models. This could be due to those individuals having different writing styles as compared with text that SensEmBERT was trained on, which is an interesting topic for further exploration. The authors that achieve approximately 0.70 or greater for SensEmBERT can have their performance hindered by personalization, although, often not by a large amount. SEBERT_PERS usually outperforms SEBERT_PERS_PREDOM for a given author.

One of the main pillars of our work is to provide personalized models that work well for authors that scored poorly with conventional non-personalized models. Therefore, we would ideally want models that do not perform poorly on any single author, which we can evaluate by averaging the accuracy over the authors that each model achieves the lowest accuracy on. In Figure 5, we evaluate our models on the $x$ authors that each model achieves their lowest accuracy on for values of $x$ ranging from 1 author to all 36 authors. It shows that SensEmBERT achieves 0.25 on its worst author, while SEBERT_PERS achieves 0.46 on its worst author. Furthermore, SEBERT_PERS, SEBERT_PERS_PREDOM, and SEBERT_DATASET_PREDOM always outperform SensEmBERT for every value of $x$ in the $x$ worst authors evaluation, with SEBERT_PERS always achieving the highest score. This finding demonstrates that Personalized WSD models such as SEBERT_PERS and SEBERT_PERS_PREDOM are more fair than non-personalized models (SensEmBERT).

6 Conclusions

In this work, we proposed a novel dataset for personalized WSD and showed that sense distributions and predominant senses of an author can be used to personalize an existing knowledge-based WSD model (SensEmBERT). Our experiments consistently show that models that consider author-specific sense distributions (SEBERT_PERS) or predominant senses (SEBERT_PERS_PREDOM) can outperform models that do not consider any knowledge of sense distributions (SensEmBERT). Furthermore, we show that models that use author-level sense distributions or predominant senses outperform models that use genre-level sense distributions (SEBERT_DATASET) or predominant senses (SEBERT_DATASET_PREDOM). SensEmBERT achieved the highest accuracy across all authors with an absolute improvement of 0.127 above SensEmBERT. We further explore the fairness of our models by evaluating their accuracy on authors that they perform poorly on and showed that the lowest accuracy achieved by SEBERT_PERS on a single author is 0.21 above SensEmBERT’s lowest accuracy. This finding demonstrates that SEBERT_PERS is more fair than SensEmBERT, which indicates that personalization can produce more fair WSD systems. Our work shows the importance of learning sense distributions of individual authors for WSD and therefore, we plan on developing methods for learning an author’s sense distributions in future work similar to Pasini et al. (2020) and Bennett et al. (2016). Our personalized models could be learning topic-related content from the author to assist with their classification, therefore, an extension of this work could further explore this dataset with a focus on topic-related features.
7 Ethical Considerations

The involvement of turkers as annotators was reviewed and approved by the University of New Brunswick’s ethics committee. We selected the authors based on their amount of text available and therefore the distributions over sexes is not equal — 26 males and 10 females — and therefore groups should consider this when working with this dataset.

Acknowledgments

This work is financially supported by the Natural Sciences and Engineering Research Council of Canada and the University of New Brunswick.

Abstract

In this paper, we present work in progress aimed at the development of a new image dataset with annotated objects. The Multilingual Image Corpus consists of an ontology of visual objects (based on WordNet) and a collection of thematically related images annotated with segmentation masks and object classes. We identified 277 dominant classes and 1,037 parent and attribute classes, and grouped them into 10 thematic domains such as sport, medicine, education, food, security, etc. For the selected classes a large-scale web image search is being conducted in order to compile a substantial collection of high-quality copyright free images. The focus of the paper is the annotation protocol which we established to facilitate the annotation process: the Ontology of visual objects and the conventions for image selection and for object segmentation. The dataset is designed both for image classification and object detection and for semantic segmentation. In addition, the object annotations will be supplied with multilingual descriptions by using freely available wordnets.

1 Introduction

We are surrounded by information represented by text, images and video data in multimodal streams. One of the processing tasks for large multimodal data streams is automatic image description (image classification, object segmentation and classification), which is directly connected with the task of image search, as well as with the expansion of the scope for automatic question answering regarding images.

The goal of our project Multilingual Image Corpus (MIC 21) is to provide a large image dataset with annotated objects and object descriptions in (at least) 20 European languages. The

Multilingual Image Corpus consists of an ontology of visual objects (based on WordNet) and a collection of thematically related images whose objects are annotated with segmentation masks and labels describing the ontology classes. The dataset is designed both for image classification and object detection and for semantic segmentation.

The main contributions of our work are: a) the provision of large collection of high-quality copyright free images; b) the formulation of the Ontology of visual objects based on WordNet noun hierarchies; c) the precise manual correction of automatic object segmentation within the images and the annotation of object classes; and d) the association of objects and images with extended multilingual descriptions based on WordNet inter- and interlingual relations.

We have divided the annotation process into four main stages: a) definition of an ontology of visual objects; b) collection of appropriate images; c) automatic object segmentation; and d) manual correction of object segmentation and manual classification of objects. The annotation protocol includes the Ontology of visual objects and the conventions for image selection and for object segmentation.

The focus of the paper is the annotation protocol which is established to facilitate the manual annotation. We begin with a brief overview of the current state in the field in Section 2. Section 3 is dedicated to the description of the Ontology of visual objects. Dataset collection is described briefly in Section 4. Section 5 provides an outline of the annotation protocol. Finally, conclusions and future directions of our work are presented.

We will show how the presented image dataset benefits from WordNet: providing ontological representation of visual objects based on WordNet noun hierarchies; building interconnectivity of classes by means of the WordNet relations; and ensuring multilinguality by using freely available wordnets.
2 Related Work

There is a tradition already established in the image dataset collection and annotation; the available datasets show an increase both in the number of training images and in the number of object classes. CalTech-256 dataset consists of 30,607 images and covers 256 object categories\(^2\) (classes). The annotation includes bounding boxes, in which the objects are located, and object outlines provided by humans (Griffin et al., 2007). The categories are organised in a taxonomy grouping categories into animate and inanimate and other finer distinctions; for example, the category electronics is divided further into entertainment, computing, home, office and others.

The CalTech 101 Silhouettes\(^3\) dataset consists of 4,100 training samples, 2,264 validation samples and 2,307 test samples. The dataset is based on CalTech 101 image annotations. Each image in the CalTech 101 Silhouettes dataset includes a high-quality polygon outline of the primary object in the scene (Marlin et al., 2010).

The TinyImages dataset (Torralba et al., 2008) is a large dataset containing 80 million small images (32 x 32 pixels) automatically collected from the Internet using 53,464 nouns from WordNet as queries. The dataset is not available online since it has not been manually evaluated\(^4\).

The Scene Understanding (SUN)\(^5\) collection contains 899 categories and 130,519 images. SUN annotates scene types and the objects that commonly occur in them. There are 397 categories designed to evaluate numerous state-of-the-art algorithms for scene recognition (Xiao et al., 2010). The SUN Attribute\(^6\) dataset consists of 14,340 images from 717 scene categories, and each category is annotated with a taxonomy of 102 attributes (Patterson et al., 2014).

ModaNet\(^7\) is a dataset consisting of annotations of street fashion images. ModaNet provides multiple polygon annotations for each image. Each polygon is associated with a label from 13 meta fashion categories (bag, belt, footwear, outer, dress, etc.), where each meta category groups highly related categories to reduce the ambiguity in the annotation process (Zheng et al., 2018).

There are several datasets which have been widely used as a benchmark for object detection, semantic segmentation and classification tasks.

The PASCAL Visual Object Classes (VOC) 2012\(^8\) dataset contains 20 object categories including vehicles, household, animals, and others: airplane, bicycle, boat, etc. Each image has pixel-level segmentation annotations, bounding box annotations, and object class annotations (Everingham et al., 2010).

LabelMe is a dynamically developing dataset\(^9\) which contains hundreds of thousands of polygon annotations, thousands of static images and sequence frames with at least one labelled object (Russell et al., 2008). A particular feature of this collection is that it is being developed by users who can add images and categories and can annotated uploaded images. This option however may result in some level of inconsistency based on the decisions of the different users about the annotation protocol. The WordNet noun synonymous sets (synsets) are used to extend the categories, to avoid the inconsistency by means of manual editing and to unify the descriptions provided by different users.

One of the collections that set standards in the increase of datasets sizes is ImageNet\(^10\). The aim is for a the dataset with about 50 million cleanly labelled full resolution images (Deng et al., 2009). Another important feature of this dataset is that it uses WordNet noun hierarchies for image collection and labelling. ImageNet uses 21,841 synsets and contains 14,197,122 annotated images organised by the semantic hierarchy of WordNet (as of August 2014) (Russakovsky et al., 2015).

The taxonomic organisation of nouns in WordNet allows for using more abstract and fine-grained categories when describing objects. WordNet is a semantic network whose nodes host synonyms denoting different concepts and whose arcs, connecting the nodes, encode different types of relations (semantic: genus-kind, part-whole, etc.; extralinguistic: membership in a thematic domain; inter-language: translation equivalents). The idea for organising the lexicon of a given language into a (lexico-)semantic network was first executed in the Princeton WordNet (Miller et al., 1990). Some of the fundamental ideas on which the WordNet

\(^8\)http://host.robots.ox.ac.uk/pascal/VOC/
\(^9\)http://labelme.csail.mit.edu/Release3.0/
\(^10\)https://www.image-net.org
is based encompass: a) the use of a semantic network which embraces taxonomies, meronomies and non-hierarchical relations with clearly defined properties which allow for quick and easy automatic processing; b) a different organisation of the lexicon in comparison with the traditional dictionaries where words are ordered alphabetically and the links among semantically related words (such as between sister hyponyms, between a whole and its parts, etc.) are not explicitly presented (Miller, 1986).

The COCO (Microsoft Common Objects in Context) dataset (Lin et al., 2014) contains more than 328,000 images with manually annotated object instances (2.5 million)\(^{11}\). The dataset has had several releases since 2014 and it addresses object detection, segmentation, keypoint detection and captioning. The different parts of the dataset are annotated with bounding boxes (for object detection) and per instance segmentation masks with 80 object categories; natural language descriptions of the images; keypoints (17 possible keypoints, such as left eye, nose); per pixel segmentation masks with 91 stuff categories, such as grass, wall; full scene segmentation, with 80 thing categories (such as person, bicycle, elephant); dense pose – each labelled person is annotated with a mapping between image pixels and a template 3D model.

The image processing is generally classified as model based (using manually-labelled training data) and search based (using automatically collected training data). The search based approaches might include: effective learning mechanisms for matching a given query (Li and Fei-Fei, 2010); methods for automatic removing of noisy images (Hua and Li, 2015); frameworks combining discovering of multiple textual queries, filtering of noisy textual queries and noisy images (Anvari and Athitsos, 2019; Yao et al., 2020).

In the largest collection of datasets available on the internet, 1,455 image datasets are listed\(^ {12}\) (as of August 2021) provided with descriptions and links to the sources and related papers. Among them 134 datasets are designed for semantic segmentation; 104 – for image classification and 102 – for object detection. Ten datasets provide polygon annotations.

To summarise, the tendency in image annotation is from small training datasets to large-scale collections which require crowdsourcing in order to engage a large amount of human effort. Although the number and the diversity of image datasets is constantly expanding still there is a huge demand for more datasets in terms of variety of domains and object classes covered.

3 Ontology of Visual Objects

In current practice, WordNet is usually used in generating text queries for creation of search based image collections. A Visual Concept Ontology is proposed which organises visual concepts (objects or abstract notions that are typically depicted in photos) (Botorek et al., 2014). For the construction of Visual Concept Ontology over 400 “significant” noun synsets (that have at least 300 hyponyms) are extracted from WordNet, then synsets with very “general” meaning such as entity or thing were removed. This results in 14 top-level ontology classes, which are divided further into 90 more specific classes. Semantically similar synsets are merged into a common class and additional links are established between semantically related synsets such as roof and house.

We identified 10 thematic domains: Sport, Medicine, Arts, Education, Food, Transport, Clothing, Security, Indoors, Nature. The proposed Ontology includes concepts which are particular for these domains.

Following the strategy for category selection of the ImageNet we applied the rule for no overlapping between the classes: “for any synsets i and j, i is not an ancestor of j” (Deng et al., 2009). Mutually exclusive classes are also defined for other well-known datasets, for example for the COCO thing and stuff classes (Caesar et al., 2018). As it was pointed out, the mutual inclusion might lead to some inconsistencies. An example was given with the PASCAL Context (Mottaghi et al., 2014) classes bridge and footbridge, which are in a parent-child relation (Caesar et al., 2018). The parent term can replace the child term in some context, but not vice versa, thus: if two images are annotated as bridge and footbridge respectively, it will not be known whether the parent concept can refer also to the child concept or not.

The Ontology of visual objects has the following components:

**Classes** which can be represented by visual objects and correspond to the respective WordNet concepts. Among the classes we made a differ-
entiation between dominant classes and attribute (contextual) classes.

Each thematic domain is represented by several dominant classes, which show the main “players” within this domain differentiated by their type or their function. For example, the dominant classes for the domain Sport are: skier, cricket player, hockey player, volleyball player, swimmer, oarsman, etc., altogether 31 dominant classes. For the definition of the dominant classes, we use the WordNet sister hyponyms at a certain level (the lowest level allowing classification without specific knowledge for the domain). So far, the selected dominant classes for all thematic domains in focus are 277.

For each dominant class a parent class is selected from the WordNet noun hierarchies and this procedure is repeated consecutively up to the final class which represents a visual object. For example, classes like basketball player, acrobat, football player, etc. are hyponyms of athlete ‘a person trained to compete in sports’. Athlete in its turn is a hyponym of contestant ‘a person who participates in competitions’ which is a hyponym of person. However, the hypernym of person is organism, an abstract notion, which is not included in the ontology. As a result of this approach, thousands of annotations will be assigned to objects representing small number of classes, while the annotations with more general classes will be inherited automatically.

Attributes in the ontology are classes related with the dominant ones. The type of the dominant class and the type of attribute class determine the type of the relation between them which expresses the specificity of property attribution: has instrument, wears, uses, has part, etc. For example, the attribute classes for cricketer are cricket bat, cricket ball, cricket helmet, wicket and referee, while for climber – climbing helmet, chalk bag, claiming backpack, and so on.

Relations between dominant and attribute classes are not hierarchical. For the definition of attribute classes, we use WordNet relations such as meronymy and morpho-semantic relations between nouns. In many cases, such relations are not overtly established in WordNet and they were additionally inserted in the Ontology.

Finally, we made some evaluation tests for all selected classes with other sources providing lists with concrete objects, such as concreteness ratings (Brysbaert et al., 2018) and acquisition ratings of words (in our case of nouns) (Kuperman et al., 2012). So far, we have identified 1,037 classes grouped in ten thematic domains: Sport, Medicine, Arts, Education, Food, Transport, Clothing, Security, Indoors, Nature.

The relations used in the Ontology are relations between classes. Part of the relations and their properties are inherited form WordNet. Additional relations are included in the ontology in case they are not explicit in the WordNet structure. Each class in the Ontology is represented by a unique label, which in most cases is one of the synonyms in the corresponding WordNet synset (in case of ambiguity, a descriptive label is constructed).

Benefits of using an ontology for image labelling can be outlined as follows:

- Selection of mutually exclusive classes.
- Build-in interconnectivity of classes by means of formal relations.
- Easy extension of the proposed ontology with more concepts corresponding with visual objects.

What it more, since wordnets for many languages are linked to Princeton WordNet (Bond et al., 2016), we will provide multilingual descriptions of the images. Freely available wordnets with various lexical coverage for 17 official EU languages (Bulgarian, Croatian, Danish, Dutch, English, Finnish, French, Greek, Italian, Lithuanian, Polish, Portuguese, Romanian, Slovak, Slovene, Spanish, Swedish) and for Albanian, Icelandic, Hebrew and Serbian will be used for a multilingual representation of the selected classes.

4 Image Collection

There are many repositories that can be used for searching and downloading images. Some of the images are assigned with multiple labels or short descriptions, which is used to facilitate the automatic collection of appropriate images. For the selected classes a focused web image search is being conducted to compile a database with images — candidates for annotation. So far, more than 450,000 images were collected from different image providers, which are selected on the basis of the following criteria: the repositories should offer an API and images should be licensed with one of

13http://compling.hss.ntu.edu.sg/omw/
the following standards: Universal Public Domain Dedication (CC0 1.0); Attribution 4.0 International (CC BY 4.0) and Attribution-ShareAlike 4.0 International (CC BY-SA 4.0)\textsuperscript{14}. Thus, we are avoiding copyrighted material, which might limit the use of our dataset only for academic purposes.

After the collection of images, we perform additional manual selection to ensure the quality of the dataset. The following criteria for selection are observed:

- The image has to contain a clearly presented object described by a given dominant class.
- The object should not (preferably) have occluded parts. If there are occluded parts of the object, they should not be essential for its recognition.
- The target object should be in its usual environment and in a position or use that is normal for its activity or purpose (for example, images in which a skier drinks a beer are not selected).
- The target object should be represented with its inherent attributes (for example, images of a man with wings are not selected).
- The target object should be represented in different positions, photographed from diverse viewpoints and angles and the object background should vary to a sufficient degree (for example, images of a chess player which slightly differ from one another are not selected).
- The instances of the target object should not represent one and the same person, animal or artefact.
- (Preferably) images with up to 10 objects are selected (the objects can belong to different classes or can be instances of one and the same class). If there are images with only one object, then it should be the dominant one.
- Images with small objects, unfocused objects in the background or images with a low quality (low resolution; blurriness caused by an out-of-focus lens, low illumination level, etc.) are not selected.
- Images which represent collages of photos, drawings or are post-processed are not selected.

The final selection of images is triple checked independently by different experts: after the automatic collection, after the automatic generation of segmentation masks and after the manual annotation: correction of the segmentation masks, new polygon outlines and selection of appropriate classes.

5 Annotation Conventions

Our aim is to provide a dataset that will support image classification, instance segmentation and object detection formats. Several open source tools for image annotation (Makes Sense\textsuperscript{15}, COCO Annotator\textsuperscript{16}, VGG Image Annotator\textsuperscript{17}, LabelMe\textsuperscript{18}, LabelImg\textsuperscript{19}, etc.) have been evaluated in order to choose the most appropriate one for our purposes. Each annotation tool is usually designed for a specific application and for a specific annotation process. For example, we experimented with the web-based image annotation tool LabelMe to create polygon annotations; with the desktop annotation tool LabelImg to create bounding boxes, etc.

To avoid converting annotations for frameworks such as YOLACT\textsuperscript{20}, DETECTRON\textsuperscript{21}, etc., which provide segmentation masks and require COCO formatted annotations, we decided to work with the COCO annotator\textsuperscript{22}. The COCO Annotator can be containerised, allows for simultaneous work on a project, and offers useful functions that facilitate image annotation: tracking object instances, labelling objects with disconnected visible parts, etc.

It is a known fact that semi-automatic annotation approaches can significantly speed up the annotation process by automatic generation of annotation proposals to support the annotators. The main idea is to reduce the human interaction with the annotation tool and to save time, while maintaining the quality of the annotations. We experimented with Mask R-CNN and YOLACT, which provides instance segmentation on datasets like COCO. Mask R-CNN (He et al., 2017) is an implementation based on Python 3, Keras and TensorFlow. The model generates bounding boxes and segmentation masks for each instance of an object in the image. YOLACT (Bolya et al., 2020) is a framework, which breaks up instance segmentation into two parallel tasks: a) generating a dictionary of non-local prototype masks over the entire image, and b) predicting a set of linear combination coefficients

\textsuperscript{18}http://labelme.csail.mit.edu/Release3.0/

\textsuperscript{19}https://github.com/tzutalin/labelImg

\textsuperscript{20}https://github.com/dbolya/yolact

\textsuperscript{21}https://github.com/facebookresearch/Detectron

\textsuperscript{22}https://github.com/jsbroks/coco-annotator
per instance. Since the number of prototype masks is independent of the number of classes (e.g., there can be more classes than prototypes), YOLACT learns a distributed representation in which each instance is segmented with a combination of prototypes that are shared across classes.

The task for the annotators is to outline polygons for individual objects in the image (either by approving or correcting the automatic segmentation or by creating new polygons) and to classify the objects against the classes from the predefined Ontology.

The annotation follows the following conventions (only the more significant ones are listed here):

- The predicted polygons are accepted or corrected (if necessary) so that they outline the object as well as possible. Every instance of the target object is provided with a polygon.
- All objects from the selected dominant class and attribute classes related with it are annotated with polygons (for example, the tennis player and the related objects racket and tennis ball; chess player and the related objects chessman, chessboard, and clock). Other objects can be also annotated if they belong to the predefined Ontology of visual objects.
- Every polygon is required to be as close to the object outline as possible. There is not much information how the overlapping objects should be annotated. The bounding boxes that embrace the estimated extent of the object are not annotated due to the ambiguity and disagreement between the annotators (Lin et al., 2014). One possible solution is to annotate only the visible parts of the objects. We accepted the following conventions: If the objects are included in each other, both objects are annotated; If two objects overlap and the boundaries of the partially occluded object are clear, then the second one is annotated with an estimation for the occluded part (for example, a car behind a road sign); In case the occluded parts cannot be determined unambiguously, they are not annotated.
- An object is not annotated if it cannot be recognised for various reasons or less than 10–20 percent of the object is visible.
- If the object can be additionally associated with a different class this is recorded within the metadata (for example, if the climber is not a man but a boy, woman or a girl).

The quality control is provided by a second annotator who validates the implementation of the conventions and discusses the quality with the annotation group weekly. If necessary, some of the images are re-annotated.

6 Conclusion and Future Work

The Multilingual Image Corpus will provide pixel-level annotations for the selected dominant classes and their parent and attribute classes in ten thematic domains, thus offering more data to train models specialised in object detection, segmentation and classification in these domains. The selected classes for annotation are organised in an Ontology of visual objects that provides options to organise annotated images in different datasets regarding the envisaged tasks.

The Multilingual Image Corpus will be released in autumn of 2021 and will provide: a) a large number of copyright-free images, b) a large number of object classes organised in an ontology, c) a large number of pixel-level annotations; and d) extended image descriptions in (at least) 20 languages based on WordNet. An important result with great significance for the development of different applications for image processing will be the open distribution of the collection.

We are currently planning some experiments with a set of state-of-the-art algorithms on each of the tasks of object detection and segmentation, in order to establish a common baseline for future work.

7 Acknowledgments

The Multilingual Image Corpus (MIC 21) project was supported by the European Language Grid project through its open call for pilot projects. The European Language Grid project has received funding from the European Union’s Horizon 2020 Research and Innovation programme under Grant Agreement no. 825627 (ELG).

Abstract

In this paper, we introduce the Greek version of the automatic annotation tool ERRANT (Bryant et al., 2017), which we named ELERRANT. ERRANT functions as a rule-based error type classifier and was used as the main evaluation tool of the systems participating in the BEA-2019 (Bryant et al., 2019) shared task. Here, we discuss grammatical and morphological differences between English and Greek and how these differences affected the development of ELERRANT. We also introduce the first Greek Native Corpus (GNC) and the Greek WikiEdits Corpus (GWE), two new evaluation datasets with errors from native Greek learners and Wikipedia Talk Pages edits respectively. These two datasets are used for the evaluation of ELERRANT. This paper is a sole fragment of a bigger picture which illustrates the attempt to solve the problem of low-resource languages in NLP, in our case Greek.

1 Introduction

Grammatical Error Correction (GEC) is the task of automatically correcting language mistakes in written texts. These mistakes can vary from grammatical mistakes to punctuation, spelling and morphology of a word. The development of a GEC system usually involves the transformation of an erroneous sentence into its correct version, while also keeping the initial meaning intact. Developing those systems requires error annotated data, which can be either learner data or artificial. High-resource languages, such as English, present a variety of learner data that cover a relatively wide spectrum of language proficiency levels, native language and topics. Some notable examples are the Cambridge English Write & Improve corpus (Yannakoudakis et al., 2018), the LOCNESS corpus (Granger, 1998), and the NUCLE corpus (Dahlmeier et al., 2013). Low-resource languages, on the other hand, are characterized by a scarcity of such corpora, as well as of other GEC resources and Natural Language Processing (NLP) tools. That is also the case of Greek.

Although, Greek is only spoken by approx. 13.5 million people (native), the fact that Greece has a high immigrant population underlines the need for learning Greek as a Second Language (GSL). Therefore, and as technology is being integrated in education (Meurers, 2012; Forcier, 2016), the need for more GEC and NLP tools for Greek becomes evident.

In this paper, we present ELERRANT, an automatic annotation tool, which is based on ERRANT (Bryant et al., 2017). ERRANT produces an annotation mainly consisting of the error location, the error type and the correction of the error, by using an original erroneous sentence along with its correction as input. ERRANT is the first toolkit that not only annotates texts but also provides automatic error typing, offering detailed feedback to Second Language (L2) learners and useful information for language analysis (Bryant et al., 2017). Most importantly, the annotator’s workload is relieved and all learner corpora, regardless of size, level and other factors can be annotated in a standardized manner. We believe that its easy application and versatility can encourage the generation of more error annotated datasets in the Greek language, thus tackling the scarcity of resources.

For the evaluation of ELERRANT we developed two datasets: the Greek Native Corpus (GNC) and the Greek Wiki Edits (GWE). GNC comprises native Greek student essays, while GWE comprises sentences extracted from WikiConv (Hua et al.,

1https://en.wikipedia.org/wiki/Greek_Language
2https://eacea.ec.europa.eu/national-policies/eurydice/content/population-demographic-situation-languages-and-religions-33_en
By evaluating ELERRANT on the latter corpus, we also show that the tool has the potential to detect edits and alterations on Wikipedia Talk Pages that are due to grammatical error correction, which can then be automatically white-flagged from being moderated for misinformation (e.g., for words introducing bias). It also paves the way for further analysis of such edits. Both datasets are shared for public use.3

The rest of the paper is structured as follows: First, we discuss related work on Error Annotated Data and the original ERRANT. Then, we describe the development of ELERRANT. Section 4 introduces the two new datasets, demonstrates our method of evaluation and presents the findings. Section 5 is concerned with the use and implications of ELERRANT. Finally, we conclude by discussing limitations and future work.

2 Related Work

Error Annotated Data - What for? Error annotated data can be useful in multiple domains ranging from real-life teaching and educational research to NLP tasks, especially in GEC. More specifically, recent advances in GEC often require large amounts of annotated data both for development and evaluation of any given systems. Mita et al. (2019) underline the need for cross-corpora evaluation when it comes to GEC systems, given that the task difficulty depends on factors such as proficiency level and essay topic. Consequently, there is a demand for standardized error-annotated corpora, while also reducing the annotator’s workload (Bryant et al., 2017). In addition, error annotated corpora can play a major role in error analysis, which has slowly started to step into CALL (Computer Assisted Language Learning). Until very recently, the staple technique to NLG (Natural Language Generation) for language learning purposes, was to train models on large bodies of correct English (Lee and Seneff, 2008). Although this technique has proven to be effective, a more recent one seems to take into account more parameters when it comes to non-native speakers. This new technique involves relying on two kinds of corpora: a source corpus from non-native texts, and a target corpus, which, in reality, is a corrected version of the source corpus. Meurers (2012) summarizes the benefits on the analysis of learner corpora claiming that the annotation of learner corpora can point out learner language properties thus supporting the aim of improving our understanding of Second Language Acquisition (SLA) and developing instructional methods and materials for SLA purposes.

ERRANT Bryant et al. (2017) attempt to solve the issue of corpora standardization by presenting ERRANT, an automatic annotation tool which serves as both annotator and system-output scorer. ERRANT only needs an erroneous sentence along with its correction to produce an annotation essentially consisting of the location of the errors, the error type, and the correction. ERRANT has paved the way for a new annotation framework, and has therefore been used in the most recent shared task, the BEA-2019 (Bryant et al., 2019), both for annotating the datasets used for the task and for evaluating the system output of the participants per error. The convenience and versatility of ERRANT has led to the adaptation of the tool in more languages, such as German (Boyd, 2018), Spanish (Davidson et al., 2020), Czech (Náplava and Straka, 2019), and Romanian (Cotet et al., 2020). In this paper, we present our Greek version.

Task difficulty Inter-annotator agreement, although a staple in computational linguistics procedures when it comes to evaluation, has been quite controversial regarding GEC. Traditionally, corpora for GEC purposes would be annotated by solely one native annotator providing one gold standard annotation, a practice which automatically renders the research highly biased and even uninformative (Bryant and Ng, 2015; Tetreault and Chodorow, 2008). The obvious solution to the problem would be to recruit multiple annotators and estimate the degree to which they agree on the correction of an error. Yet, this method also proves insufficient, since annotators usually agree up to 70%, a percentage inadequate for system evaluation. The same holds for intra-annotator agreement, where the same annotator does not always agree with themselves (κ scores of about 60%) (Bryant and Ng, 2015).

Table 1: ELERRANT and human error type annotation guide. The error types with the asterisk (*) do not exist in the human annotation scheme while the two last error types in the table do not exist in the ELERRANT annotation scheme.

SpaCy\(^3\) as the main POS tagger. Due to morphological differences between the two languages (English and Greek), we removed some error categories that exist in the original ERRANT, while adding some new ones. Due to the fact that Greek is a highly inflectional language and most POS have some sort of inflection, we “merged” some error types in order to include as much information about the error as possible. This decision can be regarded as a compromise, since many errors might have more than one overlapping error types (e.g., τον γάτα → τον γάτιων, wrong case and number), therefore by merging the sub-types into the FORM type we preserve the ambiguity and multifaceness of the error.

The main alterations are the following: We added the error type AD:FORM (Adverb Form), to convey errors that mainly concern the comparative and superlative degree of the adverb. The CONTR (Contraction) category has been removed temporarily due to the fact that contractions in Greek can happen in any word starting or ending with a vowel under certain conditions. We are currently developing a dictionary that assembles the most frequent cases of contractions in Greek and we plan to integrate it in future versions. NOUN:INFL (Noun Inflection), NOUN:POSS (Noun Possessive) and NOUN:NUM (Noun Number) are all captured in NOUN:FORM (Noun Form). PART (particles) were also dropped as in the Greek language they have a different function, mainly in tense construction. PRON:FORM (Pronoun Form) was also added, since pronouns are also inflectional. From the verb categories, only VERB, VERB:FORM, and VERB:TENSE have been preserved.

**Two new categories** We added two more categories from scratch: ACC (Accent) and FN (Final -ν/μ). The accent in Greek is signified with a stress mark (´) rather than just the intonation of the word when speaking. The maintenance or omission of the final nu in some Greek words (articles, pronouns or particles), due to its frequency as an error even by native speakers, is considered a different error type and not just a spelling error. For the two aforementioned error types, we made two

new corresponding functions and added them in the ELERRANT classifier (see Algorithms 1 and 2). Table 1 demonstrates the final error categories in ELERRANT.

Table 1 demonstrates the final error categories in ELERRANT. If a sentence contains at least one error, the corresponding error categories are documented in the table. This paper, 227 sentences have been collected and annotated. The GNC comprises essays written by High School students.

4 Empirical Evaluation

We consider this work an opportunity to introduce two novel datasets: Greek WikiEdits (GWE), and the Greek Native Corpus (GNC), which we use as gold standards in our ELERRANT evaluation. This section first describes our two datasets, their annotation and development process, and presents some statistics and inter-annotator agreement results. Then, the evaluation is discussed and the experimental results are reported, evaluating ELERRANT on both datasets.

4.1 Datasets

GWE The first corpus we evaluated ELERRANT on is based on WikiConv (Hua et al., 2018). WikiConv is a multilingual corpus that encompasses the history of conversations on Wikipedia Talk Pages, including comment deletion, modification and restoration. The authors of the respective article kindly provided us with the Greek part of the corpus, which comprises 194,499 Talk Pages. We processed the provided pages so that only sentences with edits remained. Despite the fact that edits do not necessarily regard grammatical errors (e.g., they could be about a corrected date), their employment by Grammatical Error Correction models leads to improvements (Lichtarge et al., 2019). To the best of the authors’ knowledge, this is the first dataset with edits of Wikipedia Talk Pages comprising human annotations for grammatical errors. Henceforth, we will refer to this Greek WikiEdits dataset as GWE.

GNC The existing publicly available corpora compilations, that attempt to contribute to the scarcity of Greek resources for NLP, are the Greek Learner Corpus (GLC) (Tantos and Papadopoulou, 2018), and the Electronic Learner Corpus of L2 Greek (Tzimokas, 2010). Both datasets consist of data generated by learners of Greek as a Second Language (GSL). Despite their usefulness, we observe that none of these datasets includes corrections in their annotations. This lack of corrections was intentional, in order to reflect the “error ambiguity”, rather than choosing between several corrections, given that an error can be corrected in multiple ways (Tantos and Papadopoulou, 2018). This lack of corrections, however, also means that ELERRANT is effectively inapplicable on them. This gap motivated us to develop another corpus to evaluate ELERRANT on, the first Native Greek Corpus (GNC), designed in the aim of being compatible to ELERRANT and of use to automatic grammatical error correction systems.

The compilation of GNC is currently in progress, but at the time of writing this paper, 227 sentences have been collected and annotated. The GNC comprises essays written by High School students,
whose native language is Greek. The hand-written essays were split into sentences and manually digitized (no OCR was used). Each sentence may contain none, one or more grammatical errors.

4.2 Annotation Schema

The GWE corpus comprised edits which we considered the “corrections”, in order to be able to apply ELLERRANT. GNC, however, does not comprise any suggested corrections and thus, ELLERRANT is not applicable. Hence, the suggested corrections have to be provided by the annotators. Due to this significant difference between the two datasets, the annotation process differs in the two cases, and in particular concerning the GNC it becomes slightly more complicated. Annotation for both datasets was based on the rule-based error type framework of the original ELLERRANT. Two main code categories were created. The first category (‘Error Description’), consists of the three prefix operation codes \([U(\text{necessary})/R(\text{replacement})/M(\text{issing})]\) which indicate what needs to happen to each erroneous item in order to be corrected, i.e., whether it should be removed from the sentence, whether it should be modified or replaced, or whether an item is missing. The second code category (‘Error Type’) comprises 16 codes created based on the 25 codes presented in (Bryant et al., 2017) (see Table 1), which form a simplified classification system of the errors that may occur in the written Greek language. These codes indicate what kind of error we encounter in each sentence and (in most cases) what part of speech the erroneous element that needs to be removed, modified or added is.

GWE Schema The annotation on the GWE was carried out in two steps. First, the two parallel sentences (original and changed) were input in ELLERRANT, which helped us extract the tokens of the edits. Then, the annotators classified the edits according to the ‘Error Description’ and ‘Error Type’ fields from the annotation schema described above.

GNC Schema The annotation process for the GNC was based on a schema containing four annotation fields. The first field is intended for two mutually exclusive values \([c(\text{orrect})/e(\text{rroneous})]\) in order to mark the absence or presence of an error in the sentence. The second is for the annotator to correct the existing error and rewrite the whole sentence providing the corrected string. The two remaining fields are respectively for the ‘Error Description’ and ‘Error Type’ codes that were used also at the annotation of GWE.

As can also be seen in Table 2, when a sentence contains multiple errors, such as in (a) below, then copies of that sentence are inserted in the corpus (i.e., the second and third), leading to as many records with the same sentence as the errors it comprises. In each entry, the annotator should maintain and correct only one error, while the other errors must be recorded in advance (both in the field of the original and the corrected text) as correct. Respectively, the same should happen if two or more errors are detected in a single word, such as the example of sentence (b) below:

(a) **Erroneous sentence containing more than one errors**

Αρχικά, από την μεριδατοποίηση και την ευκολοποίηση τους, προκαλεί σεις και προκαλούνται δυσαναλογικά αποτελέσματα. Αποτυχάνουν αποτελώντας, έτσι που σεις και προκαλούνται και προκαλούνται σεις και προκαλούνται.

(Αρχικά)

(b) **Erroneous word containing more than one errors**

Εμείς επιχηρούμαι.

"We attempt."

Annotation process We recruited two Greek philology graduates and provided them with 327 sentences, 227 from GNC and the remaining from GWE. In GWE, where each page comprised a single edit, we performed sentence segmentation (based on full stop) and only considered the sentence comprising the edit. We asked the annotators to follow the annotation schemas (see Sec. 4.2), in order to classify (and detect and correct in GNC) all possible grammatical errors.

4.3 Corpus Statistics

Table 3 presents the statistics of the two annotated corpora, by considering the detected errors of the two annotators on (micro) average. Sentences were longer in GWE, compared to GNC. More errors were detected on (micro) average in GNC, which is
Evidently, from the human-annotated error types and those generated by ELERRANT, the process was the same for GNC and GWE.

Inter-Annotator Agreement In GWE, Cohen’s Kappa for the human-annotated edits was 70.02%. Out of the sixteen available codes, only 10 were used by Annotator I and 13 by Annotator II. The Pearson’s correlation between the error type frequencies of the two annotators was 99.62%, which indicates that the two frequency distributions coincide to a large extent. Given that the annotators had to annotate the edits with annotation guidelines fitting for error types, they opted for more abstract categories such as OTHER, which was the most frequently annotated type. In GNC, Cohen’s Kappa between the two annotators regarding the error type was even higher than GWE, reaching 84.65%. Out of the sixteen available codes, in the annotated texts we encountered the fourteen (UNK and WO tags were not used at all). The distribution of the frequency of occurrence of these fourteen (14) error types also coincides to a large extent between the two annotators, which is reflected in the high error type frequency correlation between the two annotators (99.20%). Any disagreement is mainly due to additional errors and not to the incorrect or different rendering of the codes.

In other words, inter-annotator agreement in GWE falls within the threshold of 70% (see Section 2), while in the GNC this threshold is exceeded. In such cases, where agreement is not optimum but not extremely disheartening, tools such as ERRANT can be used as moderating tools by pinpointing any great discrepancies, as a third annotator would.

4.4 Experimental Results

Since GNC was annotated by two annotators (and therefore there might be differences in the corrections), we ran ELERRANT on both annotators’ corrections separately and compared the output error types against the error types provided by each annotator, which served as our gold standards. For GWE, first, the texts were input into ELERRANT and then the edits were assigned an error type by the annotators. Then, we calculated the accuracy, precision, recall and F1-score separately for each comparison. The three latter metrics were calculated with macro, micro and weighted averages to also be able to see whether ELERRANT performs better at more or less frequent error types. We also calculated and compared the frequencies of the human-annotated error types and those generated by ELERRANT. The process was the same for GNC and GWE.

Table 3: Overview of GWE (Talk Pages) and the GNC (essays). The respective count is shown per row.
It must also be noted that to evaluate the performance of ELERRANT against the gold standards of both datasets, we had to mitigate the differences between the ELERRANT annotation schema and the human annotator schema (see Table 1). The necessary modifications included changing all \texttt{VERB:*} error types to \texttt{VERB:FORM}, \texttt{ARTORDET} to \texttt{DET}, \texttt{PART:FORM} to \texttt{ADJ:FORM}, and temporarily change \texttt{ADJ:FORM} of ELERRANT to \texttt{AD:FORM}.

**Evaluation on WikiEdits (GWE)** For the evaluation of ELERRANT on GWE, as already discussed, we considered the annotations of each annotator as our ground truth. The results are demonstrated on the right of Table 4. All metrics are low with the accuracy reaching 31% and 27%, precision never exceeding 44.47%, recall 40.03% and F1-score 35.75%. This low performance is explained in part by the inability of ELERRANT to detect specific types (see Fig. 1). Additionally, as mentioned in Section 4.1, the edits in Greek Wikipedia are not necessarily grammatical errors. For instance, edits can be ‘vandalisms’, attempting to alter the content and context of the respective Wikipedia article.

**Evaluation on Learner Data (GNC)** GNC results are presented on the left of Table 4. Scores are considerably high for micro and weighted averaging. Error type classification is a multi-class problem and each instance of error type might be encountered in different frequencies. This is also apparent in Figure 2, where we can see that spelling, accent, and final nu errors have the highest frequencies both in terms of ELERRANT annotation and according to human annotators. In both annotator cases, micro scores are higher than macro scores indicating that ELERRANT performs better when it comes to classifying an error type that occurs frequently, while it tends to misclassify less frequent error types. The accuracy scores, 83.91% and 77.30%, by Annotator I and II, respectively, show that ELERRANT can correctly classify the error type approx. eight out of ten times, assigning the most appropriate error type possible, if we consider the annotation as the gold standard, and thus the best possible error type classification. However, and as we can see from the results, there are discrepancies between the two annotators, hence the different accuracy scores (see Section 4.3).

Taking into consideration that ground truth in GEC annotation cannot be as established as in other NLP tasks, due to the fact that one erroneous sentence can have multiple corrections (Napoles et al., 2015; Bryant and Ng, 2015), we also looked at the ELERRANT output manually to pin down where it is lacking exactly. We noticed two major issues: First, Greek SpaCy (which is the core of ELERRANT) does not perform as well as in the English version, assigning wrong POS tags or dependencies. Secondly, there are cases in Greek where a single word can contain two or more errors at the same time, and cannot be solved with the ‘FORM’ category. These cases are usually a combination of accent and spelling mistakes, spelling mistakes and morphology, accent and morphology, etc. In this case, ELERRANT assigns only one error type disregarding the rest. We hope to solve these issues in future versions.

### 5 Discussion

Our experimental results showed that ELERRANT performs better when it comes to actual error type classification (GNC) than edit classification (GWE). In terms of scores, the ELERRANT classifier works adequately (83% accuracy), especially when compared to the evaluation of the original ERRANT, for which a manual evaluation rated 86% of the output error types as “GOOD”. There is still, however, room for improvement. As mentioned in Section 4, the most important issue is Greek SpaCy which also hinders the development of a more detailed ELERRANT, i.e., with more error types such as Noun-Gender Agreement, Case, etc.

As far as the GWE is concerned, a detection and edit classification by ELERRANT is possible, provided that both the edit and the proper form of the text exist. Moreover, the addition of further edit categories is necessary because the current version of ELERRANT is based on error type classification and not edit classification. Categories such as SYNONYM and NAME might give a better insight into how the edits affect the text.

Table 5 illustrates the potential, as well as the problem of applying ELERRANT to GWE. The first edit is a name replacement, which does not entail a grammatical error, yet it does affect the meaning of the sentence. ELERRANT incorrectly classified the edit as a spelling error, while the two annotators placed it in the more general category OTHER. If both ELERRANT and the human-annotator scheme provided a category such as \texttt{R:NAME}, the performance of the system would have been better and the human annotation would have been more accurate.

---------------|----------|-------------|--------------|
Σομαλίας / Γροιλανδίας | R:SPELL | R:OTHER | R:OTHER |
the (definite feminine article) or harpafr/pe/ərpafr daily | R:SPELL | R:SPELL | R:NOUN:FORM |

leading to a more accurate and descriptive ground truth. When the edit is a grammatical error ELERRANT performs better, as we can see in the second example. Finally, there is the case where ELERRANT is right and the human-annotator is wrong, which also indicates that an automatic annotation tool such as ERRANT and ELERRANT can provide more accurate, less biased annotation.

6 Conclusion

This paper presented ELERRANT, the Greek version of the automatic grammatical error type annotation tool ERRANT. With this work we also introduced two new datasets: the GNC and GWE, which can be used for GEC and edit classification purposes. Both our datasets are released for public use. In GNC, our findings showed that ELERRANT achieves an accuracy of 77.30%-83.91%, confirming that it can be an effective tool, reducing the scarcity problem of low-resource languages, such as Greek. In GWE, the overall performance was much lower, mainly because Wikipedia edits are not necessarily due to GEC. However, despite this low performance, we observe that ELERRANT can still be helpful to Wikipedia moderators who can use it to shortlist edits that are likely due to GEC and thus white-list them. Furthermore, ELERRANT could be updated to capture more error types that are common in GWE, which we will consider in future work, along with the expansion of our datasets.
7 Ethical Considerations

All texts for the compilation of the GNC dataset were obtained with the consent of the original authors. In case of underage authors, adult parents or guardians gave their consent. Authors were thoroughly informed about the purpose of the study, and became completely aware that the produced texts would be anonymously published.

Acknowledgments

We would like to thank Jeffrey Sorensen (Jigsaw) for contributing to this research by sharing with us the Greek part of the WikiConv corpus, which led to the creation of GWE. We would also like to thank Eleutheria Stroumbouli and Maria Fasoi (Athens University of Economics and Business) for correcting and annotating the GNC and GWE datasets.

Abstract

Code-mixing has become a moving method of communication among multilingual speakers. Most of the social media content of the multilingual societies are written in code-mixed text. However, most of the current translation systems neglect to convert code-mixed texts to a standard language. Most of the user written code-mixed content in social media remains unprocessed due to the unavailability of linguistic resource such as parallel corpus. This paper proposes a Neural Machine Translation (NMT) model to translate the Sinhala-English code-mixed text to the Sinhala language. Due to the limited resources available for Sinhala-English code-mixed (SECM) text, a parallel corpus is created with SECM sentences and Sinhala sentences. Srilankan social media sites contain SECM texts more frequently than the standard languages. The model proposed for code-mixed text translation in this study is a combination of Encoder-Decoder framework with LSTM units and Teachers Forcing Algorithm. The translated sentences from the model are evaluated using BLEU (Bilingual Evaluation Understudy) metric. Our model achieved a remarkable BLEU score for the translation.

1 Introduction

Before 1990, translation was considered a difficult task due to many reasons such as ambiguity, translation mismatch, co-reference, translation divergence and development of language over time (Sreeleekha et al., 2016) but Machine Translation (MT) since 1990 has been a vast and successful research area in natural language processing. Machine translation has been given importance in the research field because it is used to translate texts for military authorities to track enemies, foreign business collaborations, marketing, etc. (Kalchbrenner and Blunsom, 2013).

Expressing the thoughts of the personal interests, daily life etc., of a person in social media networks has become a trending activity among people. Texts extracted from social media lead to measure the social dynamics of several societies (Arguello et al., 2008). Content-based search engines, personalized advertisements, recommendation systems, etc. use the user-generated content from social media to increase their value and to provide more accurate results to the users (Sippel and Brodt, 2008). Processing a content in standard language (without code-mixing) is considered as an easy task, where the text with code-mixing has been considered as a road block to extract the needed information. Code-mixing is considered as an invention of bilingualism and multilingualism. The capability of speaking in two languages, is called bilingualism and more than two languages is called multilingualism. Most of the Srilankans are bilingual. The user-generated content such as posts, comments, reviews etc., in Srilankan social media are mostly in SECM text. The main focus of this study is to translate the SECM text to Sinhala language.

To understand the necessity of processing SECM text, a survey study was conducted among 82 native Sinhala speaking citizens as a part of our research study to collect information about the usage of SECM text in Sri Lanka. Figure 1 shows the results of a few essential questions from the survey. The majority of the people have stated that they use SECM text in social media rather than their native language.
In SECM texts there are several problems identified related to morphology, syntax and the semantic structure of the text. The challenges found in SECM texts are,

- Inconsistency in the transliteration
- Spelling mistakes
- Code-switching
- Words combined with suffixes of another language
- Improper usage of discourse marker
- Unnecessary numerical characters combined with words

For example, in the SECM sentence shown in Figure 2, the words ‘lassana’, ‘ekak’, ‘ekka’ and ‘gatha’ are transliterated (Words from one language written with the alphabet of another language) Sinhala words. The word ‘atmosphere’ and ‘so’ are English words. The sentence starts with Sinhala transliterated word, switches to English and again switches back to Sinhala transliterated format. The language of words is switched from one to another in a single sentence, called as code-switching. The word ‘so’ is a discourse marker in English, which is used for joining two sentences which has Sinhala base. The ‘friendla’ is a SECM word, where English singular noun ‘friend’ is combined with Sinhala transliterated suffix ‘la’ to make it look like the plural word ‘Friends’. The word ‘4to’ represent the English word ‘Photo’ with spelling mistakes and unnecessary numerical character. The numerical character combined with the word presents the phonetic sound of the word ‘four’ and ‘to’. Together it is understood as the word ‘photo’. The research study of Kugathasan and Sumathipala (2020) clearly explains the challenges in Sinhala-English code-mixed texts.

This paper is divided into six sections. Section 2 elaborates on the works related to Machine Translation. Section 3 describes the SECM texts and corpus creation. The Section 4 explains the methodology, which explains about the model implementation and prediction. Section 5 describes the experimental setting of the model and the result gained. As the final section the paper discusses the conclusion of the research study.

Figure 1: Survey results on Sinhala-English code-mixed text usage among Srilankans
2 Related Work

The high demand for Machine translation is increased due to many reasons such as business in overseas, tracking down the information of another language for military services, high usage of social media, etc.

Machine translation was initiated by Warren Weaver in 1955. The research combined Statistical Machine Translation (SMT) with Claude Shannon’s information theory (Weaver, 1949/1955). SMT models output the degree of similarity between the source and target sentences (Carrera et al., 2009). The structure of a sentence, feature engineering and design are considered as valuable factors in SMT. Also SMT approach is noted as ‘not suitable’ for generalized sentence pair, sentences with hidden details (Kalchbrenner and Blunsom, 2013) and language pairs with different word orders (Masoud et al., 2019). Chiang (2005) and Koehn et al. (2003), showed that features focused in SMT are not helpful to track the long-distance dependency of a sentence like in Recurrent Neural Network. Collobert and Weston (2008) explained, how semantic, synthetic and morphological similarities are captured better when there is continuous representation of words that carry task-dependent knowledge.

Kalchbrenner and Blunsom (2013) introduced the Recurrent Continues Translation model, which has two parts, Convolutional Sentence Model and Recurrent Language Model. Convolutional Sentence Model, uses a convolutional n-gram approach on source sentences in the encoder. The sentences are mapped into semantic vectors. The recurrent language model is applied in the decoder. A similar approach is proposed by Cho et al. (2014), where the Recurrent Neural Network (RNN) is used for translation. Sentences needing translation are encoded into a sequence with a fixed length vector and decoded with another sequence of symbols. In this approach, the encoder and the decoder are jointly trained to increase the conditional probability of phrase pairs in the sentence using RNN.

Some research studies on translation are based on a monolingual dataset. A semi-supervised approach is proposed by Cheng and Duan (2020) with labelled and unlabeled corpus. Labelled corpus is a parallel corpus with source and target sentences of the Chinese-English dataset. Unlabeled corpus contains the monolingual dataset. In the semi-supervised setting, parallel and monolingual corpus are joined to learn Bidirectional NMT (source to target and target to source models). Sennrich et al. (2015) proposed two approaches to translate monolingual datasets. In the first approach the monolingual corpus is matched with dummy inputs to construct the parameters of the encoder with attention model (Choi et al., 2018) and the second approach utilizes a pre-trained NMT model.

Using NMT for translating one standard language to another standard language has been a success over the decade (Sreelekha et al., 2016). However, it is not experimented well with the code-mixed text due to the lack of resources. In the domain of translating code-mixed text, very few researches have been carried on. A combined approach of Statistical Modelling (Neale et al., 1999) and Knowledge Translation (Rijhwani et al., 2007) approach is introduced by Carrera et al. (2009) for cross-language social media texts. Rijhwani et al. (2016) introduce an approach for translating code-mixed text, where words in sentences are categorized as dominant and non-dominant languages. Words from dominant language are labelled as matrix language and non-dominant language are labelled as embedded language. The first task before the translation was word-level language identification. Next, the data is applied to a current translator to translate the words to another language. Dhar et al. (2018) used a code-mixed corpus from ICON 2017 tool contest for translation. Machine translation augmentation approach was used in their research study which achieved a BLEU score of 16.90. Masoud et al. (2019) used a combined corpus from OPUS3 and EnTan4, evaluated the corpus using several approaches and calculated the BLEU score. Word Hybrid Baseline approach achieved a BLEU score of 21.05, Byte Pair Encoding (BPE) Hybrid baseline approach achieved a BLEU score of 21.93, Word Hybrid Baseline Google approach received a BLEU score of 21.35. Finally, the Word Hybrid Baseline Google approach achieved the
highest BLEU score of 22.46.

3 SECM text and corpus creation

Sinhala is the native language of the majority of the people in Sri Lanka. But in Sri Lankan social media, Sinhala-English code-mixed text is used frequently because of the multi-lingual users. In 2001 International Organization for Standardization published the ISO15919 standard. It is an international standard for romanization which includes many languages including Sinhala language. Weerasinghe et al. (2005) used the IPA (International Phonetic Alphabet) format to represent Sinhala letters in their research study. ISO15919 and IPA both present Sinhala letters with English alphabets, which is called transliterated format or romanized text format (Hettige and Karunananda, 2007). Wasala et al. (2006) propose a conventional tag set, which uses the 26 alphabets of English to present the phonetic sound of Sinhala letters using the festival framework. Code mixing is described as a way of writing roman script (Davies and Bentahila, 2007). Even though the standard tag sets from Punchimudiyanse and Meegama (2015) is defined as roman representation, the romanization of actual code-mixing used by multilingual societies is different from the standard tag sets. Figure 3 and Figure 4 shows us how the standard romanization defined for Sinhala letters differs from the roman representation used in Singlish text.

According to Figure 3 and Figure 4, Phonetic Tagset (PT) and Romanized Tagset (RT) are almost similar. But there is a huge difference between these two tagset and code-mixed text representations of Sinhala letters. Due to no consistency in the pattern of Singlish text, it is not easy to translate the Sinhala code-mixed text without a parallel corpus. To achieve a good outcome most machine translation systems needs a sufficient amount of parallel sentences in the corpus.

We collected the SECM sentences from public Facebook posts, comments and reviews. For the translation of SECM to Sinhala, implementing the parallel corpus is an important part for our research study. Each SECM sentence was human translated by a linguistic expert of Sinhala language to create the parallel corpus. In the parallel corpus SECM is considered the source sentence and Sinhala is considered the target sentence. The human translator was advised to follow the Singlish to Sinhala mapping provided in the research study of Kugathasan and Sumathipala (2020) as the guide to maintain the consistency in the translation. The corpus contains around 1500 parallel sentences of SECM and it’s translated Sinhala sentences. After the human translation the dataset was checked to see whether the translated sentences are FC (Fully Correct) or CR (Correction Required). If a parallel sentence was annotated with a Correction Required tag by the annotator, the same annotator would provide the alternate translation as well. Each sentence in the corpus is annotated by two annotators. The annotators are people whose native language is Sinhala and we made sure that they are fluent in the Sinhala language. The annotators were provided with guidelines regarding the annotation process. The guidelines made sure that the annotators were checking whether there are any

![Figure 2: Example of SECM code-mixed text.](image-url)
spelling mistakes, grammatical issues in the Sinhala translation.

As shown in Figure 5, when there is a sentence tagged with two different tags, for example one annotator annotated with FC tag and the other annotated with CR tag with an alternate translation, we considered the alternate translation. Also when a sentence is annotated with CR tag from both the annotators, the alternate translations provided by both the reviewers are checked with a third annotator and the most suitable translation is selected. To evaluate the standard of the corpus, 100 randomly chosen sentences are provided to 3 experts of Sinhala for ranking. The translations are ranked as good or bad, according to the meaningful translation, grammatical pattern and spelling errors. Fleiss’ Kappa approach is used to calculate the reliability of the agreement between the raters (Randolph, 2008). The overall Fleiss’ Kappa score received for the translation is 0.88.

4 Methodology

After corpus creation, the dataset was applied with several pre-processing steps. Initially, all the sentences in the Singlish corpus are converted into lower case and all the Sinhala sentences in the target corpus are added with START and END tokens. The unique words from the corpus are extracted and unique numbers are allocated for each word according to the order of frequency of each word. These word-number arrays are called WordToIndex dictionaries.

Encoder-Decoder framework is used as the base to initiate our model. Encoder and decoder can be considered as two separate Recurrent Neural Networks. In the encoder the SECM sentence is fed as input. It produces the sentence with fixed-sized representation by encoding. Each word from the input sentence provided into the encoder would be mapped into an integer using the WordToIndex dictionary and converted into one-hot encoding. The embedding layer maps the one-hot encoded representation into a smaller dimension. The word embedding would be the input to the next layer with Long Short Term Memory (LSTM) as the basic unit. In LSTM we have a cell state that is passed with each timestep. The LSTM unit (Sundermeyer et al., 2012) determines to neglect some unnecessary information and add some new information from the input fed to the current timestep.

The significant information collected from the encoder would be passed into a context vector with the output and hidden states. Only hidden states are passed as input to the decoder.

Decoder produces the target sentence using the significant information passed through the hidden state from the encoder and the input target word. Each word from the target sentence is mapped into an integer using Word-
ToIndex dictionary and converted to one-hot encoding. The word embedding layer maps the embedding into a continuous representation which has a lot smaller dimension. Figure 6 shows the architecture inside timesteps in encoder and decoder.

Teacher Forcing algorithm (Goodfellow et al., 2017) is added in the decoder. Teacher Forcing algorithm inputs the expected output of previous timestep $t-1$ to the current timestep $t$. The advantage of using Teacher Forcing mechanism is the hidden state of the model would be updated with the correct expected outputs rather than the wrongly predicted output from the previous timestep. If the predicted output from previous timestep $t-1$ is fed to the next timestep $t$, the number of errors would be increased and the model would face difficulty in learning. Combination of encoder and decoder is called as Sequence to Sequence model (Seq2Seq) as shown in Figure 7.

Final phase of the proposed architecture of the system is prediction. Singlish sentence from the corpus is given as input, and output would be the predicted Sinhala sentence. Prediction phase is built with the sequence to sequence architecture. Each timestep in decoder passes predicted output for the next timestep unlike the decoder in the training phase of the model.

5 Experimental setting and Result

From the corpus 70% of the data is allocated for training, and 30% of the data is allocated for testing. Inputs for the encoder and the decoder are in the shape of 2D arrays. The shape of the encoder array is (10,27), where the batch size is ten and maximum length of source sentence is twenty seven. Shape of the decoder array is (10,26), where the batch size is ten and maximum length of source sentence is twenty six. Rmsprop is used as the optimizer and Categorical Cross Entropy is used to calculate the loss. The RMSprop optimizer is used because it balances the step size and, decreases the no of steps for massive gradients to neglect the exploding and increases the number of steps for small gradient to avoid vanishing gradients issue. Weights calculated after the training phase of the model are saved for the prediction phase. The model reached the training accuracy of 71.42% and testing accuracy of 37.17%.

After the model’s training, randomly se-

---

**Figure 5:** Sample sentences from annotated corpus, A1 - Annotator1, A2 - Annotator2, A3 - Annotator3, FC - Fully Correct, CR - Correction Required, N/A - Not Applicable

**Figure 6:** Architecture of each timestep in Encoder and Decoder

**Figure 7:** Encoder - Decoder framework
lected hundred SECM sentences from the corpus are inputted to predict the translated Sinhala sentence. The predicted Sinhala sentences are saved to calculate the BLEU score. Figure 8 shows examples of some predicted Sinhala translations. BLEU score is the evaluation metrics \citep{Papineni:2002:ACL:1073083.1073089} used to evaluate the translated sentences. BLEU metric provides a score for the translation based on the predicted sentence and relevant reference sentence. For each sentence in the corpus, modified precision of unigram, bigram, trigram and four-gram are calculated. The weight of 0.25 has been given to each modified precision.

\[
BLEU = BP.\exp\left(\sum_{n=1}^{N} W_n \log p_n\right)
\]

Equation 1, is used to calculate the BLEU score. \(N\) is the number of n-grams and \(W_n\) is the weight for each modified precision, \(p_n\) is modified precision. BP is the brevity penalty to penalize short machine translations\citep{Papineni:2002:ACL:1073083.1073089}.

\[
BP = \begin{cases} 
1 & \text{if } c > r \\
\exp(1 - \frac{r}{c}) & \text{if } c \leq r
\end{cases}
\]

The value of \(BP\) is decided according to the values of \(c\) and \(r\). \(c\) is the number of unigrams in all the predicted sentences, and \(r\) is the best match length for each predicted sentence in the corpus. Our model received a cumulative BLEU4 score of 31.54. Comparing to previous models proposed for code-mixed text translation \citep{Dhar:2018:1809.00742,Masoud:2019:1905.03364} our proposed approach with Teacher Forcing mechanism gives a remarkable BLEU score for the translation.

\[
\begin{array}{|l|l|l|l|}
\hline
\text{Sinhala Sentence} & \text{Reference Sentence} & \text{Predicted Sentence} & \text{BLEU} \\
\hline
dawalta crowd eka wadi & ප්‍රියඩු කොම්ඩු කවුඹ දසිලක් & සම්බන්ධ කවුඹ කවුඹ දසිලක් & 8.64E-78 \\
gali gandak enawa restaurant & මැසි දැන් මැසි දැන් මැසිය විසිදුම් දසිලක් & දසිලක් දසිලක් දසිලක් දසිලක් & 9.85E-232 \\
godaak expensive food, & මැසිබුදු කොම්ඩු කවුඹ කවුඹ කවුඹ & කවුඹ කවුඹ කවුඹ & 1 \\
 godaak senaga wadi & කවුඹ කවුඹ කවුඹ කවුඹ & කවුඹ කවුඹ කවුඹ කවුඹ & 1 \\

\hline
\end{array}
\]

Figure 8: Example of predicted sentences and relevant BLEU score. Words highlighted in red are the words that are different from the reference sentence.

6 Conclusion & Future work

This paper presents a deep analysis of Sinhala-English code mixed texts. The difference between standard tagsets available for the romanization of Sinhala letters and the romanization used in SECM text are compared. The differences are discussed in this study. Challenges in the pattern of SECM sentences such as code-switching, spelling errors, improper usage of discourse marker etc., are also discussed in this paper. A parallel corpus is created containing SECM sentences and the relevant Sinhala sentences translated by a human translator who is a linguistic expert. The corpus is validated using annotators who are native Sinhala language speakers. The parallel corpus introduced in this paper can be considered a useful resource for researches based on SECM text. We combined Teacher Forcing Algorithm with the Sequence to Sequence approach with LSTM units to translate SECM sentences to Sinhala sentences. Teacher Forcing Algorithm updates the hidden state of each timestep in the decoder with the expected output from the previous time step, which leads on providing more accurate results for the translation. The BLEU score received for our model revealed that comparing the state of the art of other translation models for code-mixed texts, our model achieved significantly higher BLEU score. The future work we would like extend this research to focus on sentiment analysis and entity extraction using the parallel corpus created in this research study.

Abstract

India is known as the land of many tongues and dialects. Neural machine translation (NMT) is the current state-of-the-art approach for machine translation (MT) but performs better only with large datasets which Indian languages usually lack, making this approach infeasible. So, in this paper, we address the problem of data scarcity by efficiently training multilingual and multilingual multi domain NMT systems involving languages of the Indian subcontinent. We are proposing the technique for using the joint domain and language tags in a multilingual setup. We draw three major conclusions from our experiments: (i) Training a multilingual system via exploiting lexical similarity based on language family helps in achieving an overall average improvement of 3.25 BLEU points over bilingual baselines, (ii) Technique of incorporating domain information into the language tokens helps multilingual multi-domain system in getting a significant average improvement of 6 BLEU points over the baselines, (iii) Multistage fine-tuning further helps in getting an improvement of 1-1.5 BLEU points for the language pair of interest.

1 Introduction

Good translation systems are an important requirement due to substantial government, business and social communication among people speaking different languages. Neural machine translation (Vaswani et al., 2017) is the current state-of-the-art approach for machine translation in both academia and industry (Bahdanau et al., 2014). The success of NMT heavily relies on a huge amount of parallel sentences as training data. But using the traditional approaches (Vaswani et al., 2017), one would still need to train a separate model for each translation direction and also a lot of parallel human translated corpora which is again expensive to generate. But on the other hand, multilingual neural machine translation (Johnson et al., 2017) enables training a single model that supports translation from multiple source languages to a single target language or from a single source language to multiple target languages. In addition to this, another benefit of a training a single model for multiple translation directions is the ability to learn not just from the training data of the language pair of interest, but also from other language pairs. But this learning is hindered in case of language pairs that do not show any kind of relatedness among themselves. But on the other hand, Indian languages exhibit a lot of lexical and structural similarities on account of sharing a common ancestry. It is therefore important to utilize the lexical similarity (Kunchukuttan and Bhattacharyya, 2020) of these languages to build efficient systems by combining all the related languages.

Also, in a typical in-domain MT scenario, the amount of parallel texts from a single domain is not enough to train a good translation system, even for multilingual systems. Apart from this, one has to train an individual MNMT system for each domain. So we propose a technique for creating efficient multilingual multi-domain NMT systems which help in overcoming the above mentioned limitations. In this work, we treat different domains as distinct languages: for example, instead of Hindi-English translation we see it as translating Hindi-health to English-health. We utilized our multilingual NMT approach in a multi-domain setting and our results confirm that our multilingual multi-domain system significantly outperforms in-domain baselines as well as it also give improvement for out-of-domain translations. The paper is organized as follows: Section 2 talks about the related work. Methodology for our
experiments is explained in Section 3, followed by experimental details and results in Section 4 and Section 5 respectively. All the conclusions and the future work have been briefly discussed in Section 6.

2 Related Work

Due to simplicity, generality and effectiveness of Neural Machine Translation (NMT), it has become the most prominent approach to machine translation (Luong et al., 2015; Bahdanau et al., 2014; Johnson et al., 2017; Wu et al., 2018; Vaswani et al., 2017). Basic training procedure of NMT does not work well with only a handful of bilingual data (Koehn and Knowles, 2017), while collecting bilingual resources is arduous for Indian languages. A lot of experiments have been made to improve the quality of translation mainly including exploiting monolingual data range from back translation (Sennrich et al., 2015), dual learning (Xia et al., 2016) to Unsupervised MT (Artetxe et al., 2017; Lample et al., 2017). On the other hand, many tried to exploit parallel data of other high resource languages (Zoph et al., 2016; Firat et al., 2017; Johnson et al., 2017; Kocmi and Bojar, 2018) to either pre-train the network or jointly learn the representation.

Recently multilingual NMT has drawn more attention by several research groups. For instance, Firat et al. (2016) modify the current state-of-the-art attention NMT approach by introducing a many-to-many system, which still relied upon separate encoders and decoders for each language along with a shared attention mechanism. In contrast, Johnson et al. (2017) and Ha et al. (2016) both introduce a simple method for training a single-model multilingual NMT system, which does not require any modifications to the NMT encoder-decoder architecture of the system. The main difference is that Johnson et al. (2017) added target language identifying token in the beginning of each source sentence of the training data and Ha et al. (2016) added a language identifying token to each subword unit and apply this pre-processing to both source and target sentences of the training data. Both aims at exploiting many different languages rather than focusing on language relatedness and observes that only the many-to-one paradigm can achieve better translation results than the individually trained models. For the other two paradigms, there are various degrees of quality degradation. Also Vertan and von Hahn (2013) has put some efforts in tackling efficient NMT system in low-resource settings by considering language relatedness.

Apart from this, researchers have also explored the area of domain adaptation for NMT (Chu and Wang, 2018) and reported significant improvements. (Tars and Fishel, 2018; Kobus et al., 2016) explored multi-domain Neural machine translation for single language by adding the domain token to the input sentence. So, we put our efforts in exploring the system performance when multilingualism is combined with multi-domain systems for major Indian languages.

3 Methodology

India is a land of diverse languages. It has many languages on the basis of regional diversities, and mainly divided into Indo-Aryan and Dravidian families. A universal characteristic of Indian languages is their complex morphology. Indian languages depict unique characteristics following default sentence structure as subject object verb (SOV) and relatively free word order. These languages also share many common words which have the same root and meaning. However they use different scripts derived from the ancient Brahmi script (Kunchukuttan and Bhattacharyya, 2020), but correspondences can be established between equivalent characters across scripts. So, we exploited lexical similarity for efficient MNMT. Also, in order to incorporate multiple domains into our multilingual system, we also introduced the technique of representing the domain as a new language.

3.1 Exploiting Lexical Similarity

Unlike the original multilingual NMT (Johnson et al., 2017) which aims at exploiting many different languages rather than focusing on language similarity. Thus, to exploit the language relatedness we efficiently combined the two different approaches namely Unified Transliteration and Subword Segmentation to ensure that there is a sufficient overlap between the vocabularies of the related languages.

3.1.1 Unified Transliteration

Since the languages involved in the models have different orthographies and relatedness among each
other, also Indo-Aryan and Dravidian family languages don’t share many common characteristics, thus in the data processing one can map these two different language families into two different common orthographies. In order to achieve this, we transliterated all the Indian language into a common script based upon their family groups using the Indic NLP library (Kunchukuttan, 2020). Indo-Aryan languages were transliterated to Hindi (Devnagri script) while Dravidian languages were transliterated to Tamil (Abugida script) to share the same surface form within their family. This unified transliteration is a string homomorphism, replacing characters in all the languages to the desired script.

3.1.2 Subword Segmentation
Most of the Indian languages are derived from the common ancient Brahmi script and share many common words at the root level. To do so, we used Byte Pair Encoding (BPE) (Sennrich et al., 2015) to break words into subwords. Also, BPE merge rules not only find the common subwords between two related languages but it also ensures consistency of segmentation among each considered language pair. We are learning the BPE rules by combining all the languages on the source and the target side respectively, thus further applying these rules for segmenting the corpora. This finally results in increasing the vocabularies overlap among the languages that we made share the same surface form by transliterating into a common desired script.

3.2 Multilingual and Multi-Domain Systems
Multilingual model enables us to translate to and from multiple languages using a shared word piece vocabulary, which is significantly simpler than training a different model for each language pair. Johnson et al. (2017) introduced a “language flag” based approach that shares the attention mechanism and a single encoder-decoder network to enable multilingual models. A language flag or token is part of the input sequence to indicate which direction to translate to. The decoder learns to generate the target given this input. This approach has been shown to be simple, effective and forces the model to generalize across language boundaries during training. It is also observed that when language pairs with little available data and language pairs with abundant data are mixed into a single model, translation quality on the low resource language pair is significantly improved.

Multi-domain model is a single model that supports multiple domains in one model and also allows switching between the domains when translating. Similar to Johnson et al. (2017), Tars and Fishel (2018) explored Multi-Domain Neural Machine Translation for single language by adding the domain token to the input sentence instead of the language token.

3.3 Multilingual Multi-Domain Systems
A lot of research areas have been explored separately for multilingual as well as Multi domain systems. But no work has been done on combining both these approaches for the Indian languages. To the best of our knowledge, this is the first time efforts have been made in combining these two techniques for the NMT systems trained for Indian languages. So in this paper, we present our
technique of training a multilingual multi-domain system using the same traditional encoder-decoder architecture with shared attention mechanism. To do so, we introduced a **special token** technique which incorporates the knowledge of the language as well as the domain. The core idea is to treat ‘domains as distinct languages’ while training multilingual multi-domain systems. The pipeline for our technique can be seen in Figure 1.

For efficiently exploiting the language relatedness, we are first identifying and grouping the languages based on their lexical similarities with each other. In our case of Indian languages, all of the languages were first divided into 2 groups namely Indo Aryan and Dravidian. For each group, we appended our special token \((\text{2Lan-Domain})\) for one to many systems and \((\text{Domain})\) token for many to one systems. Then each group is being transliterated to a common script. For our purpose, Indo aryan languages were transliterated into Hindi while Dravidian languages were transliterated into Tamil. Then to increase vocabulary overlap amongst related languages at root word level, we are using BPE as discussed in Section 3.2. Further, we used this model learning for multistage fine tuning.

### 3.3.1 Multistage Fine Tuning

In the normal transfer learning Zoph et al. (2016) approach for NMT, the parent model is trained on a single high-resource language pair which may or may not be related to the child language pair of interest. To the best of our knowledge, previous transfer learning approaches for Indian languages do not exploit parallel data from multiple languages and domains. However, learning from multiple languages and domains can result in better knowledge transfer. Therefore, in this work, we propose a new transfer learning approach called as ‘**Multistage Transfer Learning**’ to enable the low-resource languages to efficiently learn from multiple related languages as well as domains which may or may not be high-resourced. In this approach, the parent model is our multilingual multi-domain NMT system and after pre training the parent model, the child model is initialized with parent model parameters and is then fine-tuned multiple times.

The proposed approach delivers better results than multilingual multi-domain NMT because adding more languages and domains into one model may result in better knowledge transfer but it can also result in ambiguities between different languages and domains at the inference time. Accordingly, a multilingual multi-domain NMT system fine-tuned can potentially remove all the inconsistencies at the inference time. For the scope of this paper, we have performed multistage fine tuning in three different scenarios: (i) single domain multiple language, (ii) multiple domain single language and (iii) single domain single language.

### 4 Experimental Settings

#### 4.1 Dataset

In our experiments, we are using the multi parallel corpus of two completely different domains namely PMI (Prime Minister of India) (Haddow and Kirefu, 2020) which contains the news domain aligned sentences and ILCI (Indian Language Corpora Initiative) (Jha, 2010) which is a combination of health as well as tourism domain sentences. ILCI corpus contains translation of the same sentence in every language pair but PMI contains roughly 60% of common sentences being translated to all language pairs, where Hindi being the high resource language.

#### 4.2 Data Preprocessing

We also noticed the ILCI corpus contains a lot of disalignments and empty translations, so we put our efforts in cleaning the entire corpus maintaining multi parallelism. We ended up in removing 3099 sentences from the corpus. Training data set statistics of both the data sets are mentioned in Table 1. All of our experiments were tested on 1870 sentences from ILCI and 2390 from the PMI corpus with validation data of 500 from both. We also made sure that there is no overlap between the

designed test and training set of PMI corpus. We used the Moses (Koehn et al., 2007) toolkit for tokenization and cleaning the English side of the data and we used the Indic NLP library (Kunchukuttan, 2020) for the normalization, tokenization and transliteration for the Indian languages. In all cases, we used BPE segmentation with 12k merge operations as described in Section 3.1.2

4.3 Training and Evaluation Details

For all of our experiments, we use the OpenNMT-py (Klein et al., 2017) toolkit. We used the Transformer model with 6 layers in both the encoder and decoder, each with 512 hidden units. The word embedding size is set to 512 with 8 heads. The training is done in batches of maximum 4096 tokens at a time with dropout set to 0.3. We use the Adam (Kingma and Ba, 2014) optimizer to optimize model parameters. We validate the model every 5,000 steps via BLEU (Papineni et al., 2002) and perplexity on the development set. We are training all of our NMT models with early stopping criteria based on validation set accuracy. During testing, we rejoin the translated BPE segments and convert the translated sentences back to their original language scripts. Finally, we evaluate the accuracy of our translation models using BLEU.

5 Results and Analysis

We report the results of bilingual baseline, multi-domain bilingual baseline, multilingual, multilingual multi-domain and multilingual multi-domain with special tokens for both the translation directions, XX-En and En-XX (where XX denotes Indian Languages). Later, we also compared the results of multistage fine tuning with the above experiments for one language from each family.

Table 2 and 3 shows our main results for English to Indian languages (En-XX) translation direction for PMI and ILCI corpus respectively. In both the cases, we observed that our multilingual model shows significant improvements over the baseline, increasing average BLEU score of 5 and 4 respectively. The reason behind this is that in the En-XX direction, language flags are used on the source side which then helps the decoder to identify the direction it translates to.

Table 4 and 5 shows our main results for Indian languages to English (XX-En) translation direction for PMI and ILCI corpus respectively. In the case of the ILCI dataset, we do not observe any significant improvements. The reason for this might be the multi parallel nature of the ILCI dataset where each English sentence on the target side appears multiple times in the model, thereby creating ambiguities in the model. But for the case of the PMI dataset, we observed an average improvement of 6 BLEU points, mainly due to large improvements in low resource languages. The reason for the increase in BLEU score for PMI is that the distribution of data is not uniform. Some of the languages in PMI corpus are low-resource as compared to others thus allowing other high resource languages to assist in the learning process for low resource languages thus removing the ambiguity. We also showed that the results of the multilingual multi-domain system with our special language domain outperforms the without token case for both the domains giving
an average improvement of \textbf{1.5 Bleu points} in the En-XX direction and \textbf{4 BLEU points} in XX-En direction over a normal multilingual system. We also experimented the Multistage Fine tuning for Punjabi and Tamil following the above three different scenarios mentioned above in Section 3.3.1 and observed an improvement within \textbf{1 - 1.5 BLEU points} over the multilingual multi-domain system.

6 Conclusions and Future Work

In this paper, we explored different effective methods to exploit parallel data from multiple related languages and domains to improve the translation between Indian languages and English. Our results show that the multilingual models accuracy depends upon the type of dataset in hand. As we observed in the case of PMI and ILCI, multilingual models trained on the PMI dataset increased our average BLEU score while the model trained on the ILCI dataset decreased the BLEU score due to increase in ambiguity. We then introduced multilingual multi-domain models and observed that this idea helps in removing the ambiguity we faced in the multilingual system using multi parallel data for training thus improving the translation quality by showing improvements in BLEU scores. In this work, we also introduced a new technique of adding a domain as a separate language by modifying the language token to language domain token. Our experiments also confirm that this new technique always outperforms all the models we discussed above. At last, we also explored the concept of Multistage Fine Tuning in which we transfer the learning of the parent model to the child in multiple stages. In future, we would like to work on effective techniques to exploit monolingual data and parallel data from other languages together to improve the translation quality. Also, we will try to generalize this idea of exploiting the related languages to other NLP related applications like sentiment analysis.

Abstract

This paper presents a translationese study based on the parallel data from the Russian National Corpus (RNC). We explored differences between literary texts originally authored in Russian and fiction translated into Russian from 11 languages. The texts are represented with frequency-based features that capture structural and lexical properties of language. Binary classification results indicate that literary translations can be distinguished from non-translations with an accuracy ranging from 82 to 92% depending on the source language and feature set. Multiclass classification confirms that translations from distant languages are more distinct from non-translations than translations from languages that are typologically close to Russian. It also demonstrates that translations from same-family source languages share translationese properties. Structural features return more consistent results than features relying on external resources and capturing lexical properties of texts in both translationese detection and source language identification tasks.

1 Introduction

This paper reports results of a translationese study based on literary texts translated from 11 source languages into Russian and included into the Russian National Corpus¹. Translationese is understood as specific linguistic properties of translations distinguishing them from non-translated language. Most existing investigations into the properties of translations have focused text types other than translation and, to the best of our knowledge, there were no large-scale investigations into translational Russian, especially based on literary texts. The research applications of the parallel multilingual corpus of translations into Russian are limited to contrastive studies such as (Dobrovolskij and Pöppel, 2017) and translation studies such as (Krasnopeyeva, 2016), and deal with a few individual items or constructions. We explore linguistic differences between fiction translated into Russian and originally-authored literature in Russian with a focus on the impact of the source language (SL).

The comparison between translated and non-translated Russian is based on an extended feature set capturing structural and abstract lexical parameters of texts, including collocational properties. This investigation mostly relies on the text classification approach and univariate statistical analyses following a methodology established in computational studies of translationese (Baroni and Bernardini, 2006; Volansky et al., 2015; Evert and Neumann, 2017, amongst others). Translationese indicators that cut across all translated subcorpora (if any) or are specific to a particular language pair are identified through feature selection.

It does not come as a surprise that researchers are wary of using fiction for translationese studies. Fiction can be less homogeneous register because each literary work and author might display unique conceptual and linguistic properties reflecting a particular manner of artistic expression and idiolect. With literary translation established as a form of creative endeavour of its own standing and with the covert ‘domesticating’ translation paradigm accepted as a professional standard, little difference between translations and non-translations is to be expected in this register. This study is based on a carefully balanced and representative sample of literary texts from each language pair designed to reduce possible impact of author/translator idiolects on the results.

We aim to establish if and how Russian non-translated literary texts differ from literary translations from a variety of SLs (our first research question, RQ1).

Following a recent trend in translationese stud-
ies (Dutta Chowdhury et al., 2020; Bjerva et al., 2019; Rabinovich et al., 2017), we are interested in exploring the link between the amount of translationese and the SL involved. Translations from more distant languages were shown to return better classification results indicating greater differences from non-translations. Can we corroborate this finding on our data and features (our second research question, RQ2)?

Our results are relevant to typological and contrastive studies that use parallel data to draw conclusions about the properties of target language (TL) because we are highlighting that translations constitute a TL variety, significantly diverging from comparable non-translations. This study also contributes to a direction in translationese studies that seeks to establish links between SL-TL cross-linguistic distance and the amount of observed translationese as well as to the task of document-level SL detection.

2 Related Work

Translations vs non-translations Our work is related to studies showing that translated texts share linguistic features that make them distinct from non-translations (Gellerstam, 1986; Baker, 1993). These features have been useful in automatic classification of translated and non-translated texts (Baroni and Bernardini, 2006; Volantsky et al., 2015; Rubino et al., 2016; Kunilovskaya and Lapshinova-Koltunski, 2020). Some studies show that combinations of features perform better in machine learning settings for translationese-related tasks (Lynch and Vogel, 2012; Evert and Neumann, 2017; Sominsky and Wintner, 2019). This paper compares the effectiveness of two feature sets: morphosyntactic and lexical indicators. The former are count-based features extracted directly from automatically annotated research data. The latter are estimated using language models trained on a large, register-comparable TL corpus. They capture dissimilarity of translations with regard to the TL norm manifested in this additional TL resource.

Translationese in literary texts There are several corpus-based studies of literary translations. Most of them explore single features: passive constructions (Kolehmainen and Rionheimo, 2016) that-complementiser (Olohan, 2001), non-finite constructions, phrasal verbs, connectives (Kunilovskaya, 2017), keywords (Puurtinen, 2003), etc.

The only two works known to us that use machine learning to study translationese in literary texts include (Popescu, 2011) and (Lynch and Vogel, 2012). The first study explored the effectiveness of character 5-grams comparing originally-written English literature with translations from French and German. The second study is more similar to the design proposed in this study. It reports the results of SL detection based on English literary translations from Russian, German and French. A Support Vector Machine (SVM) 4-class classifier achieves the accuracy of 80% in the train-test scenario using a combined set of 50 features. The authors attempt the analysis of some of the top-ranking features, trying to link them to the SLs. In our work, we also employ multiclass classification to identify best translationese predictors. However, we rely on very different features and experiment on a twice bigger data from a wider range of SLs.

Tracing source languages Source language detection is based on the assumption that translations tend to retain features of the SLs (shining through effect, Teich, 2003). Rabinovich et al. (2017) showed that translations carried enough signal from SLs to restore the phylogenetic language tree. The authors experimented on English translations of the European parliamentary speeches in 17 SLs representing three language families. They noticed that misclassified instances were frequently assigned to genetically related languages. Translations from SLs with isomorphic structures displayed a tendency to share more translationese features. Another study by Bjerva et al. (2019) used three levels of syntactic abstraction to explore genetic, geographical and structural distances between SLs. In their results, structural similarities were a better predictor of similarities between languages than genetic ones. Dutta Chowdhury et al. (2020) used isomorphism between embedding spaces, hypothesising that the more isomorphism was detected between translations into English and non-translated English, the closer the source and target languages. They learned delexicalised multi-view representations – embeddings based on parts-of-speech (PoS) tags, lexical semantic tags, and conceptual-semantic tags from WordNet. However, these studies are based on EuroParl, a corpus of parliamentary speeches, which might be more homogeneous in style, more conventionalised as a text type and in terms of translation strategies than literary texts focused in this paper.
The relation between predictability of translated texts and the divergence between the TL and the SL in terms of morpho-syntax was analysed in a recent study by Nikolaev et al. (2020). The authors used Parallel Universal Dependencies to analyse 1000 sentences from the news domain and Wikipedia translated from English into eight languages. The results showed that translations from similar and distant languages were both predictable, but in different ways: structurally-similar SLs favoured the use of a narrower range of syntactic patterns limited to those shared by two languages, which constituted one type of translational specificity. In translations from highly-divergent languages, however, translators tended to produce non-idiomatic renditions, that were not recognised by models trained on the TL. Sominsky and Wintner (2019) also used the SL signal to detect translation direction. They found that the more distant were the source and the target languages, the higher the SL-detection results.

3 Methodology

3.1 Research Corpus

Our data comes from the parallel component of the RNC. It is a bidirectional corpus, which contains translations from and into Russian for 19 language pairs. Fiction is by far the most represented register, however Russian translations of newspaper texts from some SLs are also included. At the time of writing, parallel RNC includes Russian translations of fiction from 19 SLs, with the overall size of this translational material estimated at 36.6 million tokens. This corpus was sampled to include all language pairs with Russian as the TL that have at least five documents of lengths over 20k tokens produced by a unique combination of author and translator. The document size limit is intended to exclude short stories and retain only novellas and novels. In the absence of a genre annotation, this restriction maintains some comparability of our documents with regard to the type of literary work. The author/translator condition minimises the impact of individual writing style on our results. Another data selection constraint ensures that translations were produced within a time span of 100 years (1925–2020). We excluded document pairs where the author’s mother tongue was not the respective SL (e.g. Nabokov) and where the translations were done by the author (e.g. Vasil Bykov). This sampling frame leaves us with a corpus of 210 document pairs in 11 parallel subcorpora. At pre-processing stage, we discarded all sentence pairs with empty source or target as well as by-lines and headings.

To build a comparable collection of non-translated Russian fiction, we used the same sampling frame on the monolingual part of the RNC. We retained only the largest work by every author, deleted the works in Russian by bilingual authors (e.g. Nabokov) and novels explicitly marked as translations. These selection criteria yielded a corpus counting 439 documents (longer than 20K tokens), 33.8 M tokens (3.2M sentences) in total. Details on the distribution of document lengths in the samples for each SL and Russian reference sample are presented in Figure 1. This material was used for chunking (see below).

The SLs in the resulting collection are distributed among four language families in our collection: Romance (French, Spanish), Germanic (Swedish, English, German), Balto-Slavic (Baltic: Latvian, Slavic: Polish, Belarusian, Ukrainian, Bulgarian), Uralic (Finnish) based on linguistically motivated phylogenetic language tree (see Serva and Petroni, 2008). In total, we have 859 documents in our data, including parallel and monolingual components. To balance the data in terms of document size, we randomly selected 10 book with unique author-translator combinations. For Bulgarian, Spanish, French, Finnish and Latvian we had to do with fewer books to meet this restriction. After that, each literary work was chunked into portions of 100 consecutive sentences and 10 random chunks were extracted. This collection of text chunks was used in the experiments below.

3.2 Features for classification

The key component of this methodology is the features. We classify them into structural and abstract lexical features.

Structural features. The first subset includes 45 features extracted from Universal Dependencies (UD) annotations of the data (UD features). The values for UD features are normalised frequencies of various UD tags and their combinations, reflecting the morphological and syntactic structure of language. They are selected to capture the differences in the linguistic make-up of translations demonstrated in translationese studies for other language pairs and anticipated in out-of-English Russian translations in the practical translation text-
books based on the typological differences of English and Russian. It has been shown that translations usually have lower type-to-token ratio, higher sentence length and greater number of connectives in a number of language pairs. It is also expected that Russian translations from English would have higher frequencies of modal predicates, analytical passive forms, inflated frequencies of several types of pronouns due to typological differences. The values for most features are cumulative frequencies of all lemmas that belong to a word class or all forms that received a specific tag. We summarise the types of structural features in Table 2 in Appendix2.

The normalisation basis varies depending on the type of item, following the motivation in Evert and Neumann (2017): it is total text tokens for word classes; number of sentences for conjunctions, modal predicates; total verbs for verb forms; total number of dependencies for the select types of dependencies, etc. The values for discourse markers features are normalised cumulative frequencies of four semantic types of connectives and of epistemic markers (e.g. of course, probably, actually), extracted based on pre-defined lists of lemmas (183 items in total for connectives and 86 items for epistemic markers). The lists are informed by Russian grammars and special linguistic dictionaries. Though most items on the lists are set phrases, we allowed for possible lexical and structural variability during extraction. We also used positional heuristics and punctuation to disambiguate our items. The output of the extraction procedure was manually checked to exclude greedy matching.

Abstract lexical features. The second subset, counting 23 features, requires language models learnt from a separate (bigger) corpus resource of original Russian literature (LM features). We used the corpus described in Section 3.1, excluding the 10 random books used to get 100 chunks of non-translated Russian subcorpus. We used a 3-gram language model learnt on this corpus with KenLM library (Heafield, 2011) to generate average sentence perplexities and their standard deviation for each text chunk in our data. We hypothesise that this model will return higher perplexities depending on how unusual the sequences of lexical items are in the translated language. N-grams frequency lists (of orders 1, 2 and 3) from the same corpus were used to calculate the ratios of lemmas that belonged to the highest- and lowest-frequency quartiles of this list for each order of the n-grams cumulatively. Ratios of out-of-vocabulary (OOV) items was used as separate features for each n-gram order. These features were supposed to capture the overuse of the TL high-frequency items and, possibly, a higher ratio of OOV items. These features were inspired by feature-based quality estimation approaches used for machine translation (Specia et al., 2015). We

2The extraction code is available from https://github.com/kunilovskaya/translationese45

Figure 1: Distributions of document sizes, number of observations and unique translators by SL in the filtered research corpus.
also experimented with 10 collocational features that are assumed to capture various aspects of co-occurrence patterns in the data. To define these features we relied on the concept of coligrams, defined by Bestgen and Granger (2014) as n-grams with an association score above an arbitrary threshold. For association measures we used normalised pointwise mutual information (NPMI) and t-score to detect coligrams composed of less-frequent and more-frequent words respectively. For each association measure we trained a bigram model on the large reference corpus described above with the Phrases module from the Gensim library (Řehůřek and Sojka, 2010). Then, the model was applied to the chunks of text in the test corpus. In this approach the coligrams were detected and the average association scores across all coligrams in each chunk were produced based on the frequency statistics in the reference corpus. T-score measure was calculated using the formula from Gries (2010). For NPMI we relied on the Gensim inbuilt scorer (Bouma, 2009). In both measures 0 means independence of bigram components; NPMI lies in the [-1:: 1] range, while t-score bounds were experimentally established within [-11:: 9] scope. To train the models, we set the association score threshold to the lower bound of each metric. The bigram frequency threshold was set to 1 to score all bigrams in the 33-million reference corpus. While learning the phraser model, we allowed for intervening words from the functional word classes to access items like альфаА:анга (alpha::and::omega), пакт::о::ненападение (non::aggression::pact). In calculating feature values we relied on bigram/collgram types, not tokens. To sum up, the collocational features for each association measure extracted from each chunk in the research corpus include: (1) ratio of highly-associated coligrams to all bigrams (the cut-off for high association was set to recommended NPMI > 0.5 and t-score > 6); (2) ratio of negatively-associated coligrams to all bigrams; (3) ratio of all detected coligrams with the score > 0 to the total word count; (4) ratio of bigrams absent in the model to all bigrams in the test corpora; (5) average association score for all detected coligrams with the association score > 0; (6) standard deviation for the association scores in each text chunk.

We expect that translations would have a higher ratio of t-score-based highly-associated bigrams, and lower ratio of NPMI-based highly-associated bigrams than in the comparable subcorpus of non-translations. This hypothesis is based on the known properties of translation to prefer high-frequency items and on the known properties of the association measures: MI is known to favour sequences of low-frequency items, while t-score assigns higher scores to high-frequency items (Gries, 2010). The ratio of negatively associated bigrams and the ratio of bigrams not seen in the reference is aimed to capture less usual sequences which can be a sign of shining though or errors, including acceptability in the register (e.g. тяжела критика, крепкая основа).

Finally, we calculate the average association score for each text chunk to reflect general ‘collocatedness’ of translations and non-translations and standard deviation across all chunks in each source-language subcorpus. All lexical features were produced on lemmatised corpora, where proper names and their sequences were replaced with PROPN and all numbers were represented as XXX (e.g. Борис Николаевич Юрьев -> PROP, 1984 -> XXXXX). We also deleted all punctuation, except end-of-sentence marks.

The features were extracted into a table containing 1060 rows representing all text chunks in our experiments, labelled with SL, including ‘ru’ for chunks selected from the reference corpus and 68 features, including 45 UD-based (inc. list-based features), 11 ngram-based and 12 collgram-based ones. The features in the last two groups were extracted with reference to several LMs learnt from a reference corpus of non-translated fiction. The input feature values were z-transformed with the scikit-learn Standard Scaler.

### 4 Results and Discussion

To find out whether our features capture any differences between translations and non-translations in SL subcorpora and whether the scale of these differences is traceable to the typological group of the SL, we ran 11 binary classifications and a multiclass classification. In all experiments we used Support Vector Machine (SVM) algorithm with the default scikit-learn settings (C=1.0, kernel=‘rbf’, degree=3, gamma=‘scale’). For the five subcorpora where we have fewer observations than in the reference sample, we used class_weight=‘balanced’ option.

Table 1 presents the accuracy (acc) and macro F1-score (F1) results of the binary classifications.
for each translational subcorpus (represented by SL) against non-translations. The SLs are presented in two groups: Typologically distant and close languages (in relation to Russian). We also group the scores according to the feature sets and combinations: all 68 features, 45 UD features (structural features), 11 n-gram and 12 collogram (both abstract lexical features). The last two columns show the results expected by chance. This simple baseline was implemented as a random classifier which predicts classes with respect to the distribution of instances across classes. We report the scores for the 10-fold cross-validation scenario.

**RQ1** Overall, we are able to detect differences between translated and non-translated fiction in Russian. Combined features and each feature set individually performed better than the chance-level baseline, except collocational features for translated Spanish, which were on par with the dummy classifier. Remarkably, structural features (45 UD in Table 1) performed better than lexical features (11 n-gram and 12 collogram in Table 1). One explanation could be the size of the corpus underlying the language models, which does not provide enough evidence for the frequency of items in non-translated Russian. Note that our lexical features do not directly rely on the frequencies of individual items. Instead, they estimate the ratios of high- and low-frequency items in translated and non-translated subcorpora of text chunks. Combining two lexical feature sets brings the performance of the classifiers to the area of 70-81% accuracy, with the exception of translations from French (66%). It seems that n-grams and collograms complement each other in capturing lexical distinctions from the reference corpus. It is not surprising, given that frequencies of OOV n-grams and collograms are commonly picked among the top five predictors in each feature set by most of the classifiers. The combined features accumulate the effects of the individual feature sets and are harder to interpret. They can be used to generally demonstrate the extent to which translations are distinguishable from non-translations. In our experiment, the accuracies of translations from any SL on all features were in the range from 82% to 91%.

To explore the impact of the individual features on the classification outcome, we employed Recursive Feature Elimination (RFE) algorithm based on Support Vector Regressor (SVR), which selected a unique combination of N features. RFE selects features that return the best classification results. There were only two features shared in RFE-based selections by all classifiers, if N=30: the ratio of high frequency trigrams and the frequency of modal predicates (defined as the cumulative frequency of lemma мочь, lemma следовать with a dependent infinitive, three modal adverbs (можно, нельзя, надо) and 11 adjectives in the short form (e.g. должен, способный, возможный)). However, the frequency analysis for these features shows no significant differences in their values in many test subcorpora. Even if the difference was significant at p < 0.05,
the effect size did not exceed Cohen’s d of 0.2.

RQ2 Interestingly, the results from the binary classifications for lexical features, unlike UD features, are more volatile with regard to the assumption that translations from more distant languages are more predictable. On structural features, this statement holds with the bold exceptions of Finnish and Bulgarian which returned too low or too high classification results for 84-91% and 79-83% brackets for distant and close languages, respectively. However, on either of the lexical feature sets, there is hardly any consistency to be seen.

In feature selection, there were no features that cut across all language pairs among top N=10 and N=20 UD features. However, typologically similar languages shared up to five features. For example, the selections for English, German and Swedish included ‘ccomp’, ‘mquantif’, ‘xcomp’, ‘nnargs’, ‘ppron’. We interpret this finding as evidence of the SL traces in translations, leaving a more in-depth analysis of these features for future work.

To find out whether the SL signal in each language pair is strong enough to make the respective translations stand out of the bulk of other translations and non-translations, we applied a multiclass classification on the entire feature set. In this experiment, each of the 12 subcorpora (Russian reference and 11 source-language subcorpora) was classified against the rest of the subcorpora. We achieved the overall accuracy of 53% (F-measure of 0.53), which was well above the random baseline of 6%. The darker areas in the confusion matrix (Figure 2 in Appendix) shows that translations from same-family SLs were confused more often between themselves than with translations from distant languages. For instance, Belarusian is often confused with Ukrainian, but never with English and Spanish. In a similar manner, Russian non-translations were more likely to be misclassified as translations from Ukrainian, Belarusian or Latvian than from English or Swedish.

The results for individual languages also confirm the hypothesis that SL footprints specific for each language group are discernible in translations. Particularly, distant SLs generate translations that are more distinguishable as such than translations from closer languages. Better results (darker blue squares in Figure 2) are achieved for more distant languages, e.g. French, English and Swedish (F-measure of 0.62, 0.58 and 0.58, respectively). At the same time, the results are worse for typologically closer languages, such as Bulgarian and Latvian (both with an F-measure of 0.46). Against our expectations, the scores for the closest languages, such as Ukrainian and Belarusian, are not the lowest (0.50 and 0.54, respectively). This may be explained by fewer instances that we have for the lowest-scoring Bulgarian and Latvian.

5 Conclusion

We analysed translationese in literary texts, exploring differences between fiction originally authored in Russian and fiction translated into Russian from 11 languages. We found out that overall, we can automatically predict translations in this register with the accuracy well above the chance level. Besides, we compared performance of classifiers for translations from various SLs. We expected that translations from more distant SLs would return higher results in a series of binary classifications and would be easier to recognise in a multiclass setting than translations from typologically closer languages. This was confirmed for the subset of structural features, but not for lexical features, which returned mixed results. Possible explanations for the opposite tendencies observed in the data when using lexical features could be deficiency of the reference model and variation in literature style or literary translation tradition.

At the same time, we also understand the limitations of our data selection and research design. For example, experiments demonstrate that average sentence length might have been a better indicator of genre comparability than the length of a literary piece. The reference model for collocational features should probably be trained on a larger corpus to ensure greater coverage of lexical items. We leave detailed statistical analysis of the best-performing features for each language group and case studies based on parallel concordances for future work.

Abstract

Code-Mixing (CM) is a common phenomenon in multilingual societies. CM plays a significant role in technology and medical fields where terminologies in the native language are not available or known. Language Identification (LID) of the CM data will help solve NLP tasks such as Spell Checking, Named Entity Recognition, Parts-Of-Speech tagging, and Semantic Parsing. In the current era of machine learning, a common problem to the above-mentioned tasks is the availability of Learning data to train models. In this paper, we introduce two Telugu-English CM manually annotated datasets (Twitter dataset and Blog dataset). The Twitter dataset contains more romanization variability and misspelled words than the blog dataset. We compare across various classification models and perform extensive bench-marking using both Classical and Deep Learning Models for LID compared to existing models. We propose two architectures for language classification (Telugu and English) in CM data: (1) Word Level Classification (2) Sentence Level word-by-word Classification and compare these approaches presenting two strong baselines for LID on these datasets.

1 Introduction

Language is one of the significant aspects which makes humans different from other species. It is not a fixed entity, and it has evolved with time and will continue to do so. As a part of such an evolutionary process, we are at the stage of Code-Mixing where people communicate by mixing linguistic units such as phrases, words, and morphemes of one language embedded within an utterance of another language (Sankoff and Poplack, 1981), (Poplack, 1980).

India has 22 officially recognized languages and many dialects. For a land with such linguistic diversity, bilingualism and multilingualism is a prevalent trait. Telugu belongs to the family of Dravidian languages. It is primarily spoken in Southern India and is also the third most spoken language in India. Telugu is the mother language of a large population native of Andhra Pradesh and Telangana states. English is a primary mode of teaching for most of the population across the globe. With such an influence of a language, people tend to use a mix of both English and their native language in an informal conversation (both speech and text).

CM is classified into two types: Intra-Sentential and Inter-Sentential Code-Mixing (Zirker, 2007). Intra-Sentential Code Mixing refers to the use of multiple languages in a single sentence. Inter-Sentential Code-Mixing is when the language switching is done at the end of the sentence. In this paper, we will focus on Intra-Sentential Code Mixing.

In a multilingual setting, most of the conversations that happen informally are CM. CM is also used extensively in Social Media platforms, blogs, and forums as posts, chats, and comments. The processing of CM text poses an exciting and challenging problem to the linguistic community. This is because of the added complexities in the traditional processing tasks such as Spell Checking, Named Entity Recognition (NER), Parts-Of-Speech (POS), Natural Language Generation (NLG) and Machine Translation (MT) due to the unavailability of prior information about the language at any point of time. Intra-Sentential LID is the task of identifying the languages

1 Eighth Schedule to the Constitution of India
of each word. Researchers have made significant progress in the LID module in the automated processing of CM text. However, in low-resourced agglutinative languages like Telugu, LID is still a challenging task (Parupalli et al., 2018).

In this paper, we introduce two datasets and propose various pipelines to tackle Intra-Sentential language identification problem in CM data using deep learning models. This example sentence illustrates the CM addressed in this paper:

**Example:** Elen/NE everyday/EN school/EN ki/TE buslo/TE velthundi/TE ./UNIV (Translation: Elen goes to school by bus everyday)

The words followed by /NE, /TE, /EN, and /UNIV correspond to Named Entity, Telugu, English, and Universal tags. In the above example, some words exhibit morpheme level Code-Mixing, like in “buslo” : “bus” (English word) + “lo” (plural morpheme in Telugu). We also consider the clitiques like “supere”: “super” (English root word) + “e” (clitique) as code mixed.

The **key contributions** of this paper are the following:

- We open-sourced\(^2\) two datasets of low-resourced CM English-Telugu data from popular global social media sites like Twitter and local blogging sites like Chaibisket.com, and Wirally.com.
- We propose extensive benchmarking with both Classical and Deep Learning Models for LID in CM data and infer that BiLSTM + CRF, BiLSTM + LSTM have higher classification metrics (overall and per-class) as compared with other models.
- We analyze the impact of contextual information of the word in a sentence for this task.

The rest of this paper is organised into 6 sections. In section 2, we discuss the related work. Section 3 elaborates on challenges while working with CM data, followed by the dataset and its annotation in section 4. Section 5 describes the approaches for LID in CM data. Section 6 reports the results of the proposed approaches. Finally, in section 7, we discuss the conclusions and future work.

## 2 Related Work

A significant amount of work has been done recently in the field of code-mixed data, especially in the area of LID. Kachru (1978) discussed the syntax and structure of multilingual language organization and the role of language dependence in linguistic convergence of CM from an Indian perspective.

To create a word-level language identifier, King and Abney (2013) used weakly semi-supervised methods. According to Noor Al-Qaysi (2017), code-switching is very popular on social networking sites such as Facebook, Twitter, and WhatsApp and 86.40 percent of students use code-switching on social networks, while 81 percent of educators do so.

Yogarshi Vyas and Choudhury (2014) used logistic regression and a module that calculates code-switching probability. Das and Gamb (2014) merged two classifiers into an ensemble model for Hindi-English CM LID using multiple features such as word sense, dictionary, n-gram, and edit distance. The first classifier takes changed edit distance, word frequency, and character n-grams as features. The first classifier’s output and the POS tag of the neighboring words are given as features to the second classifier to predict the final label.

Sharma (2007) used the shallow parsing pipeline to perform successful text analysis in Hindi-English CM social media data. For the task of LID, most of the experiments depend on dictionaries, supervised classification models, and Markov models.

The basic distinguishing features such as specific character combinations, repeated or unique words, diacritics, or typical n-grams are used in the simplest LID methods (Dunning, 1994; Clive Souter and Johnson, 1994; Ciprian-Octavian Truic˘a and AlexandruBoicea, 2015).

Some LID methods model sequences of words, characters, or bytes as model complexity increases. Some approaches concentrate on modeling the frequency of n-grams, such as character n-gram frequency (Bashir El-haj Ahmed and C.Tappert, 2004; Clive Souter and Johnson, 1994). These methods outper-
form techniques that rely on one-of-a-kind terms.

In (Gundapu and Mamidi, 2018), efforts have been made to propose an accurate model to address the problem of classification in CM data. However, the recent advancement in deep learning models have led to better performance in various NLP tasks. We thus leverage these deep models for classification involving low resource language (Telugu) in CM data with the help of larger corpus which have been sourced from Twitter and other popular blogs.

3 Challenges Observed in CM Data

1. **Gathering Data:** Data collection is the primary and the most crucial step while dealing with the problem with any neural-network-based approaches (Roh et al., 2021). There is a huge challenge for collecting CM data due to fewer resources and its informal nature of use in limited places. Datasets for low-resource languages like Telugu are challenging to find, making it difficult to build supervised models.

2. **Misspelled Words:** Since most of the data for CM comes from informal resources like social media posts, casual blogs, some of them are misspelled (refer Table 1). This is a significant challenge while building spell agnostic models.

3. **Romanization Variability:** One other defiance/challenge in CM data apart from spell checking is the variability in romanization output. For example, the Telugu word ‘enduku’ (Meaning: why) can either be written as ‘endhuku’ or ‘nduku’ (For more examples, refer Table 1).

4. **Feature Extraction:** Due to misspelled words and romanization variability, popular feature extraction methods like Word2Vec cannot be used due to high variations of the same word. We, therefore, used low-level features (explained in 5.1), which we found to be working well for this task.

5. **Morpheme-level CM:** As explained in section 1 example, Handling morpheme-level CM adds more complexity to the problem as the word is a combination of two words from two different languages.

In the next section, we explain the procedure used to create LID dataset for CM English-Telugu data.

4 Dataset

We created two different types of code-mixed datasets sourced from Twitter3 and popular blogs4 using Code-mixed language.

As shown in table 1, the Twitter dataset has significant variability in style, whereas the second dataset consists of sentences from articles written by professionals, hence have minimal variability. Table 1 shows the variability in styles of writing the same word in different ways across both the datasets.

For the Twitter dataset, we manually identified 40 user accounts who tweet with CM; these user accounts often tweet on different aspects such as Movies, Politics, and Sports. We used the Twitter API to get 1000 tweets of each user. For the blog dataset, we scrapped chaibisket.com and wirally.com websites which provide high-quality code-mixed content. We manually picked 350 articles containing code-mixed data for this dataset. The pre-processing of the data involved the following steps:

1. Converting tweets into sentences
2. Removing sentences containing Dravidian characters
3. Removing sentences that contain only English words and only Telugu words
4. Removing sentences with less than five words
5. Removing URLs and other similar tokens
6. Tokenizing emojis and hashtags

After preprocessing the data, it is then manually annotated into four classes, i.e., Telugu (TE), English (EN), Named Entities (NE), and Universal (Univ). Named Entities include names of people, organizations, and locations. Universal includes punctuation marks, acronyms, emojis, hashtags, and numbers.

4.1 Inter Annotator Agreement

Three people proficient in Telugu dialects and English language and having a linguistic background have annotated the dataset. We calculated Inter Annotator Agreement score using Cohen’s kappa score (Cohen, 1960) in order to assess the quality of both datasets. Table 3 reports the Inter Annotator Agreement scores.

5 Methodology

In this work, we consider LID in CM data as a classification problem where we label each word to its corresponding language class. With the advent of deep learning, many popular tasks like Named-entity recognition, Parts-of-speech identification have shown promising results (Singh et al., 2018), (Meftah and Semmar, 2018). In section 5.2 we explain an extensive set of deep learning models for LID in CM data. We show the quantitative results of LID in section 6. We provide the following architectures based on the type of input the model is supplied with to solve this problem:

1. Word Level Classification (WLC)(fig. 1): Given a word, we classify it into one of the four classes. This approach does not take advantage of the contextual information of the given word in the sentence. The example given below illustrates the input and output from this approach.
   **Input:** bagundi (Translation: good)
   **Output:** TE

2. Sentence Level word-by-word Classification (SLC)(fig. 2): Given a sentence, we predict each word’s label in the sentence. This approach utilizes the contextual information of the word in the sentence and predicts the output of each word. Below example illustrates the input and output from this approach.
   **Input:** Sai class ki velli book theesadu . (Translation: Sai went to class and opened a book)
   **Output:** Sai/NE class/EN ki/TE velli/TE book/EN theesadu/TE ./UNIV

In the following subsections, we explain our approach as a two-fold process: (1) Feature representation (2) Model Training.

5.1 Feature Representation

Feature representation plays a crucial role in the training of a deep learning model and increasing its efficacy. The following subsection introduces two types of feature representa-
Character Level Encoding (CLE)
In this approach, each character of the word is made into a one-hot encoding vector.

\[
FCLE : [c1 \times m, c2 \times m, ..., cn \times m] \times m
\]

Where \( c1, c2, ..., cn \) are one-hot encodings of the characters of a word of length \( n \).

Word Level Encoding (WLE)
In this approach, each word in a sentence is encoded as a vector having the following features:

- **Character N-Grams**: Character N-Grams of the word.
- **TF-IDF**: Term-Frequency and Inverse-Document Frequency of the N-Grams feature vector.
- **Hand-picked features**: The below high level features are chosen to capture semantics of various types of words such as Acronyms, numbers and punctuation.
  - Count of special characters
  - All capital letters
  - Starts with capital letter
  - Number of digits
  - Length of the word

Deep Learning Models
Deep learning models have been successful in understanding the semantic representations and learning complex tasks in Natural Language Processing (NLP). This section puts forward the various deep learning models we have implemented to solve LID in English-Telugu CM data. To provide an extensive benchmark, we also compare the above models to classical models such as Naive Bayes, SVM, Logistic Regression, and CRF in Table 6.

We divide our deep learning models into two categories. The first set of models namely: LSTM, CNN, RNN, MLP Network are used in our first architecture - WLC (fig 1) and the second set of models namely: BiLSTM + CRF, BiLSTM + LSTM are used in our second architecture - SLC (fig 2).

Word Level Classification (WLC)
In this method, we take each word and extract the features with CLE. The sequence of vectors from CLE is given to a Word Level Classifier, which then classifies the given word into four classes, viz. EN, TE, NE and UNIV. The following models use the pipeline illustrated in fig 1.

- **CNN**: CNNs are mostly used for Images,
but we have seen that CNNs perform on text as well in few applications. For the features, One-Hot encodings of each word are concatenated to get a 2-Dimensional grid, on which the CNNs are applied. We used two Convolutional Layers, one with 32 filters and the other 16 filters.

- **RNN, LSTM**: The major problems faced by CNNs are handling sequential data, considering only current input, and lack of memorization of previous inputs. All these shortcomings are better handled by RNNs. A Recurrent Neural Network works on the principle of saving the output of a particular layer and feeding this back to the input in order to predict the output of the layer. Long Short-Term Memory (LSTMs), on the other hand, is a type of RNNs which prevent the vanishing gradient problem often found in RNNs.

The above-explained models (CNNs, RNNs, LSTMs) utilize positional information of characters either through a kernel convolution (CNN) or through hidden layer propagation (RNNs, LSTM). Thus, we also tried with an MLP model which lacks the above positional knowledge using the feature representation technique explained in 5.1.2.

**MLP**: A Multi Layer Perceptron (MLP) is a supervised feed forward neural network, which consists of an input, an output layer and few hidden layers. Each layer consists of a set of neurons that receives input from the previous layer and sends output to neurons in the next layer based on activation function. We added three layers of Dense Networks with 256, 64, and 32 neurons for each layer, respectively. Figure 3 shows the pipeline for LID using MLP.

### 5.2.2 Sentence Level Word-by-word Classification (SLC)

In this method, we input an entire sentence and extract features with WLE and classify the output of each word with deep learning models, namely BiLSTM + CRF and BiLSTM + LSTM.

- **BiLSTM + CRF**: Bi-directional LSTM was proposed by (Schuster and Paliwal, 1997), is a variant of LSTM which allows data to flow forward as well as backward in time. BiLSTM + CRF improves the performance by giving more context of previous and next occurring data to the model. BiLSTM + CRF have been known to work well in sequence labeling tasks (Poostchi et al., 2018), and hence we have used this model to carry out experimentation on our proposed datasets. Figure 4 illustrates the pipeline for this model.

- **BiLSTM + LSTM**: Each word in a sentence is passed to WLE for feature extraction and then passed to the BiLSTM layer. We then use the hidden outputs of the BiLSTM layer as inputs to the LSTM layer to make the final prediction. Figure 5 illustrates the pipeline for this model.

### 6 Results

We have put forward an extensive set of deep learning models to tackle LID in English-

Figure 5: BiLSTM + LSTM model.

Telugu CM data in our present work. To validate these models, we show quantitative results on both the proposed datasets, namely Twitter and Blogs datasets (explained in section 4). We also compare with the existing classical Machine Learning models (refer Table 6). We show Precision and Recall metrics for each class in table 4, 5. It is observed that RNN had faced the problem of vanishing gradients, thus precision and recall of RNN for NE is zero. The BiLSTMs property of propagating contextual information in both directions helps it to have the edge over WLC models like MLP, CNN, and RNN models. From table 4, 5 we see that the BiLSTM + LSTM, BiLSTM + CRF models outperform the other

Deep learning models in this task and achieves an improvement in accuracy over the classical models (Baseline: CRF) of around 2.38%, 2.09% on the Blog and Twitter data-set respectively. It can also be noted that, though our primary task is to identify Telugu and English words in CM Data, from (from 4, 5) we observe that the precision and recall of the Named Entity class is on the higher side in

SLC (BiLSTM) as compared to WLC models (MLP, CNN, LSTM, RNN). We also see that the accuracy of RNN falls as it suffers from vanishing gradients, which hampers the learning of long data sequences as observed in the Twitter dataset.

One of the few challenges that were encountered was the Romanization of Telugu words and social media acronyms and abbreviations. As explained in section 3, there is no standard way to transliterate the code mixed data, and thus Romanization variability leads to different spellings of the same word. For example, the romanization variability of a single word can be: “eppudu”, “epdu”, “epudu”, “yepudu” (Translation into English: “when”). Similarly, social media chat conversations/tweets using SMS language “you” can be written as “U”, “hello” as “helooo”, “What’s up” as “wassup” etc. All these examples pose a significant challenge while training the LID models in code mixed data.

7 Conclusion and Future Work

In this paper, we have put forward two Telugu-English CM manually annotated datasets which are an order of magnitude greater than the existing dataset, and proposed two architectures for language classification (Telugu and English) in CM data: (1) Word Level Classification (2) Sentence Level word-by-word Classification. We have conducted thorough experimentation and extensive benchmarking across various Deep Learning models and Classical Machine Learning models. We found out that BiLSTM + LSTM, BiLSTM + CRF performs the best among others. We also plan to make our data corpus consisting of low-resource Telugu and English languages generated from Twitter, and online blogs opensourced to encourage further experimentation and research. The LID models developed here can also be used in other NLP tasks like Named Entity Recognition (NER), Parts of speech (POS) tagging, and spell-check. The results of the current work are encouraging, and future work will be focused on using sequence level labeling SOTA models like attention in LID. We are also focused on developing spell-checking models which normalize the misspelled and romanization variability as a part of our future work.

Abstract

In a multilingual society, people communicate in more than one language, leading to Code-Mixed data. Sentimental analysis on Code-Mixed Telugu-English Text (CMTET) poses unique challenges. The unstructured nature of the Code-Mixed Data is due to the informal language, informal transliterations, and spelling errors. In this paper, we introduce an annotated dataset for Sentiment Analysis in CMTET. Also, we report an accuracy of 80.22% on this dataset using novel unsupervised data normalization with a Multilayer Perceptron (MLP) model. This proposed data normalization technique can be extended to any NLP task involving CMTET. Further, we report an increase of 2.53% accuracy due to this data normalization approach in our best model.

1 Introduction

In recent times, huge volumes of data are being generated on social media and online blogging. The usage of multiple languages in day-to-day conversations and the minimal linguistic restrictions on the online content lead to the generation of Code-Mixed data. Code-Mixing or Code-Switching is the usage of two or more languages in a single sentence or a conversation. The generated code-mixed data can be used to extract potential knowledge like emotion, news or information.

Sentimental analysis on Code-Mix social media data helps us to understand the underlying sentiment of the phrase or sentence, which can have many practical use cases in the real world. For example, it can be used to understand the sentiment of restaurant or movie reviews.

Code-Mixed Data can be easily extracted from various online platforms like social media and blogs using APIs and various web-scraping tools. In spite of having huge amounts of data, performing sentiment analysis on it is still challenging because of its unstructured and noisy nature (Arora and Kansal (2019), Gautam and Yadav (2014), Barik et al. (2019)). Hence, this requires robust preprocessing techniques to normalize this unstructured data.

In this paper, we have performed sentimental analysis on Code-Mixed Telugu-English Text (CMTET) with an unsupervised data normalization. We analyse and classify each sentence into three sentiments, positive, negative and neutral. To the best of our knowledge this is the first work to propose a framework to perform sentiment analysis on CMTET. The reason for choosing English as our secondary language for the Code-Mixed data is because we observed that most of the Telugu data available in social media is very often Code-Mixed with English.

The rest of the paper is organized as follows. In section 2, we discuss the existing Sentiment Analysis approaches in other Code-Mixed languages. Section 3 introduces the dataset and describes the methodology involved in preprocessing and annotating this dataset. In section 4, we discuss in detail various challenges faced in performing sentiment analysis in CMTET. In section 5, we discuss about the proposed data normalization technique for CMTET. In section 6, we explain the process of feature extraction and sentiment classification. In Section 7, we show the results of the proposed methods and make a comparative study on the accuracy of all those models. In section 8, we discuss the problems faced by the models in predicting the sentiment. Section 9 concludes the paper with the summary and scope for future work.
2 Related Work

For the task of Sentiment Analysis on Code-Mixed Hindi-English text, Sharma et al. (2015) used a lexicong-based approach on the FIRE 2013 (Roy et al., 2013) and FIRE 2014 datasets. The dataset consisted of the user comments from public Facebook pages of two of the most popular celebrities. Joshi et al. (2016) introduced a new dataset and used subword-LSTM to address the noisy nature of the text and reported an improvement of 18% on the baseline. Choudhary et al. (2018) proposed clustering of Code-Mixed word variations with skip-gram vectors based on similarity. They also used contrastive learning and projected the Code-Mixed sentences into a common sentiment space using shared parameters. Sukhpreet Kaur (2021) used attention based models with word-level, sub-word level and character-level representations of the sentences, and reported that Bi-LSTM performed the best.

Chakravarthi et al. (2020) had presented an annotated code-mixed corpus in Malayalam-English language of Youtube comments for the task of Sentiment Analysis. Kalaivani and Thenmozhi (2020) performed Sentiment Analysis in Code-Mixed Malayalam-English and Tamil-English text using AWD-LSTM(Merity et al., 2017) and reported a weighted F1-Score of 0.6 on both the datasets. Mishra et al. (2018) proposed an ensemble model to perform sentiment analysis in Hindi - English and Bengali - Hindi - English corpus. The ensemble model is built on linear SVM, logistic regression and random forest based on a voting classifier.

Sabri et al. (2021) created a Persian-English code mixed data corpus from tweets. They also proposed a Bi-LSTM based ensemble model which uses BERT embeddings and translation models to learn sentiment of tweets. Yadav and Chakraborty (2020) proposed a zero-shot approach to solve Sentiment Analysis task on Code-Mixed Spanish-English text. They used multilingual and crosslingual embeddings to transfer knowledge from monolingual text to Code-Mixed text. They reported an increase of 3% in accuracy over the previous state-of-the-art.

In the task of Sentiment Analysis on Social Media text, there is a lot of research on using different models to address the problem of its noisy nature. Our work differs in this context, where, we propose an unsupervised approach for normalizing CMTET. And to the best of our knowledge, this is the first work of Sentiment Analysis in CMTET.

3 Dataset

In this paper, we introduce a new dataset for sentiment analysis in CMTET. The methodology consists of three main phases: data collection, data cleaning, and data annotation. The below sections describe each phase in detail.

3.1 Data Collection

We have identified a few Twitter users and regional movie review Youtube videos. We have observed that these Twitter users tweet in CMTET on different aspects such as Movies and Sports. Also, the identified Youtube videos contain user comments expressing their sentiment of the movie or the video in CMTET. We used Twitter public streaming API\(^1\) and Youtube Comments API\(^2\) to collect this data.

3.2 Data Cleaning

We removed irrelevant text such as URLs and markup text, using regex-based\(^3\) pattern matching to ensure basic data quality. Then, with the help of NLTK Tokenizer\(^4\), we tokenized each sentence into words. We then removed sentences containing less than five words, as we observed that these sentences are noisy and hardly contain any information.

3.3 Data Annotation

We adopted the three-class classification for sentiment of the sentences, i.e., positive, negative, and neutral (Koppel and Schler, 2006). The objective of this phase is to annotate each sentence. We also annotated this data at word-level with their language using the language tags, i.e., English (EN), Telugu (TE), Named Entities (NE), and Universal(UNIV).

---

\(^1\)https://developer.twitter.com/en/docs/twitter-api
\(^2\)https://developers.google.com/youtube/v3/docs/comments/list
\(^3\)https://en.wikipedia.org/wiki/Regular_expression
\(^4\)https://www.nltk.org/api/nltk.tokenize.html
After the word-level annotation, we removed the sentences having only English or only Telugu words.

The annotation was carried out by 5 Telugu native speakers who are also proficient in English. We developed an efficient annotation process with the help of Telegram Bot API\(^5\), where the annotator can annotate from their Telegram App with a single tap on their device. Figure 1 shows a screenshot of the user interface of the Telegram Bot made for this task.

In most of the earlier works, the annotation task has been done by developing an application, which is usually web-based (Aprosio et al. (2020), (Wadden et al., 2020)). Using this process would either have device compatibility or user-experience issues. There will be a significant increase in application development overhead to address these issues. On the other hand, using a Telegram Bot API offered excellent user experience, lesser maintenance, lesser development overhead, and its availability in most devices (both mobile and desktop). Our annotators gave us positive feedback for the tool, pointing out the flexibility offered to perform the annotation task in any environment.

Inter Annotator Agreement: We calculated the Inter Annotator Agreement score using Cohen’s Kappa score (Cohen, 1960) in order to assess the quality of the dataset. We

\[ \text{Sentiment: Positive} \]

At the end of data annotation we got a total of 19,857 sentences of which 7,925 are Positive, 7,713 are negative and 4,219 are neutral sentences. The data is open-sourced\(^6\) to encourage further research.

Sample Data:

Sentence: super/EN bro/EN nuvvu/TE morn-ing/EN adiga/TE appude/TE review/EN icharu/TE tnq/EN soo/EN much/EN

Sentiment: Positive

4 Challenges in CMTET

The CMTET poses new challenges because of its unstructured nature due to the following phenomenons.

4.1 Informal Transliterations

Users in social media follow no standard when transliterating Telugu from Dravidian to Roman text. Hence many transliteration variants are observed in the CMTET. Below, we discuss the various transliterations observed.

4.1.1 Long Vowels

People tend to transliterate long vowels in many ways. For example, the word తినాన్వా (winnA vA) is transliterated into tinnaaavaa

\[ \text{https://github.com/ksubbu199/cmtet-sentiment} \]
(repeating the long vowel twice) or just tinnava (not indicating the long vowel at all) or tinnavaa, tinnaava (mixture of double and single vowels).

### 4.1.2 Double Consonants

Similar to long vowels, even double consonants are transliterated in many ways. For example, ཕྲན་མ། (winnA vA) is transliterated into tinnava, tinava or བྲན་ཕྲ (sariggA) into sariggaa, sarigaa.

### 4.1.3 Aspirated Consonants

Aspirated Consonants are the syllables which require burst of breath to pronounce. In Telugu ఖ, ఛ, ఘ, ఠ, ఝ, భ, ఠ are the aspirated consonants. In CMTET, we observed that these characters are transliterated in multiple ways. For example, ధర (xara) is transliterating into dhara or dara.

### 4.1.4 Homophones

Homophonic syllables are usually transliterated in multiple ways due to their nature of having same pronunciation with different spellings. For example, ఉనాన్యి (unnA yi): unnayi, unnai or ఎక్కడా (ekkada): ekkada, aekkada, akkada.

### 4.2 Informal Language

Some of the variations in the spellings are caused due to the lack of formal setting on social media. Following are some variations caused by the informal setting of social media.

#### 4.2.1 Elongation

To express certain sentiments like excitement, users stretch some words in an informal setting. For example: helloooo, niceeee, gooood, okayyy, bagundhiii, ichaavv.

#### 4.2.2 Shortening

Due to limited characters in Twitter, users tend to shorten words, yet capturing the word’s phonetics. For example, plz, grt, cref, ndku (నాడును). In Telugu, shortening is usually done by dropping vowels or using single characters for double consonants.

### 4.3 Spelling and Typing Errors

Ritter et al. (2010), in their modeling of Twitter conversations, found that posts were “often highly ungrammatical, and filled with spelling errors” and resorted to selecting clusters of spelling variations manually. In CMTET, we observed spelling errors in both English and Telugu.

From the above, we can understand that CMTET has high entropy in spellings and thus poses a lot of challenges. To resolve these challenges, we propose an unsupervised data normalization technique for CMTET.

### 5 Data Normalization

In this section, we propose an unsupervised data normalization technique for normalizing CMTET. The architecture for data normalization can be found in Fig 2. As a first step, we performed elongation normalization and then used the language tags in the dataset to normalize Telugu words and English words separately. We then spell-checked English words using a defined similarity metric with an English dictionary. For Telugu words, we performed a two-stage normalization to normalize transliteration and spelling errors. The below sections explain this architecture in detail.

#### 5.1 Elongation Normalization

To deal with the problem of Elongation (refer 4.2.1), we convert each character to lower-case, and then limit the repetitions of sequential characters to two. For example, hel loo to helloo, nicely to nicely, goooo to goood, bagundhi to bagundhii. Errors persisting after this step like hel loo and bagundhi are treated as spelling errors and are normalized in the next steps.

#### 5.2 Normalizing English Words

To address spelling and typing errors, we have used dictionary-based spell-check with Levenshtein Distance (Levenshtein, 1966) as a similarity score between two words. We used SymSpell\(^7\) to compute this efficiently.

#### 5.3 Normalizing Telugu Words

In Telugu, the objective is to cluster the vocabulary into groups capturing the transliteration variants and spelling errors of each word. We propose a two-stage normalization for this. The below sections will explain this method in detail.

---

</tbody>
</table>

5.3.1 Normalizing Transliterations
In this stage, we aim to capture all the transliteration variations mentioned in Section 4.

- Limiting Character Repetition to One: This helps to address the issue of Long Vowels (refer 4.1.1) and Double Consonants (refer 4.1.2) transliterations. For example, tinnaavaa to tinava and sariigga to sariiga.

- Normalizing Aspirated Consonants: The transliterations of aspirated consonants in Telugu i.e., kh (.Sdk), chh (చే), gh (ఘే), th (ఠ), jh (ఝ) dh (డ) and bh (భే) are replaced with k, ch, g, t, j, d and b respectively. This will address the problem of Aspirated Consonant Transliterations (refer 4.1.3).

5.3.2 Clustering with PBLD
In this stage, we aim to normalize Homophones and spelling errors. As there is no standard dictionary for the transliterated Telugu text we aim to normalize the text by clustering them. We have experimented with Levenshtein Distance(LD)(Levenshtein, 1966) as a similarity score to cluster Telugu words. But, we observed a limitation that, LD treats all the characters equally leading to the clustering of wrong words. For example: According to LD, rasthaaru (రాసాత్రు:rAswAru) and vasthaaru (వసాత్రు:vaswAru) are unit distant. To address this issue, we propose a modified LD called Phonetic Based Levenshtein Distance (PBLD) with the following changes:

- Insertions and deletions are allowed only if they are vowels. This will address the issue of Shortening (refer 4.2.2) in Telugu.

- Characters can only be substituted with other characters if they have similar phonetics. This will address the variations in transliteration of Homophones (refer 4.1.4).

Table 2: Clustering error and Vocabulary Reduction with clustering transliteration variants with varying Edit Distance ($d$).

### 5.3.3 Error Analysis

In this section, we perform an error analysis on normalization of Telugu words with LD and PBLD. Clustering of words leads to the reduction of Telugu vocabulary in the dataset. We randomly picked clusters having a total of 500 words and observed a significant difference between the two methods in terms of clustering error. These metrics are reported in Table 2.

### 6 Method

In this section, we focus on explaining our Sentiment analysis pipeline. Fig. 3 shows our end to end approach wherein we take raw data i.e. a sentence and perform data normalization (transliteration and spelling normalization) as explained in section 5. Once we have this normalized data we perform feature extraction using N-Grams and Term-Frequency and Inverse-Document Frequency (TF-IDF) (Chowdhury, 2010). These features are then passed to our sentiment classification models which outputs one of the labels namely positive, negative and neutral.

We experimented on Logistic Regression (LR), Naive Bayes (NB), Support Vector Machine (SVM), Random Forest (RF) and Multi Layer Perceptron (MLP) classification models to classify the final sentiment.

### 7 Experiments and Results

The motivation of the current work is achieve better Sentiment Analysis in CMTET using machine learning models. Majority of the existing approaches majorly focus on single language sentiment analysis (Zulkifli and Lee,

9 Conclusion and Future Work

In this paper, we published a huge annotated dataset for sentiment analysis in CMTET to encourage further research. Also, we presented a pipeline for this task with a novel data normalization technique. For each model, we have shown quantitatively that the proposed data normalization improves the overall performance across various metrics (precision, recall and F1-score) (refer Table 4). To the best of our knowledge this is the first such method carrying out sentiment analysis on CMTET.

Although the current work addresses some of the most crucial challenges in sentiment analysis on CMTET it can further be extended to other languages. The proposed data normalization technique can also be leveraged in various other NLP tasks. We can further make the bench-marking more extensive by including other deep learning models like LSTM, RNNs and CNNs.

Abstract

This paper deliberates on the process of building the first constituency-to-dependency conversion tool of Turkish\(^1\). The starting point of this work is a previous study in which 10,000 phrase structure trees were manually transformed into Turkish from the original Penn Treebank corpus. Within the scope of this project, these Turkish phrase structure trees were automatically converted into UD-style dependency structures, using both a rule-based algorithm and a machine learning algorithm specific to the requirements of the Turkish language. The results of both algorithms were compared and the machine learning approach proved to be more accurate than the rule-based algorithm. The output was revised by a team of linguists. The refined versions were taken as gold standard annotations for the evaluation of the algorithms. In addition to its contribution to the UD Project with a large dataset of 10,000 Turkish dependency trees, this project also fulfills the important gap of a Turkish constituency-to-dependency conversion tool, enabling the quick compilation of dependency corpora which can be used for the training of better dependency parsers.

1 Introduction

There are two types of annotated treebanks used in natural language processing (NLP) systems: constituency treebanks and dependency treebanks. They are used to represent syntactic relations, argument structures, and other hierarchical relations. Constituency treebanks display groups of phrases as trees and dependency treebanks marks head-dependent relations for each item. Today, dependency parsers are expected to adapt to new data from a variety of genres. The Universal Dependencies (UD) Project (Nivre et al., 2020) provides convenient corpora for these parsers. However, this kind of an adaptation requires a huge amount of data that is not suitable for manual annotation. Thus, the existent constituency treebank corpora are being automatically converted into dependency treebanks as the need for dependency treebanks increased in order to train dependency parsers (Marneffe et al., 2006; Johansson and Nugues, 2007; Choi and Palmer, 2012).

Constituency to dependency conversion requires a big corpus and a coherent annotation framework. UD helps to provide a framework for annotated treebanks to be used in different languages. There have been several attempts made to represent Turkish language in this project and to create a common framework in Turkish language treebank studies (Sulubacak et al., 2016; Oflazer et al., 2003; Cöltekin, 2015) (Kuzgun et al., 2020). However, Turkish language
has flexible word order as a consequence of its agglutinative morphology. Such features complicates the annotation scheme for Turkish and renders the language harder to parse while giving rise to problems such as non-projectivity. In their work, Türk et al. (2019) edited the IMST Treebank (Sulubacak et al., 2016) according to the UD framework considering the needs of the Turkish language but its corpus does not provide a parallel treebank in terms of a cross-linguistic attribution to the literature and even this refinement could not help the IMST Treebank to adapt the new versions of the UD framework. In spite of all the attempts and refinements which have been mentioned above, Turkish still lags behind compared to similar languages in the area. For instance, a dependency conversion tool is yet to be developed for Turkish while there are studies present for similar languages such as Hungarian (Simkó et al., 2014).

We have applied our conversion algorithms to the biggest Turkish Constituency Treebank which is the Turkish counterpart of the original Penn TreeBank corpus (Marcus et al., 2002), the first annotated treebank of English that set the gold standard for other treebanks. There have been several studies done for the parallel constituency treebank creation in Turkish. Yıldız et al. (2014) developed an automatic translation process to translate trees from the Penn Treebank. They created a tool that learned from the 5000 manually translated sentences and offered possible translations. Yıldız et al. (2015) fine tuned this work by deleting empty projections, and rearranging the two word constructions that were appearing in one node due to the cross-linguistic consequences. In their study, Bakay et al. (2019) translated sentences using a tree-based approach to deal with the long distance dependencies that are not present in the corresponding English sentences. These long distance dependencies occur as a result of the difference between English and Turkish in having a fixed word order and a flexible word order respectively.

The Turkish Penn Constituency Treebank used in this conversion study, however, is distinct from the previous parallel Turkish constituency treebank studies as the most recent one is translated and annotated manually. It consists of 10,000 annotated sentences\(^2\) translated from the original version of the Penn Treebank (Kara et al., 2020). In order to make the translations suitable for the Turkish language, a team of linguists deleted, changed some tags from the original Penn Treebank, and also they introduced new tags that are necessary for a better syntactic representation of the Turkish language. We preferred using The Turkish Penn Treebank in our conversion study as it offered an accurate and less complicated constituency treebank that is necessary for the demands of our conversion tool.

Our main objective in this study is to introduce the first Turkish constituency to dependency converter by using the parallel Turkish constituency treebank introduced above. Another contribution of this work to the literature comes from its cross-linguistic nature. Since most of the conversion studies used the Penn Treebank corpus (Mareeffe et al., 2006); (Johansson and Nugues, 2007); (Choi and Palmer, 2012), our choice of employing a translated corpus results in a Turkish-English parallel constituency to dependency conversion study.

All the previous converter studies employed a rule-based approach. Johansson and Nugues (2007) differs from these studies in that they included extra labels to include semantic information and to handle syntactic phenomena such as topicalization, clefting, gapping, and so on. They put the semantic annotations in the Penn Treebank in use to achieve a more semantically rich dependency treebank. However, as the labels were more complicated, the employment of semantic information decreased the parsing accuracy. The Stanford dependency approach, on the other hand, did not use these function labels that were manually annotated over the Penn Treebank corpus. In their study, Choi and Palmer (2012) combined the Stanford approach with the CoNLL dependency approach which uses different labels and relation rules. This combination allowed them to achieve better accuracy without eliminating the semantic information encoded in the Penn Treebank corpus.

In our study, the translated version of the Penn Treebank does not include these semantic labels, and therefore our conversion rules does not employ these semantic information as in the Stanford approach.

2 Conversion Process

2.1 Turkish Penn Treebank as Input

Using the Penn Treebank as an input for converter algorithms is a very common procedure. So as not to break this tradition, we have also decided to use the Turkish version of Penn Treebank. As mentioned above, this widely-used constituency treebank was first adapted to Turkish by Yıldız et al. (2014). We found the latest version of the dataset to be simplistic and yet an adequate representation of the Turkish language, especially thanks to its being manually edited by a team of linguists. The tree in Figure 1 illustrates the final version of a sentence in the Turkish Penn Treebank corpus.

The input we used follows the main principles of the Penn Treebank annotation. However, there are differences in some aspects. In their study, Kara et al. (2020) excluded the bar level projections such as NONE, VBN, NNP, IN, NSBJ-1. They aimed for a more minimal approach to reduce the number of branches while keeping the necessary constituency information. In addition to this difference, this version has additional tags such as NEG, NOMP, and QP. In conversion, we used word level non-terminal nodes while benefiting from the headedness of Turkish language.

2.2 Algorithms

2.2.1 Rule-based Approach

While constructing an algorithm for constituency to dependency converters, there are some basic and simple steps that should be followed. The real hardship lies in creating specific rules for the needs of each language. Turkish has a rich morphology, with many suffixes and different cases carrying semantic or syntactic information. This made it compulsory to include in the algorithm some information from a morphological analyzer. As our input dataset already had each word morphologically analyzed through a semi-automatic process (Yıldız et al., 2019), we had the opportunity to extract information from their analyses.

The first problem to tackle is determining a head for each phrase in the phrase structure trees. Whereas in phrase structure trees the head of a constituent is not transparent due to its non-binary representation and linking style, in dependency structures the head and its dependents are always marked. This requires a head to be determined for each constituent. The most efficient way to achieve this is by constructing a hierarchical table which allocates a number to each type of phrase and listing them according to their prioritization. Table 1 contains the hierarchical head table used for the Turkish Penn Treebank. Hierarchical head table allocates priority numbers (from 1 to 5, with 1 having the top priority and 5 having the lowest) to different phrase labels. In a node with more than one daughter, the one with the lowest number becomes the head. In a case where phrases with the same priority number are sisters, the one on the right becomes the head.

The hierarchy of the tags are decided by considering the behaviors of the UD tags and the head final structure of Turkish. For instance words with VP/NOMP labels are always the root of the sentence. Therefore, they have the highest priority for being labeled as the head. The following group is the adjunct category. When these types of words are linked to the root, they are always dependents. The third category is the post positions and they can be linked to a word that is in the first or in the second category in the hierarchy, either case it is always a dependent. The fourth category consists of determiners and numeral modifiers. These are always dependents to noun phrases, therefore it is crucial that they are lower in the hierarchy. The last category of the hierarchy consists of the tags that are always dependents.

This table allows for an accurate head determination, especially in exceptional cases. Due to its head-final nature, in Turkish, heads of phrases generally appear on the right, thus at the end of the phrase. To write such an algorithm would be perfectly simple if it weren’t for some exceptions such as postpositions and negation. For instance, in the phrase *senin içın* ("for you") the postposition *için* is the rightmost word which should be the head according to a head-final algorithm. However, in UD annotations, the adpositions should be dependents of NPs, so the leftmost element *senin* (NP) should be head and the postposition
An NP is found as a sister to a PP, the NP has the priority to be the head. Another example to this can be the labels NOMP (nominal predicate) and NEG (negation), which appear as sisters with this respective order. However, the negation, even though it appears on the right of the main predicate, cannot be the head according to UD annotations. By allocating the number 5 to NEG and 1 to NOMP, we make sure that whenever NOMP appears with NEG, the algorithm will choose NOMP as the head and NEG as its dependent.

After the heads were determined, certain rules had to be written to link structures and phrase labels of the constituency trees with UD annotation tags. Figure 2 is a list which illustrates some of these conversion rules. There are 21 conversion rules in total, excluding the DEP rule which is used whenever the listed conversion rules fail to apply. The rules take the POS information of the head and dependent nodes in the constituency tree along with the morphological information of the word tokens. For instance, the sentence “hızlı koşuyor” meaning “s/he is running fast.” consists of an adverb and a verb. The tag hierarchy marks the verb “koşuyor” as the head and the adverb “hızlı” as the dependent. Then, the rules in Figure 2 apply and determine the relation between them. There are two labeling options for the relation between an adverb and a verb: ADVCL or ADVMOD. The difference between the two relations is that the ADVCL relation is used when the dependent is clausal, otherwise the adverb relation is labeled with ADVMOD. The clausal adverbials have a verbal root in their morphology. Therefore, the algorithm questions the existence of a verbal root in an adverb to determine the correct dependency relation. The adverb “hızlı” does not have a verbal root, so it is marked as ADVMOD. If it had a verbal root as in “hızlanarak”, meaning “in an increasing speed”, then, it would create an adverbal clause. Therefore, the algorithm would mark it as the ADVCL.

2.2.2 Machine Learning Approach

In training a machine learning algorithm, there are two main issues to consider: determining the head and how it is linked to its dependents, and determining the dependency relations between the head and its dependents. In order to achieve this, first, the algorithm sees a tree as a whole. Then, it finds the correct constituents by scanning the nodes of the tree. Once a node is matched, it cannot be overwritten by the upper nodes. This procedure continues until there are no more nodes left in the tree. Once the algorithm has established the constituents, we use an oracle which is the mechanism that determines the correct linkings between the heads and their dependents as well as the dependency relation types between them. We use two different oracles to find these constituents. One of them is the rule-based basic oracle and the other is a classifier oracle which is used as a machine learning model. After the constituents have been determined, they are put together to form a sentence.

The classifier oracle forms an instance list by taking the Parts of Speech (POS) tags of the words in the constituent and assigns them an index according to its position in the constituent. In another iteration, the head of the constituent is not included in the ranking. For instance, in a con-
if dependentNode == ADVP:

Table 2: Error rates according to constituency length (Random Forest, ensemble size = 50)

As for the second problem of choosing dependency relations, the first task was to assign the POS-tags and class information flags of heads and its dependents for the entirety of the instance list. For instance, in a constituent with an adjective and a noun, the instance would be ADJ NOUN 0 1. Here, the ADJ marks the POS tag of the first word of the constituent, the NOUN marks the second word, and the numbers mark their indexes. The instance lists are classified according to the length of the constituent. Later, the index of the head of the constituent is converted into class information. Thus, an instance like “ADJ NOUN 0 1” turns into ADJ NOUN 1 given that the head of this pair is the NOUN.

Subsequently, we have tested decision tree, Naive Bayes, KNN, and Random Forest models by using constituency and dependency treebanks of the same corpus. Running the models separately and as ensemble resulted in similar error rates. Thus, we decided to use the Random Forest which had the least errors. We tested the Random Forest model with several parameters and chose the one that minimizes the error rates. Table 2 shows error rates according to the constituency length. The error rates get higher as the constituency length increases. Therefore, we did not include constituents bigger than 7 words length and applied a rule-based algorithm for them.

As for the second problem of choosing dependency relations, the first task was to assign the POS-tags and class information flags of heads and its dependents for the entirety of the instance list. For instance, in a constituent with an adjective and a noun, the instance would be ADJ NOUN AMOD. Here, the first two tags mark the POS tag of the two words in linear order, and the last one marks the type of the dependency relation by considering the information provided by the POS tags.

However, the first results achieved by the random forest model were not satisfying. So as to achieve better performance, each word, including the head, was evaluated according to the following questions concerning their morphological
structure:
What is the POS-tag of the root?
Does the word have an ablative tag?
Does the word have a dative tag?
Does the word have a genitive tag?
Does the word have a nominative tag?
Does the word have an accusative tag?
Does the word have a proper tag?
Does the first word in the constituent share the same sense ID in Turkish WordNet with the head of the constituent?

These questions result in a sequence of true/false outputs along with the POS-tag information of the head of the constituent and its dependents, in addition to the class information provided at the end of the instance. The performance was satisfying after the implementation of the questions. The following string illustrates an instance of an ADJ-NOUN constituent which consists of two words. The string begins with the POS tag information of the first word of the constituent and it is followed by the true/false outputs relevant to this word. Then, it continues with the POS tag information of the second constituent and its applicable true/false outputs. The last "false" output stands for the last question and shows that the two words do not share the same word ID. The ADJP and NOMP marks the node names of the constituents in the phrase tree. Lastly, the AMOD label shows the relation between the two words.

ADJ false false false false false false
NOUN false false false true false false
false
ADJP NOMP
AMOD

3.2 Results & Discussion

Table 3 and 4 show the LAS, UAS and LA scores of our converted dependency treebank for the two approaches. The scores are calculated according to the amount of changes made by the human annotators on the converted dependency treebank. It should also be noted that the output sentences were all projective in both conversion methods.

Since this is the first converter for the Turkish language, we were unable to compare our results with other Turkish conversion tools. However, the results show that the rule-based approach lags behind the conversion studies held in other languages. The relatively lower LA score of the
Table 4: LAS, UAS, and LA parsing scores of the Machine Learning algorithm

</tr>
</tbody>
</table>

A rule-based approach reflects the fact that confusion is existent between similar tags which cause debates even among the human annotators. On the other hand, the relatively higher UAS score of the rule-based algorithm shows that our head finding algorithm works better than the overall performance of the converter. This might be the outcome of the corpus we used since it consisted of formal sentences with mostly canonical order. A less formal corpus could give different results since the amount of scrambling would be different.

Nevertheless, the rule-based approach is not as successful as the machine learning algorithm. This is an interesting finding given that the machine learning approach resulted in better scores even though the rule-based algorithm was specifically tailored for the requirements of the Turkish Language. The results indicate that dividing the conversion problem into two phases as head finding and determining the dependency relation is a better methodology for conversion studies because it not only results in better scores but also provides a more adaptable algorithm that can be used for other languages. This supports the idea that there is confusion between similar tags, and this affects the performance of the converter. The main reasons for the confusions have been explained below.

Tables 5 and 6 shows the confusion matrices of the 13 most frequent tags used in the data for rule-based and machine learning algorithms respectively. From this table, some of our mistakes can be explained as a result of the co-occurrence of the same lexical items with different functions in Turkish. For instance, the word yumuşak meaning "soft" can occur as an adjective as in yumuşak yastık meaning "soft pillow", as an adverb modifying a verb in a sentence like "Yumuşak davranın," meaning "S/he acted softly." It can also function as an adjectival predicate to be labelled as a root as in “Onun kumaşı yumuşak,” meaning “Its cloth is soft”. Notice that the three words with different functions do not show any morphological variance on the word. These kinds of structures affect the labeling of ADVMOD, AMOD, OBL, and NMOD the most. Table 6 shows this effect. For example, 5.6% of OBL had been mistakenly labelled as ADVMOD and another 34.8% of them were labelled as NMOD. Considering the syntactic position helps to differentiate between these tags to some extent, especially in OBL-ADVMOD cases. However, understanding the function of morphologically identical structures is still an important issue because of the flexible word order. Assumptions on syntactic position often cause problems as a result of the flexible word order of Turkish language. An example is the NSUBJ tag. The table shows that 25.3% of the total mistaken tags for NSUBJ consists of the NMOD tags and another 16.4% consists of the OBJ tags. Some of these mistakes can be explained by scrambling. In the canonical word order, we would expect the first NP of a sentence in Turkish to be the subject as in the treebank all the complements of the verb were put under the predicate node. However, there were sentences where other NP structures occurred before the subject. As a result, both flexible word order and the morphological reasons mentioned above gave rise to the confusion among these tags in the rule-based algorithm.

Table 6 shows that the machine learning algorithm prioritizes the learning of the more frequent tags such as AMOD, ADVMOD, NMOD and so on in that it shows higher performance than the rule-based algorithm over these tags. This proves that the machine learning approach does not tackle the same confusion problems as the rule-based model stated above. On the other hand, there are areas in which the machine learning algorithm performed poorer than the rule-based algorithm such as identifying FLAT and CASE relations. These tags share the common property of reversed attachment type. This uniqueness of these relations can easily be applied in rule-based algorithm but apparently it causes confusion to the machine learning models.

All of these examples show that machine learning approach is helpful to increase the parsing accuracy for languages with rich morphology and flexible word order since it takes each sample as an input, and evaluates the patterns according to the relevant information provided by the data rather than trying to fit the data into a structure. Both the rule-based model and the machine learning model
employ the use of dependency relations which are standardized according to the UD annotation scheme. In a different domain, the frequency of the labels used can change slightly. However, as the edge cases are a result of the structure of the language, a domain change would not significantly affect the accuracy difference between the two models. Therefore, the scores presented in this study are not domain specific. In addition, it should be noted that the comparison of the models are based solely on the accuracy. The two models require different kinds of prior work. For instance, machine learning approach requires an annotated corpus to be trained on while the rule-based model does not need this kind of a training data. This is one of the reasons that all of the previous conversion studies employed a rule-based approach as there was not any data to train the converter in most languages. However, there are now enough training corpora to employ machine learning approach for further studies.

4 Conclusion

Overall, this project presents a remarkable contribution to UD studies in Turkish, in that it introduces the first constituency to the dependency conversion tool. Furthermore, the performance comparison which was provided shows that machine learning algorithms are able to achieve better accuracy scores compared to rule-based approaches. We hope that this tool will prove to be useful in future studies on Turkish dependency corpora as well. Thanks to the rapid transformation from phrase structure trees, it will allow for the creation of more dependency data, paving the way for better Turkish dependency parsers.

Moreover, as a result of this conversion, a corpus of 10,000 new sentences has been added to the Turkish dependency corpora, constituting one of the largest dependency corpora in Turkish. Besides, considering that the Penn Treebank constituency trees have previously been transformed into dependency trees with the help of many conversion tools such as the Stanford conversion tool (Marneffe et al., 2006) and ClearNLP (Choi and Palmer, 2012) the output we provide represents an impeccable overview of comparative structures of English and Turkish UD trees, thus offering a cross-linguistic perspective.

Abstract

In the social media, users frequently use small images called emojis in their posts. Although using emojis in texts plays a key role in recent communication systems, less attention has been paid on their positions in the given texts, despite that users carefully choose and put an emoji that matches their post. Exploring positions of emojis in texts will enhance understanding of the relationship between emojis and texts. We extend an emoji label prediction task taking into account the information of emoji positions, by jointly learning the emoji position in a tweet to predict the emoji label. The results demonstrate that the position of emojis in texts is a good clue to boost the performance of emoji label prediction. Human evaluation validates that there exists a suitable emoji position in a tweet, and our proposed task is able to make tweets more fancy and natural. In addition, considering emoji position can further improve the performance for the irony detection task compared to the emoji label prediction. We also report the experimental results for the modified dataset, due to the problem of the original dataset for the first shared task to predict an emoji label in SemEval2018.

1 Introduction

The advent of emojis has dramatically changed the style of human communication. Currently, emojis are widely used on social media platforms such as Twitter, Facebook, and Instagram. Owing to the prevalent use of emojis in the last few years, they become a target of recent researches.

As reported by Kralj Novak et al. (2015), exploring the interplay between emojis and texts can be a clue for better natural language understanding (NLU) in social media datasets with full of emojis. In response to this report, Barbieri et al. (2017) proposed a task to predict an emoji label given a text, which can contribute to various natural language processing (NLP) tasks such as information retrieval, social media content generation, and sentiment/emotion analysis. To solve this task, they used an LSTM-based tagger and achieved even higher performance than human prediction.

However, in spite of the success of the previous researches, the existing emoji prediction task targets only at predicting a single emoji given a text without considering its position. Kralj Novak et al. (2015) reported that social media users place an emoji differently based on its emoji type in a tweet. They analyzed 751 emoji labels by dividing them into positive, negative and neutral types to show that the type of an emoji strongly correlates with its position in a text. This indicates the information of the emoji position can be a good clue to boost emoji label prediction.

Hence, it is necessary to consider an emoji label and its position together. Social media users do not simply put an emoji at the end of a sentence. Automated systems of predicting an emoji with its position that consider surrounding linguistic information can further enhance the aforementioned...
tasks in the field of NLU and NLP. Figure 1 describes the difference between the previous task of emoji prediction and our proposed task of emoji insertion to texts. In the first and second examples, we can understand that the position of emojis is important and indispensable in cases where they are used instead of a word or a character. In the third example, the position of an emoji is required to investigate the relationship between the emoji and multiple sentences. To take into account the position of emoji labels, we first demonstrate that the information of the emoji position can improve the performance of emoji label prediction by using the gold emoji position.

We then extend the task of emoji prediction by proposing a novel task of inserting a suitable emoji into a suitable position in a given tweet. To solve this new method, we propose Bi-Affine-based and Bi-LSTM-based models that can jointly predict both emoji label and its position without relying on any linguistic features.

Class-imbalanced data is one of the major concerns in the field of emoji prediction (Barbieri et al., 2017) because emojis of positive emotion are more frequently used on social media and dominate minor classes of negative and non-emotional emojis (Kralj Novak et al., 2015). It is difficult to obtain better results for imbalanced emoji classes. Figure 2 shows the imbalanced frequencies of emojis that obey a power-law distribution. To deal with the imbalanced frequencies of emojis, we also propose a novel method, Contextualized Dynamic-Smoothing (CDS), which can be adopted in our proposed models.

Due to the problems of the original dataset for the shared task for multilingual emoji prediction in SemEval2018 task2 (Barbieri et al., 2018b), that sometimes mistakenly contains “traces” of emojis in tweets, we prepared the modified dataset for our experiments.

Experimental results show that incorporating the gold emoji position can improve the performance of emoji label prediction. In addition, our proposed models of jointly predicting an emoji label and its position outperform the baseline model for emoji label prediction that does not consider the emoji position in terms of F-1 scores. Specifically, the results of our models with CDS, that solves the problem of the imbalanced emoji frequency, show the additional improvement on infrequent and non-emotional emojis. Human evaluation shows that there is a suitable emoji position in a tweet. In addition, our proposed task to insert an emoji in a tweet can actually make the tweet more fancy and natural, compared to the current emoji prediction task. Considering emoji positions can further improve the performance on the irony detection task compared to the current emoji prediction.

2 Related Work

Social media platforms contain various types of emotion expression methods such as emojis and kaomojis (Kwon et al., 2019). Recently, emojis occupy a large proportion on social media owing to the richness in their information. Emoji information can enhance the quality of social media datasets for researches such as sentiment, irony, emotion, and sarcasm analysis (Felbo et al., 2017; Singh et al., 2019). Although emojis can be interpreted differently based on social media platforms (Miller et al., 2016), their usage is similar in multiple countries (Barbieri et al., 2016), meaning that they can be predicted in different languages such as English, Spanish (Barbieri et al., 2018b), and Italian (Ronzano et al., 2018). Emoji prediction can be boosted by incorporating not only texts but photos in the Instagram dataset (Barbieri et al., 2018a) and can directly improve the task of sentiment analysis (Chen et al., 2019). Also, emoji prediction can be used in dialogue systems to recommend a suitable emoji (Xie et al., 2016), and using emojis in chatbot systems is effective to attract users, specifically in the conversation for mental wellbeing (Fadhil et al., 2018). Recently, Ma et al. (2020) released an emoji label prediction dataset with passage-level multi-class/multi-label, and aspect-level multi-class annotations.
Our work to predict both an emoji label and its position is in accordance with sequential labeling tasks. In dependency parsing, the Bi-Affine dependency label classifier was proposed to study the relationship between two words, and achieved the state-of-the-art performance (Dozat and Manning, 2017). Currently, Bi-Affine layers have been widely adopted in various tasks, such as relation extraction (Nguyen and Verspoor, 2019), mention detection and clustering (Zhang et al., 2018), owing to their effectiveness. Because they have demonstrated the standout performance in the aforementioned tasks, we employ them to learn emoji positions to predict emoji labels.

3 Models

We introduce our proposed models for jointly predicting an emoji and its position in each tweet. Bi-LSTM networks are first used to encode a given tweet (Graves et al., 2013) and a Bi-Affine layer is used to predict the position of an emoji. Then, the predicted emoji position is used to predict the label of the emoji with CDS.

3.1 Bi-LSTM

Bi-LSTM networks are used to capture the forward and backward context of the input text, given words of input text \( S = \{w_0, w_1, w_2, ..., w_N, w_{N+1}\} \), which are encoded as word embeddings \( \{e_0, e_1, e_2, ..., e_N, e_{N+1}\} \). \( w_0 \) and \( w_{N+1} \) indicate “<s>” and “</s>” tokens for the beginning and end of a sentence, respectively. Then, these word embeddings are fed to the forward and backward LSTMs and are converted to forward and backward hidden states \( h_f \) and \( h_b \), respectively. We use the concatenated hidden state \( h_t = [h_f; h_b] \) as the output of Bi-LSTM for each time step.

3.2 Selective Gate

To enhance the information of each hidden state for the eligible emoji label and its position, we incorporate an selective module (Zhou et al., 2017) on top of the Bi-LSTM networks. Specifically, each \( h_t \), which is the output of Bi-LSTM, is passed through the selective gate, \( sGate_t \). The \( sGate_t \) decides the importance for each hidden state by considering the entire sentence information that consists of \( s = [h_0; h_{N+1}] \), where \( h_0 \) is the first backward hidden state and \( h_{N+1} \) is the last forward hidden state. The formula for \( sGate_t \) is defined as follows:

\[
\begin{align*}
    sGate_t &= \sigma(W_h h_t + W_s s + b), \\
    h_t' &= h_t \odot sGate_t,
\end{align*}
\]

where \( W_h \) and \( W_s \) indicate weight matrices, \( b \) is the bias term. \( \odot \) is a symbol for element-wise multiplication and \( \sigma \) is a sigmoid activation function for normalizing ranges of gate outputs. The sequence of hidden states, \( \{h_0, h_1, h_2, ..., h_N, h_{N+1}\} \), is computed through the selective gate. Then, a new sequence of embeddings, \( \{h_0', h_1', h_2', ..., h_N', h_{N+1}'\} \), which takes into account the sentence information for each time step, is generated.

3.3 Position Module

This module predicts an emoji position, \( p\text{os} \). The emoji position is predicted by the following equation:

\[
\text{p\text{os}} = \arg \max_{\text{pos}} \text{score}_p(\text{pos}),
\]

where \( \text{pos} \) is possible emoji positions. To calculate the position score, \( \text{score}_p(\text{pos}) \), we propose the following two networks.

3.3.1 Simple Concatenation

We simply use the concatenation of the neighboring two hidden states, \( [h_i', h_{i+1}'] \), to calculate each position score as follows:

\[
\text{score}_p(\text{pos}) = v_p t_i,
\]

\[
t_i = \sigma(W[h_i'; h_{i+1}'] + b),
\]

where \( W \) is the parameter matrix, and \( b \) is the bias term. \( v_p \) is the learnable vector for emoji position prediction. \( \sigma \) is the activation function of the Rectified Linear Unit (Nair and Hinton, 2010). The function, \( \text{score}_p \), returns a scalar value for each possible emoji position.

3.3.2 Bi-Affine

The simple concatenation approach can explain the interaction between the two hidden states, \( h_i' \) and \( h_{i+1}' \). However, the clues from a single state without any interaction with the other state might also be informative for emoji position prediction. To facilitate extraction of such pure clues, we additionally propose a method to use Bi-Affine-based transformation of the hidden states \( h_i' \) and \( h_{i+1}' \), which contains the terms only with \( h_i' \) or \( h_{i+1}' \). Specifically, instead of using Equations (4) and (5), the
Bi-Affine function is used to calculate each position score as follows:

\[
\text{score}_p(\text{pos}) = \text{biaffine}(h'_i, h'_{i+1}), \quad (6)
\]

\[
\text{biaffine}(h_i, h_r) = v^T_i h_i + h^T_r W_3 h_r + v^T_r h_r, \quad (7)
\]

where \(v^T_i\) and \(v^T_r\) are learnable vectors. \(W_3\) is the weight matrix.

3.4 Label Module

As a downstream procedure, this module predicts an emoji label, \(\text{label}\). The emoji label is predicted by the following equation:

\[
\text{label} = \arg \max_{\text{label}} \text{score}_l(\text{label}), \quad (8)
\]

where \(\text{label}\) is emoji class labels. Following two types of networks were used for modeling the score function, \(\text{score}_l(\text{label})\), to predict an emoji label.

3.4.1 Linear Projection

We used a linear projection layer to map the simple concatenated hidden states in Equation (5) to the emoji label space. To take the predicted emoji position into account in predicting an emoji label, \(\hat{p}\) is applied to calculate the score function:

\[
\text{score}_l(\text{label}) = W_l t_{\hat{p}} + b, \quad (9)
\]

where \(W_l\) and \(b\) are the weight matrix and the bias term for emoji label prediction, respectively.

3.4.2 Contextualized Dynamic-Smoothing (CDS)

As shown in Figure 2, the frequencies of emojis are imbalanced, that can result in difficulties to obtain better performance in emoji label prediction (Barbieri et al., 2017). To address this issue, we propose a novel smoothing method based on the left and right context vectors for the emoji label prediction. In Equation (9), the bias term \(b\) for predicting an emoji label is shared in all emoji positions regardless of the predicted emoji position \(\hat{p}\). It would be beneficial for the bias term to consider the eligible value at each emoji position to predict an emoji label. Hence, we calculate the contextualized bias term based on the information of each emoji position using Bi-Affine layers, revealed as follows:

\[
b_{\text{dynamic}} = h'^T_l W_4 h'_r, \quad (10)
\]

where \(W_4\) is the weight matrix. We use \(h'_l\) and \(h'_r\) to obtain various bias values as the effect of smoothing the distribution of emoji classes. \(b_{\text{dynamic}}\) is added to calculate the emoji label score as follows:

\[
\text{score}_l(\text{label}) = W_l t_{\hat{p}} + b_{\text{dynamic}}. \quad (11)
\]

3.5 Objective Function

Our objective function is composed of two Cross-Entropy losses for the emoji label and its position. To learn parameters by backpropagating two losses, we sum two losses through a hyperparameter \(\lambda\):

\[
\text{loss} = \text{loss}_{\text{label}} + \lambda \cdot \text{loss}_{\text{pos}}. \quad (12)
\]

4 Experimental Settings

In this section, we report the problems of the original datasets from the SemEval2018 task2. Then, we describe the datasets we modify and use in predicting emoji labels and their positions.

4.1 Datasets

4.1.1 Original SemEval2018 datasets

The SemEval2018 task2 was the first shared task in predicting emoji labels with multilingual datasets: English and Spanish tweets (Barbieri et al., 2018b). Although various submitted systems attained good results in predicting emoji labels, we found the released SemEval2018 task2 datasets have some problems.

The trial and test datasets were composed of 50k tweets and were released by dividing them into two files, target emoji labels and their corresponding input tweets. However, some of English and Spanish input tweets contained hidden “traces” of the corresponding target emoji labels. Specifically, English input tweets in the test dataset whose target emoji labels are \(\heartsuit\) and \(\star\) had such hidden “traces” over than 85% and 98%, respectively. They essentially consisted of two Unicode fragments of emojis: “\ufe0f” and “\ufe0e”. They indicated the target emojis with their exact positions in the input tweets. Moreover, the released code, which splits the raw training dataset into the two files of input tweets and target emoji labels in the preprocessing step, also had a problem. It affects the training dataset to contain such hidden “traces”.

The emoji \(\heartsuit\), including the “traces”, is the most frequent in all of the training, trial and test datasets. It may influence the performance of emoji label prediction.

4.1.2 Modified Dataset

To remedy the above problems, we modified the shared English dataset from the SemEval2018
task2. We refrained from using the original trial and test datasets owing to no information of emoji positions and the problems of hidden “traces” in them. In addition, we did not use the released code, which divides the raw training dataset into two files of the input tweets and target emoji labels.

Thus, we retrieved 450,021 tweets in the training dataset. To use exact positions of emojis, we discarded a few tweets with an emoji appearing more than once (e.g., My baby bear 😍) from the extracted training dataset. As a result, we obtained our final dataset of 357,305 tweets in total with 20 emoji class labels. Figure 2 indicates the statistics of emojis in the final dataset. We also prepared its subsets for the 10 (250,747 tweets) and 5 most frequent emojis (180,767 tweets), with the same procedure in the previous work for emoji label prediction (Barbieri et al., 2017, 2018a). We randomly shuffled and split them into three parts: training (80%), validation (10%), and test (10%) datasets.

4.2 Baseline Model

Barbieri et al. (2017) proposed the task of emoji label prediction with a simple emoji classifier. Their Bi-LSTM classifier received an input tweet without an emoji label to predict a suitable emoji label. In this study, we used their network as our baseline model to examine whether the information of emoji positions can improve the performance of emoji label prediction.

4.3 Parameter Settings

We used one-layer stacked Bi-LSTMs with hidden states of 256 dimensions for all models. The Adam optimizer was used with a learning rate of 0.001, betas of 0.9 and 0.999, and epsilon of $1.0 \times 10^{-8}$. The value of $\lambda$ in Equation (12) is 0.2, which was estimated based on the performance of the average macro F-1 score in emoji label prediction on the validation dataset. Glove embeddings are well-known pre-trained vector representations for words (Pennington et al., 2014). We used 27 billion pre-trained word embeddings of 200 dimensions trained from the Twitter dataset. We concatenated Glove embeddings with the initialized word embeddings to obtain each word embedding.

5 Experiments and Evaluation

5.1 Emoji Insertion

5.1.1 Emoji Label Prediction

As the evaluation metrics, we employed the precision, recall, and macro F-1 scores, officially used in the SemEval2018 task2.

In Table 1, we compare the results of emoji label prediction for the baseline and proposed models with the gold and jointly learned emoji positions, respectively. The baseline was described in Section 4.2. Upper Bounds 1 and 2 used the gold emoji positions to predict emoji labels without and with applying CDS, respectively. The results for Upper Bounds 1 and 2 demonstrate that the information of emoji positions can improve the performance of emoji label prediction. Specifically, using gold emoji positions in the model of Upper Bound 1 improved +3, +4.41, and +2.36 average F-1 scores on the modified datasets for top 5, 10, and 20 emojis, compared with the Baseline that does not consider emoji positions. Incorporating the proposed CDS to deal with the class-imbalanced problem yields the further improvement of +1.22, +1.14, and +1.57 on each dataset between Upper Bounds 1 and 2.

Joint Learning models 1 and 2 predicted the position of emojis using simple concatenation and Bi-affine layers, respectively. Joint Learning models 3 and 4 incorporate CDS to predict emoji labels. The joint learning models without any external resources outperformed the Baseline model. The highest F-1 score was obtained by Joint Learning 4, that uses Bi-Affine layers to predict the position of emojis and applies CDS to predict the emoji labels. It improved +2.77, +2.5, and +1.93 average F-1 scores on the modified datasets for top 5, 10, and 20 emojis, compared with the Baseline.

Table 2 describes F-1 scores for top 20 individual emojis with the Baseline and Upper Bound 2. Applying CDS with the position information can improve the performance of predicting non-emotional emojis. The performance for the non-emotional emojis, 😐, 😄, 😎, 😘, 😍, 😂, 😊, increased by +7.7, +2.6, +3.5, +2.5, +5.3, +4, and +5.3, respectively, compared with the baseline model. In addition, incorporating CDS with the information of emoji positions is effective for infrequent emojis, 😞 (+2.5), 😓 (+5.3), 😞 (+10.2). It also helps the model to predict 😞 and 😞 with F-1 scores of 5 and 3, respectively.
Table 1: Average F-1 scores for emoji label prediction and accuracy for emoji position prediction. The best scores in all the models except Upper Bounds are shown in bold. † indicates that the improvement from the Baseline is statistically significant by using the paired bootstrap resampling method (Koehn, 2004) (p < 0.001).

Table 2: F1 scores for emoji label prediction with top 20 emojis. Base. indicates the baseline model and UB2. describes the Upper Bound 2. % is the proportion of each emoji in the test dataset.

Table 3: Examples of predicting emoji labels and their positions with our best model, Joint Learning 4, compared with the baseline model.
rank-probability from Joint Learning 3 shows that the probability distribution of emoji positions is in accordance with emoji labels, meaning that the probability distribution is not uniform. Thus, the emoji position is predictable because the emoji label is predictable (Barbieri et al., 2017). Moreover, the probability distributions of emoji labels from Joint Learning models 3 and 4 demonstrate that our proposed CDS successfully smoothed estimated probabilities of emoji labels, and the probabilities of low ranked emoji labels increased.

**Algorithm 1** Construction of the human evaluation dataset.

```
Require:
Tweets T = \{T_1, T_2, ..., T_n\}
tweetNLP = part-of-speech tagger
Initialize the filtered tweets, F = [ ]
for i = 1 to n do
  tagged ← tweetNLP(T_i)
  v ← tagged.count(‘v’), o ← tagged.count(‘o’)
  if v > 2 and o ≥ 2 then
    F.append(T_i)
  end if
end for
return F
```

5.2 Human Evaluation

We carried out an experiment to show that there is a suitable emoji position for individual emojis in tweets. Then, we conducted an experiment in which we compared current and our proposed tasks.

To encourage and guide the human evaluation, we applied a filtering step to harvest suitable tweets from the SemEval2018 training dataset. Algorithm 1 describes how to filter tweets. We first applied a tweetNLP, which is a part-of-speech tagger for tweets that can take into account emoji information (Gimpel et al., 2011). It can annotate part-of-speech tags to emojis. Specifically, emojis can be tagged with “v” (Verb) when they are used instead of a word (e.g., ‘ is frequently used instead of a word “love”). Thus, we inserted rules that the number of “o” (Pronoun) and “v” (Verb) tags is greater than two to extract tweets including an emoji used instead of a word and tweets with multiple sentences.

To show there exist a suitable emoji position, we constructed a dataset, **Gold (Inside)**, by randomly selecting 1,000 tweets that emojis are not located at the end from the filtered dataset. We prepared a **End** dataset by moving emojis to the end of the tweet from the **Gold (Inside)** dataset. Because the gold emoji position can be end of the tweet, we also constructed a **Gold (End)** dataset by randomly selecting 500 tweets that emojis are located at the end from the filtered dataset. We also prepared a **Random (Inside)** dataset by randomly relocating emojis in each tweet from the **Gold (End)** dataset. Then, we constructed a **Current (End)** and **Proposal** datasets by applying Baseline model (See. 4.2) and our best model, Joint Learning 4, on the modified test dataset. Because Baseline model cannot insert an emoji in a tweet, we attached a predicted emoji at the end of a tweet. **Current (End)** and **Proposal** datasets consist of randomly selected 500 tweets after the filtering step.

We asked humans to select better tweets to demonstrate that there exists a suitable emoji position and our proposed task can contribute to making tweets more fancy and natural compared to the current emoji prediction task. After presenting two tweets from **Gold (Inside)** and **End** datasets, **Gold (End)** and **Random (Inside)** datasets, and **Current (End)** and **Proposal** datasets, we asked two questions for the human annotators “Which tweet is more fancy?” and “which tweet is more natural?”’. The crowd-sourcing platform, “Mechanical Turk”, was used to design an experiment. The same tweets were displayed to five human annotators\(^1\) and the final decision was selected based on majority agreement.

Table 4 shows results of human evaluations between the gold emoji position and relocated emoji position. When the gold emoji position is inside of tweets, it can make fancy and natural tweets more than 90% and 87%, respectively, compared to moving emojis to the end of tweets. In addition, when the gold emoji position is end of tweets, it can make fancy and natural tweets more than 73% and 78%, respectively, compared to randomly relocated.
cating emoji in tweets. Thus, individual emojis are not always located at the end of tweets and there exists a suitable emoji position in tweets. To assess the reliability of the agreement between the human annotators and their decision, we used a statistical measure called Fleiss’ Kappa (L. Fleiss, 1971). We obtained Kappa scores of 0.52 for Fancy and 0.68 for Natural between Gold (Inside) and End datasets, which indicate moderate and substantial agreement, respectively. In addition, we obtained Kappa scores of 0.41 for Fancy and 0.26 for Natural between Random (Inside) and Gold (End) datasets, which indicate moderate and fair agreement, respectively. Thus, considering emoji position is necessary to understand social media texts. As can be seen in Table 5, our proposed task can actually make tweets be more fancy and natural compared to the current task.

5.3 Irony Detection

To validate the effectiveness of considering emoji position to understand social media texts, we conducted the downstream task, irony detection. We used the 2-class (ironic or not ironic) and 3-class (ironic by clash, other, or not ironic) raw irony detection datasets released by the SemEval2018 Task 3A and 3B, respectively (Van Hee et al., 2018). The macro-average F1 score was used to evaluate the performance by following previous work. Because raw datasets were provided with training and test sets only, we randomly shuffled and split the training dataset into two parts: training (80%) and validation (20%). For each raw dataset, we constructed Emoji w/o position and Emoji w/ position datasets by inserting an emoji using Baseline and Joint Learning 4 models. Because Baseline cannot insert an emoji, we simply attached a predicted emoji at the end of the sentence. Thus, three datasets of the released raw, constructed Emoji w/o position, and Emoji w/ position were used to perform irony detection.

Table 6 shows the results. The first block shows the reported scores of the top 2 previously submitted systems on the SemEval2018 Task 3A and 3B. We used the second best model, NTUA-SLP, which used Bi-Lstm with the self-attention networks. The second block shows the re-run performances using the NTUA-SLP model\(^2\) with raw, Emoji w/o position, and Emoji w/ position datasets. Using the Emoji w/o position dataset improved the performance of irony detection compared to using the raw dataset in both task3A and 3B. In addition, using Emoji w/ position dataset on the NTUA-SLP model outperformed using Emoji w/o position dataset and achieved better performances compared to the best models of the THU-NGN and UCDCC in both task3A and 3B. This improvement can be explained by the fact that social media users put an emoji carefully to convey their meaning and the position of emoji is effective to understand social media texts.

6 Conclusion

In this paper, we presented a novel task of jointly predicting the emoji label and its position by using Contextualized Dynamic-Smoothing (CDS) with Bi-Affine layers. The experimental results showed that the information of emoji positions is important and can improve the performance of emoji label prediction without external resources. Because the original public datasets of emoji label prediction had problems, we prepared the modified datasets. Human evaluation validated there exists a suitable emoji position in a tweet and our proposed task can make tweets more fancy and natural compared to the current emoji prediction. Moreover, considering emoji position is effective on the task of irony detection.

Abstract
Recent task-oriented dialogue systems learn a model from annotated dialogues, and such dialogues are in turn collected and annotated so that they are consistent with certain domain knowledge. However, in real scenarios, domain knowledge is subject to frequent changes, and initial training dialogues may soon become obsolete, resulting in a significant decrease of the model performance. In this paper, we investigate the relationship between training dialogues and domain knowledge, and propose dialogue domain adaptation, a methodology aiming at adapting initial training dialogues to changes intervened in the domain knowledge. We focus on slot-value changes (e.g., when new slot-values are available to describe domain entities) and define an experimental setting for dialogue domain adaptation. First, we show that current state-of-the-art models for dialogue state tracking are still poorly robust to slot-value changes of the domain knowledge. Then, we compare different domain adaptation strategies, showing that simple techniques are effective to reduce the gap between training dialogues and domain knowledge.

1 Introduction
Conversational agents are receiving great attention in recent years, both in research and applications (McTear, 2020), mainly because of the progress achieved by neural approaches in modeling dialogue phenomena (Louvan and Magnini, 2020), (Balaraman et al., 2021). Particularly, we focus on task-oriented dialogue systems (Young et al., 2010), which are able to assist a user for specific tasks (e.g., booking a restaurant, taking an appointment, execute commands) in a certain conversational domain. Such data-driven dialogue systems typically learn a model from annotated training dialogues (e.g., (Budzianowski et al., 2018), (Du et al., 2020), (Price, 1990)), and such dialogues, in turn, are collected and annotated according to a certain domain scenario (e.g., restaurants in a certain town, songs in a certain music data-set, etc.). Once the model is trained, it is applied to understand new conversations in the same domain, or in a similar domain.

However, in real scenarios, domain knowledge is subject to frequent changes, and initial training dialogues may soon become obsolete, resulting in a significant decrease in the model performance. It is common that new domains (e.g., RESTAURANT) are added or removed for a certain conversational scenario, as well as slots, slot-values and instances. Such situations require the capacity of the dialogue system to adapt its behaviours to domain knowledge changes. Depending on the complexity of the changes that occur, domain adaptation of data-driven systems can be approached in two directions: (i) improving the model robustness, and (ii) adapting the training dialogues to the new situation. While the first direction has been largely explored through several techniques, including transfer learning (Louvan and Magnini, 2019), and zero-shot learning though schema-guided models (Wu et al., 2019a; Kim et al., 2020; Zhang et al., 2019; Heck et al., 2020; Balaraman and Magnini, 2021), and delexicalization (Henderson et al., 2014a,b; Yu et al., 2020), in this paper we take the second, less investigated, perspective, focusing on the relation between training dialogues and domain knowledge.

We have defined a new experimental setting for dialogue domain adaptation, where, given an initial conversational domain (KB-SOURCE), available training dialogues (D-SOURCE) are adapted to be as much as possible consistent to a modified knowledge base (KB-TARGET), resulting...
in new set of dialogues (D-TARGET). Then, we use a state-of-the-art model for dialogue state tracking and assess the performance of different adaptation strategies against a gold standard of manually adapted target dialogues. We run a number of experiments showing that: (i) current state-of-the-art models are very poorly robust to changes over the domain knowledge; (ii) a particular class of domain changes, i.e., slot-value changes, can be effectively addressed through simple dialogue domain adaptation techniques, which operate substitutions over D-SOURCE. Finally, as part of our study, we highlight that current component-based evaluation settings for task-oriented dialogue systems (i.e., slot filling, intent detection, dialogue state tracking, utterance generation) are not sensible to correctness of system responses, which, instead, is crucial to assess domain adaptability.

The paper is structured as follows. Section 2 provides basic background in task-oriented dialogue systems. Section 3 defines the conversational adaptation task, while in Section 4 we introduce the proposed dialogue domain adaptation approach. Section 5 introduces the new experimental setting, and Section 6 provides the results of our experiments and discusses them.

2 Task-oriented Dialogue Framework

This section provides background related to task-oriented dialogue systems, particularly about how domain knowledge is managed and about dialogue state tracking.

2.1 Domain Knowledge

According to most of the recent literature (Budzianowski et al., 2018; Bordes et al., 2017; Mrkšić et al., 2017), we assume a task-oriented dialogue between a system and an user, composed of a sequence of turns \( \{t_1, t_2, ..., t_n\} \). The goal of the dialogue is to retrieve a set of entities (possible empty) in a domain knowledge base \((KB)\) that satisfy the user needs. A domain ontology \( O \) provides a schema for the \( KB \), and typically represents entities (e.g., RESTAURANT, HOTEL, MOVIE) according to a pre-defined set of slots \( S \) (e.g., FOOD, AREA, PRICE, for the RESTAURANT domain), and values that a certain slot can assume (e.g., EXPENSIVE, MODERATE and CHEAP, for the slot PRICE). On the basis of the entities defined in the domain ontology, the application knowledge base, \( KB \), is then populated with instances of such entities. As in most of the literature, we distinguish informable slots, which the user can use to constraint the search (e.g., AREA), and requestable slots (e.g., PHONE NUMBER), whose values are typically asked only when a certain entity has been retrieved through the dialogue.

At each turn in the dialogue, both the user and the system may refer to facts in the \( KB \), the user with the goal of retrieving entities matching his/her needs, and the system to propose entities that can help the user to achieve the dialogue goals.

2.2 Dialogue State Tracking

In a task-oriented system a dialogue state tracker (DST) maintains a distribution over the dialogue states based on the dialogue history. A dialogue state \( d_i \) for a turn \( t_i \) is typically represented as a set of slot-value pairs, such as \{PRICE=Moderate, FOOD=Italian\}, meaning that at \( t_i \) the system assumes that the user is looking for an Italian restaurant with a moderate price.

After being collected through Wizard of Oz, turns of each dialogue are annotated with the corresponding dialogue state, consisting of an intent and a set of slot-value pairs. The following is an example of the annotation provided in a portion of a MultiWOZ 2.0 dialogue:

**USER:** I would like a moderately priced restaurant in the west part of town.
**SYSTEM:** There are three moderately priced restaurants in the west part of town. Do you prefer Indian, Italian or British?
**USER:** Can I have the address and phone number of the Italian location?

3 Dialogue Domain Adaptation: Task Definition

In this section we define dialogue domain adaptation (DDA) and its core properties. In
our setting we assume an initial conversational domain, represented in a KB-SOURCE, and corresponding annotated training dialogues D-SOURCE. Then, as in real application scenarios, we assume that a number of changes occur in KB-SOURCE, such that a new conversational domain KB-TARGET needs to be considered. Dialogue domain adaptation consists in the capacity to automatically produce new annotated dialogues D-TARGET, such that they maintain both the linguistic structure and the linguistic variability of the initial D-SOURCE dialogues, while, at the same time, being consistent with the new KB-TARGET.

Figure 1 provides a concrete example of DDA. Here we have a source dialogue, taken from the MultiWOZ data-set of restaurant booking conversations, mentioning restaurants in a certain region. Notice that it is implicitly assumed that the system responses are true facts in a KB-SOURCE (e.g., if the system says What about Eraina?, it means that KB-SOURCE contains a restaurant named Eraina). However, this might not be true in KB-TARGET, where the Eraina restaurant might not exist anymore. The target dialogue in Figure 1 is basically the same dialogue as the source dialogue, although adapted to be consistent with a KB-TARGET. DDA focuses on the automatic generation of such D-TARGET dialogues starting from D-SOURCE dialogues.

In the rest of the section we consider three core characteristics that affect DDA: domain changes, dialogue internal coherence, and KB-dialogue adherence.

3.1 Domain Changes

DDA strongly depends on the amount and types of changes that differentiate KB-SOURCE from KB-TARGET. Intuitively, the more the changes, the more the difficulty to adapt D-SOURCE to dialogues consistent to KB-TARGET.

As described in Section 2, we assume that domain knowledge is represented through a domain ontology, providing a schema that describes entities with slots and corresponding slot-values, and through a knowledge base, providing instances of domain entities. Accordingly, changes in domain knowledge may occur in four cases: (i) a domain is introduced or removed (e.g., adding HOTEL); (ii) a slot for a domain is introduced or removed (e.g., adding PARKING among the slots for RESTAURANT); (iii) a slot-value for an existing slot is introduced or removed (e.g., adding TUSCAN as slot-value for the slot FOOD of the RESTAURANT domain); (iv) an instance for a certain domain is introduced or removed (e.g., adding a new restaurant like BELLA NAPOLI with its features). In a concrete situation, such changes may occur either in an incremental way, as small changes of the domain knowledge reflecting modifications of the world, or as a consequence of a domain shift, when, for instance, a dialogue system is moved from one city to another.

In this paper we focus on slot-value changes, and we assume that, while moving from KB-SOURCE to KB-TARGET, both domains, slot names and number of instances are kept without any change.
3.2 Dialogue Internal Coherence

Human collected dialogues (as D-SOURCE dialogues) possess an internal coherence that needs to be preserved in D-TARGET dialogues. As an example, in the source dialogue in Figure 1, we assume that the Eraina restaurant mentioned by the system is coherent with the request of the user for an *European* restaurant. We assume that co-reference between anaphoric expressions and their references (e.g., *those* on the D-SOURCE) are kept consistent within the scope of a dialogue. Similarly, language variations (e.g., using different spellings for referencing the same entity) should be used consistently in the same dialogue.

Moreover, the semantic annotations of the dialogues need to respect the references of the utterance, even when anaphoric expressions occur. For example, if the user says *I want to book a table on the same day as my train arrival*, the annotation for "booking-day" has to be consistent to the referent mentioned in the previous part of the conversation.

3.3 KB-Dialogue Adherence

The core assumption behind *dialogue domain adaptation* is that system utterances have to be as much as possible aligned with domain knowledge, meaning that the system responses should correspond to true facts in the domain knowledge. As an example, in Figure 1, the D-SOURCE dialogue reports that there are 5 restaurants in KB-SOURCE with certain characteristics, while the corresponding D-TARGET turn has been adapted reporting 4 restaurants in the KB-TARGET.

When the dialogue collection is carried on manually, KB-Dialogue adherence is supposed to be checked by humans, so that each system utterance is coherent to the KB. However, human mistakes may occur, for instance in case crowd workers in a Wizard of OZ setting make wrong queries to the domain KB. The relevance of KB-Dialogue adherence in our experimental setting will be discussed in Section 5.

4 Substitution-based DDA

We approach the dialog domain adaptation task described in section 4 through the substitution of slot-values in D-SOURCE with slot-values selected from KB-TARGET. Figure 2 depicts the elements of our experimental setting, highlighting the relationships between them.

The dataset D-SOURCE consists of both training and test dialogues, with the latter possibly containing a certain number of slot-values that are unseen in the training set. D-SOURCE dialogues are collected in a strong connection with KB-SOURCE, which has been quantified through a KB-Dialogue adherence measure. Given a certain KB-TARGET, which differs from KB-SOURCE for a proportion of slot-values estimated by the KB-overlap, the KB mapping defines the substitutions that need to be done for every slot-value, and, on the basis of this mapping, the adaptation process generates the D-TARGET data-set.

![Figure 2: Scheme of dialogue domain adaptation methodology.](image)

4.1 D-TARGET Generation

Starting from an annotated D-SOURCE dialogue, a KB-SOURCE and a KB-TARGET, the creation of a D-TARGET dialogue follows a general substitution-based procedure. For each slot-value found in D-SOURCE, according to the semantic annotations provided in the dataset, the first step consists of checking whether the slot-value is known in KB-SOURCE. If it is known, then we try to substitute it with a corresponding slot-value in the KB-TARGET. Otherwise, we keep it as it is in D-TARGET.

In order to check whether the slot-value is known in KB-SOURCE, we compare the source slot-value with all slot-values in KB-SOURCE that have the same slot-name, applying a similarity function based on a variation of the Gestalt Pattern Matching algorithm (Black, 2004). We used a
threshold for deciding when to consider two slot-values as equal or different. The threshold has been determined by using a data-set of positive and negative examples and empirically finding the value that best separates the two sets (e.g., with the similarity value of 0.6, 10 slot-value pairs are classified as equal while they are different, and 8 pairs are classified as different while they are the same).

If at least one slot-value in KB-TARGET with similarity above the threshold is found, then we apply a mapping function that selects a target slot-value \( v_t \) to be used for substitution. We have defined three mapping functions.

**Random-DIALOGUE.** For every slot-value \( v_i \) in a D-SOURCE dialogue, this mapping function randomly chooses one value from all the slot-values in the dialogue, both from User and System, that have the same slot-name as \( v_i \). Then, the randomly chosen slot value is assigned to \( v_t \).

**Random-KB.** For every slot-value \( v_i \) in KB-SOURCE, this mapping function randomly chooses one value from all the slot-values in the KB-TARGET that have the same slot-name as \( v_i \). Then, the randomly chosen slot value is assigned to \( v_t \).

**Frequency-KB.** For every slot-value \( v_i \) in KB-SOURCE, this mapping function chooses a value in KB-TARGET that has the same slot-name as \( v_i \), on a frequency mapping (e.g., “indian” may correspond to “italian” if the proportion of instances for the two slot-value is similar). Then, the chosen slot value is assigned to \( v_t \).

In order to generate a D-TARGET dialogue, we then go through all the slot-values in D-SOURCE and for each of them we check if there is a \( v_t \) mapping. If a mapping is found, we perform the substitution, otherwise we leave it as it is.

### 4.2 KB Overlap
We use *Knowledge Bases Overlap* as a measure that determines how much KB-SOURCE is equivalent to KB-TARGET. In order to assess this, all unique possible values for every slot of the domains in one KB need to be compared to all the unique values of the same slot for the other KB. For instance, if the slot is "restaurant-area", KB-SOURCE may have values ["north", "south", "east", "west"], while KB-TARGET may have values ["centre", "north", "south"]. In such case, the equal values for the slot would be 2, and the total different values would be 5, resulting in a KB overlap of 40%. In other words, the KB overlap indicates the percentage of changes that need to be done for changing from one KB to another.

#### 4.3 Estimating KB-DIALOGUE Adherence
In accordance to what has been defined in paragraph 3.3, we intend the KB-DIALOGUE Adherence as the extent by which a dialogue is consistent to the content of the KB. In order to estimate this, we distinguish two cases:

- Case 1: the slot-values of one instance mentioned in the utterance correspond to the description of the instance in the KB (e.g., "The Old Cambridge is an expensive restaurant in the centre").
- Case 2: the system states a certain number of instances that meet certain conditions, and the KB actually contains the same number of instances (e.g. "There are 15 hotels with 4 stars in the north").

The adherence for each case is given by the percentage of the system’s utterances that complies with the respective condition, and the total KB-dialogue adherence is then calculated by averaging the two cases.

#### 4.4 Unseen Slot-value Ratio
Given a dialogue data-set split into training and test set, the *unseen slot-value* ratio measures the number of slot-values that are present in the test set dialogues, but that are not present in the training set dialogues. This is an important indicator, which significantly affects the performance of a model, as, for every unseen slot-value, the model has to make a prediction over something for which it had not been trained on.

### 5 Experimental Setting
This section describes the experiments that we carried on to test *dialogue domain adaptation* based on slot-value substitutions. The experimental setting includes an initial KB-SOURCE and corresponding D-SOURCE dialogues; a set of handcrafted test D-SOURCE dialogues; few substitution algorithms that we experimented to produce different D-TARGET dialogues; and a state-of-art dialogue state
tracker to check the performance of different adaptation strategies.

5.1 KB-SOURCE and D-SOURCE

Our experimental setting is derived from the MultiWOZ 2.3 data-set (Han et al., 2020). Experimental D-SOURCE dialogues consists of the 10,438 MultiWOZ dialogues, with an average of 11.06 turns per dialogue, collected with the technique of the Wizard of Oz and spanning over 7 domains: Train, Attraction, Restaurant, Hotel, Police, Taxi, Hospital. Through dialogues the user asks information about things to do in Cambridge, such as restaurant or hotel reservation, request for train timing, information about an attraction, etc. The MultiWOZ knowledge base (i.e., our KB-SOURCE) presents an average of 525 instances per domain and 8.5 slots per instance.

Figure 3: Slot-value overlap between Cambridge KB-SOURCE and Pisa KB-TARGET.

5.2 KB-TARGET

We decided to experiment DDA on a conversational domain with similar characteristics as MultiWOZ, simulating an application for the city of Pisa, in Italy. Pisa presents a number of characteristics that are very similar to Cambridge, such as the dimension, the presence of an important University with many departments spread all over the city, and the characterization of being a touristic city. The information necessary to create the Pisa KB-TARGET has been taken from a number of publicly available data-sets1. Starting from the MultiWOZ KB, as discussed in Section 3, we focused on slot-value changes, i.e., preserving all information but slot-values. The overlap between the resulting Pisa KB-TARGET and the initial Cambridge KB-SOURCE is shown in Table 3. We show both the breakdown slot-value overlap for single domains, as well as the aggregate overlap by slots and domains. Overall, 12.59% of the slot-values overlaps, indicating that the domain shift from Cambridge to Pisa has produced a drastic change in term of slot-values.

5.3 Test D-TARGET Dialogues

We created a Pisa test set (Pisa-T), using the test portion of the FREQUENCY KB Pisa data-set, which has then been manually revised with the aim of creating an error free data-set with respect to the Pisa KB, for what regards system messages. This means that every system utterance should tell the truth relatively to what is contained in the KB.

Test dialogues have been produced according to a semi-automatic procedure. First we apply substitutions to the original MultiWOZ test dialogues according to the frequency strategy described in section 4.1. In order to perform these corrections, we automatically identified the dialogues that showed a lack of adherence, and we adjusted them manually, both for the system utterances and for the semantic annotations, making sure that all test dialogues comply with the information reported in the respective KBs.

5.4 DDA Substitution Algorithms

We intend to compare different DDA substitution algorithms against the no-adaptation situation (i.e., the original MultiWOZ). We created three different training datasets that have been used for running experiments against the manually constructed test set.

1http://www.datiopen.it
No Adaptation Cambridge (NO ADAPT.). This is the original dataset from MultiWOZ 2.3. It is the baseline for our experiments, as no dialogue adaptation has been applied.

Random Selection from Dialogues (RANDOM-D). This substitution strategy is intended to preserve as much as possible the linguistic variety of D-SOURCE in D-TARGET. The dataset has been created in two steps: first, a preliminary Pisa dataset has been created with a frequency strategy, then all the slot-values in the dialogue have been randomly shuffled.

Random Selection from KB (RANDOM-KB). This substitution strategy is intended to take advantage of the alignment between KB-SOURCE and KB-TARGET, although with a basic random selection of target slot-values. This strategy does not preserve linguistic variety in D-SOURCE. Starting from the Cambridge dialogues, the substitutions have been done taking one random slot-value from KB-TARGET, only when the original slot-value was present in the KB-SOURCE.

Frequency-based Selection from KB (FREQ-KB). This substitution strategy is intended to take full advantage of the alignment between KB-SOURCE and KB-TARGET, choosing target slot-values that maximise their frequency in KB-SOURCE. This strategy does not preserve linguistic variety in D-SOURCE. Starting from the Cambridge dialogues, the substitutions have been done taking one slot-value, decided on the basis of a frequency strategy, from the KB-TARGET, only when the original slot-value was present in the KB-SOURCE.

### 5.5 DST Model and Evaluation Metrics

We compare the substitution strategies presented in Section 5.4 according to their capacity to provide training data for a dialogue state tracker. For all of our experiments we used the dialogue state tracking algorithm TRADE (Wu et al., 2019a). The algorithm is optimized for being used on multi-domains datasets like MultiWOZ, and it has actually been evaluated on this data-set (in its first version) for assessing the performance during the development of the algorithm.

The main evaluation metric is joint goal accuracy, largely used for DST, defined as the set of accumulated turn level goals up to a given turn in predicting all slots in a given turn correctly and it is computed by the fraction of turns in a dialogue where all slots in a turn are predicted correctly.

### 6 Results and Discussion

Table 1 shows a summary of the results that we obtained from our experiments. We started from the original MultiWOZ 2.3 data-set, referred as "Cam" in the Table, based on the Knowledge Base "Cam-KB". We obtained a Joint Goal Accuracy of 0.490 for "Cam", which is aligned with the value reported for TRADE on MultiWOZ 2.3 (Wu et al., 2019b).

The NO ADAPT. experiment aimed at reproducing a zero adaptation situation, training a model on D-SOURCE and testing it on D-TARGET, which in our case was based on a KB-TARGET that differs of around 88% from the KB-SOURCE (see paragraph 4.2). As expected, the value for the unseen slots is much higher (more than 12 times) compared to the original setting. This contributed to a decrease of almost 75% in the Joint Goal Accuracy performance.

The remaining experiments were ran on three different D-TARGET datasets, created on the basis of different strategies, as explained in Section 5.4. RANDOM-D was made by substituting every source slot-value with a slot-value that was taken randomly from a list of all unique slot-values that are present in the dialogue. This means that for every substitution, there was the same chance of picking a very frequent value - such as "Indian food" - than picking a value that occurs only once - such as "south Caribbean spicy food". For this reason the Joint Goal Accuracy is very low, even if significantly better than in the no adaptation setting. A major improvement, however, happens when we use data-sets that are based on an adapted strategies based on the KB.

The RANDOM-KB strategy, in fact, has a Joint Goal Accuracy slightly lower than the original Cam experiment, while the frequency-based strategy even exceeds Cam with an goal accuracy over 50%. The difference in performance between these last two data-sets can be explained by considering that with RANDOM-KB we randomly changed the assignment of the slot-values to be substituted once for every dialogue, which can be beneficial for the model capability of generalizing, but that does not allow it to maximize the

Table 1: Results of the dialogue domain adaptation experiments. All experiments use the TRADE model. The first row corresponds to the original MultiWOZ 2.3 dataset tested over itself. The second row is the same dataset tested over our Pisa dataset, which has been manually ensured to be perfectly fitted to the KB-TARGET, and which has also been used for testing the other adaptation strategies.

6.1 Linguistic Variability

The different substitutions approaches that we have adopted, radically diverge in the linguistic variability they produce in D-TARGET. On one side, for the RANDOM-D dialogues we substitute slot-values that are taken from the dialogue, this way preserving their variability (e.g., typos, synonyms, abbreviations, etc.), on the other side, for the RANDOM-KB and FREQUENCY KB, we always substitute slot-values that are present in the KB, which are only in their normalized version. This way we flatten the linguistic variability, and significantly reduce the total number of unique slot-values in the dialogue. This aspect is clearly highlighted by the different values for the Unseen Ratio. While RANDOM-D, which has a high number of variations for every slot-value (even if not as high as in Cam), produces a percentage of 2.27, RANDOM-KB and FREQUENCY KB show an Unseen Ratio percentage of more than the double. By substituting all possible variations of a slot-value with one unique value, in fact, the portion of slot-values that are not seen in the training, but that instead are present in the test, strongly increases.

7 Conclusion

Domain knowledge in conversational agents is subject to frequent changes, and this leads to the necessity of continuously updating training dialogues in order to keep them consistent with domain knowledge. As collecting conversational dialogues by hand requires a significant effort, approaches for automatically updating are required. In this paper we have proposed dialogue domain adaptation, a methodology for operating changes to an initial training dialogue, so that it becomes adherent to a modified domain knowledge. The experiments that we conducted reveal a twofold evidence: they demonstrate that zero adaptation results in a significant loss in DST performance, and they show that simple substitution-based adaptation methods bring instead effective results. Moreover, the experiments on different adaptation methods showed diverse phenomena. While the best performance is obtained using a frequency strategy - which maps the most frequent slot-value of the source domain to the most frequent slot-value of the target domain - a random strategy based on KB values performed slightly worse, and a severe drop in the results occurred when using a random strategy based on dialogue values. Linguistic variability is perhaps an important factor that emphasises this difference, and it will be an interesting topic to be explored in further works.
References

Abstract

The use of pretrained language models, fine-tuned to perform a specific downstream task, has become widespread in NLP. Using a generic language model in specialized domains may, however, be sub-optimal due to differences in language use and vocabulary. In this paper, it is investigated whether an existing, generic language model for Swedish can be improved for the clinical domain through continued pretraining with clinical text.

The generic and domain-specific language models are fine-tuned and evaluated on three representative clinical NLP tasks: (i) identifying protected health information, (ii) assigning ICD-10 diagnosis codes to discharge summaries, and (iii) sentence-level uncertainty prediction. The results show that continued pretraining on in-domain data leads to improved performance on all three downstream tasks, indicating that there is a potential added value of domain-specific language models for clinical NLP.

1 Introduction

Pretrained language models, trained on a variety of readily accessible and large-scale unlabeled corpora, and subsequently fine-tuned on downstream tasks using labeled datasets, have led to substantial performance gains across a whole host of NLP tasks. This has contributed to ameliorating a major bottleneck in the development of NLP systems, i.e. the need for access to very large amounts of labeled data for supervised learning.

In many cases, obtaining large, task-specific datasets in the form of human-annotated corpora is challenging and prohibitively expensive. As a result, the paradigm of pretraining and fine-tuning has become fundamental for contemporary NLP. In particular, with the introduction of models such as BERT (Devlin et al., 2018), which are based exclusively on self-attention, i.e. Transformers (Vaswani et al., 2017), and leverage transfer learning techniques, language models have become increasingly accessible; yet, pretraining language models from scratch requires substantial computational resources.

While generic language models, trained and released to the public by resource-rich organizations, can be utilized and fine-tuned to perform a particular downstream NLP task without a need for significant resources – neither computational nor in terms of data – it has been shown that their use in specialized domains may be sub-optimal as a result of differences in, for instance, language use and vocabulary (Lewis et al., 2020; Gururangan et al., 2020). This has motivated efforts to develop domain-specific language models, e.g. SciBERT (Beltagy et al., 2019) and BioBERT (Lee et al., 2020).

Specialized language models have been developed either by (i) pretraining a language model with in-domain data from scratch, possibly in combination with out-domain data, or by (ii) continuing to pretrain an existing, general language model with in-domain data (domain-adaptive pretraining), either by using large amounts of in-domain data, if available, or by only using task-related unlabeled data (task-adaptive pretraining).

The need for language models is particularly pronounced in low-resource settings – both in terms of languages and domains. While there is a publicly available generic language model for Swedish, KB-BERT (Malmsten et al., 2020), pretrained using text from the National Library of Sweden, there is no domain-specific variant for Swedish clinical text.

In this paper, we report on the development of a clinical language model for Swedish. The approach is based on continual pretraining of KB-BERT with in-domain data in the form of clinical text. The
model is fine-tuned and evaluated on three downstream clinical NLP tasks: (i) detection of protected health information, i.e. a named entity recognition task, (ii) automatic assignment of ICD-10 codes to discharge summaries, i.e. a document-level multiclass, multi-label classification task, and (iii) uncertainty classification, i.e. a sentence-level multiclass, single-label classification task. The clinical KB-BERT is compared to the original KB-BERT and we report downstream performance of various checkpoints during the pretraining process. The domain-specific and generic BERT models are further evaluated on a generic NER task in order to understand if performance gains are best explained by the quantity or the domain-specificity of the additional pretraining data.

2 Related Work

There has been a substantial amount of effort in recent years dedicated to exploring and developing domain-specific and specialized language models by pretraining with in-domain data, particularly for the biomedical domain and for English.

An early and notable effort was the release of BioBERT (Lee et al., 2020), a BERT model pretrained on large-scale biomedical corpora (PubMed abstracts and PMC full-text articles) in addition to general-domain corpora (English Wikipedia and BooksCorpus). Rather than training the model from scratch, BioBERT was initialized with the general-purpose BERT model and also inherited its vocabulary, after which pretraining continued using biomedical data. It was shown that BioBERT significantly outperforms BERT on biomedical NLP tasks.

Subsequent efforts, e.g. BioMegatron (Shin et al., 2020), have shown that additional improvements can be gained by training larger models on even larger in-domain corpora and, in some cases, using a domain-specific vocabulary. In another study, experimental results indicated that training biomedical language models from scratch, as opposed to continued pretraining of a generic language model, may yield improved performance on downstream domain-specific tasks (Gu et al., 2020), although requiring substantial computational resources.

Domain-specific language models have also been developed for the clinical domain, albeit not for Swedish. Alsentzer et al. (2019) pretrained clinical BERT models on MIMIC-III (Johnson et al., 2016) using either (i) all types of clinical notes or (ii) discharge summaries only.

It was found that initializing the clinical BERT models with parameters from BioBERT, as opposed to parameters from BERT, led to better downstream performance, while the types of clinical notes used made little difference on most downstream tasks. However, the clinical language models yielded an increased performance on some – but not all – of the clinical NLP tasks compared to BERT and BioBERT.

There have been efforts to develop language models using a combination of biomedical and clinical data. In Lewis et al. (2020), the authors develop such models by applying recent advances in pretraining introduced by RoBERTa (Liu et al., 2019), while studying the impact of using different (combinations of) training corpora and model sizes along with a domain-specific vocabulary. Liu et al. (2019) compare their models with previously published language models on a number of downstream tasks in different domains. Their results suggest that using a larger, more powerful general-purpose language model may be better than using a smaller, less powerful domain-specific language model. However, it is also shown that using in-domain data does lead to improved performance: in particular, using clinical data for pretraining leads to large performance gains on clinical tasks but has little impact on biomedical tasks. Learning a domain-specific vocabulary yielded improvements on sequence labeling tasks, while the impact was less clear for classification tasks.

Another very relevant study was conducted by Gururangan et al. (2020), where they also explore the potential advantages in continuing to pretrain an existing BERT model with in-domain data. The authors explore a number of different settings, such as continuing pretraining on a collection of in-domain corpora for a limited amount of time, continuing the pretraining on the unlabeled training set of the intended downstream task, or continuing pretraining on available unlabeled data directly related to the future downstream task at hand. They explore the duration of each of the continued pretraining setups, and they show that this approach can be very beneficial, especially for the setup in which unlabeled data related to the task at hand is exploited for further pretraining. These results are promising and partly inspired the current work, as all the annotated corpora are very small subsets of
the pretraining data.

3 Methods and Data

In this paper, we report on the development of a clinical language model for Swedish. The hypothesis is that a clinical language model, in this case obtained by continuing to pretrain KB-BERT (Malmsten et al., 2020) – a generic language model for Swedish – using large amounts of in-domain clinical text, will yield improved performance over a generic language model on downstream clinical NLP tasks. The pretraining process of KB-BERT is continued using 17.8 GB of clinical text from the research infrastructure Health Bank – Swedish Health Record Research Bank at DSV/Stockholm University (Dalianis et al., 2015). This is, in fact, a similar amount of data that was used for pretraining KB-BERT.

The clinical BERT model is pretrained using a GeForce RTX 1080 GPU and 17.8 GB of uncompressed clinical text in the form of all available types of clinical notes over a period of seven years. The clinical BERT model is trained for one epoch, corresponding to a total duration of ten days. The clinical BERT model is fine-tuned and evaluated on three downstream clinical NLP tasks: (i) detection of protected health information, i.e. a named entity recognition task, (ii) automatic assignment of ICD-10 codes to discharge summaries, i.e. a document-level multi-class, multi-label classification task, and (iii) uncertainty classification, i.e. a sentence-level multi-class, single-label classification task. The clinical BERT model is compared to the original KB-BERT and we report downstream performance of various checkpoints during the pretraining process.

Furthermore, as the clinical BERT model is developed using more data compared to KB-BERT, it is important to investigate whether potential differences in downstream performance can be attributed to the amount of pretraining data rather than the domain-specificity of the data. To that end, the two language models are also evaluated on a NER task in the general domain. A similar improvement on this task could imply that the clinical BERT model is primarily benefiting from additional pretraining data, whereas degraded performance would indicate the value of pretraining specifically on in-domain data.

3.1 Data

Health Bank contains over 2 million patient records encompassing 500 clinical units from the years 2007-2014 from Karolinska University Hospital in Sweden. All clinical notes available in Health Bank – comprising 17.8 GB of uncompressed text – are used for continued pretraining of KB-BERT in order to develop a clinical BERT model for Swedish. In addition, the following four annotated datasets are used for fine-tuning and evaluation, corresponding to three clinical NLP tasks and one generic NLP task.

The Stockholm EPR PHI Corpus comprises 21,653 sample sentences, 380,000 tokens and contains 4,480 annotated entities corresponding to 9 PHI (Protected Health Information) classes: First Name, Last Name, Age, Phone Number, Location, Health Care Unit, Organisation, Full Date, and Date Part. Identifying PHI in clinical notes is a fundamental step in de-identification and is typically approached as a NER task. Details about the dataset can be found in (Dalianis and Velupillai, 2010a).

The Stockholm EPR Gastro ICD-10 Corpus, or ICD-10 Corpus for short, consists of 6,062 samples in the form of discharge summaries belonging to a number of ICD-10 diagnosis blocks. This is a document-level multi-class, multi-label classification task, where the ICD-10 codes are grouped into 10 groups with a more coarse granularity compared to the full ICD-10 codes. These groups are decided based on body parts and range from the ICD-10 code K00 to K99 and average 1.2 labels per sample. Details about the dataset can be found in (Remmer, 2021; Remmer et al., 2021).

The Stockholm EPR Sentence Uncertainty Corpus contains 5,515 samples in the form of sentences classified as Certain, Uncertain, and Undefined. The dataset is highly unbalanced with 88% of the samples belonging to the Certain class, 10% to the Uncertain class and the rest to the Undefined class. This is a sentence-level multi-class, single-label classification task. Details about the dataset can be found in (Dalianis and Velupillai, 2010b).

Swedish Web News Corpus comprises approximately 8,000 samples in the form of sentences and contain the entities PER, LOC, ORG and MISC.

The dataset comes from Webbnyheter 2012\textsuperscript{4}, which was annotated semi-automatically. This dataset is used for the general-domain NER task.

### 3.2 Pretraining

The pretraining of the model with the Masked Language Modeling (MLM) task started from the released checkpoint of KB-BERT and lasted for 40,000 steps, approximately corresponding to one data epoch, or ten days in real time for our GPU. The pretraining procedure of BERT is closely followed with the notable difference that only sequence lengths of 512 are pretrained, acknowledging the significant evidence in the literature suggesting improved performance in later downstream tasks (Liu et al., 2019). Due to the high variability of the different note lengths in the pretraining data, and to construct the 512 chunks of text, the aforementioned work is carefully followed and each note is treated as a document, concatenating the different notes and separating them with extra [SEP] tokens to indicate the end of each document. Lastly, following the original BERT pretraining, a learning rate of 1 · 10\(^{-4}\) with a linear schedule is used, a batch size of 256 utilizing gradient accumulation, and 10,000 warm up steps. Below, in Table 1, the hyper parameters of the pretraining session are presented.

### 3.3 Fine-tuning

The primary way in which pretrained models can be evaluated is to fine-tune them to perform a number of tasks and evaluating their performance on these downstream tasks. Utilizing transfer learning, BERT allows for fine-tuning a model to any traditional NLP task with minimal changes. For each task, the core of the language model is kept intact, in this case the KB-BERT model or the subsequent checkpoints of clinical KB-BERT, and only the final classification layers are changed as appropriate depending on the task. The parameters of BERT are not held frozen but are updated for each task since this has been shown to yield an increased performance compared to only training the final layer (Devlin et al., 2018). As the main aim is to compare the further pretrained checkpoints of KB-BERT with the original KB-BERT, an extensive hyper-parameter search is avoided for the different downstream tasks; instead, the hyper parameters used are within the suggested ranges described by Devlin et al. (2018). As such, and as shown in Table 2, a batch size of 32 is used with a learning rate of 2 · 10\(^{-5}\) for the multi-label classification task, while a batch size of 64 along with a learning rate of 3 · 10\(^{-5}\) is used for the NER and multi-class classification tasks. In all of the cases, training proceeds until loss convergence and early stopping is utilized to stop the training process at that point.

Table 2: Fine-tuning hyper parameters.

However, it should be noted that when the goal is to reach the best possible performance, it is critical to perform a proper hyper-parameter search, as other parameter choices may yield a better result. Furthermore, learning rate schedulers, warm up steps, and gradient constraining approaches, such as gradient clipping, should also be explored as possible performance-enhancing changes. In this study, no extensive hyper-parameter search is conducted, nor are other optimization techniques applied, as the goal is to compare the relative performance of two models rather than obtaining state-of-the-art results on the downstream tasks.

All tasks were performed in a conventional setup where three subsets of each dataset are used: a training set that contains approximately 80% of the dataset, a validation set containing approximately 10%, and a test set containing approximately 10%. However, in the case where a train-test split is already provided, as in the case of the Web News Corpus, the test set is left unchanged and the training-validation split corresponds to 90-10% of the original training set.

Table 3: Comparison of the performance of KB-BERT with its clinical KB-BERT counterpart after the end of 1 epoch of further pretraining on 17.8 GB of clinical text. The first three tasks belong to the clinical domain, while the fourth task belongs to the general domain. The best scores are annotated in bold.

The results indicate that there is a clear benefit in continuing the pretraining process with in-domain data. The clinical KB-BERT outperforms its KB-BERT counterpart on all three clinical NLP tasks, in terms of F1-score. On the PHI NER task, it performs close to two percentage points better in terms of F1-score, with a large increase in recall and more or less the same precision. The improvement on the ICD-10 code assignment task is in the same range as the PHI NER task, but in this case yielding a further increase of both precision and recall. On the Uncertainty task, the performance improvement is not quite as large as for the other two clinical tasks. However, clinical KB-BERT still improves in all the metrics when compared to its KB-BERT counterpart.

However, on the general-domain NER task, the clinical KB-BERT underperforms compared to KB-BERT. It falls short by around 4 percentage points in terms of F1-score and recall, and by more than 2 percentage points in terms of precision. This indicates that adding more pretraining data does not necessarily lead to better downstream performance, and also that the improved performance on the clinical NLP tasks can likely be attributed to including in-domain data specifically, and not simply more data in general.

Furthermore, a number of checkpoints during the pretraining process of clinical KB-BERT are evaluated on the downstream tasks, the results of which are reported in Figure 1. As can be seen in the figure, for the clinical NLP tasks, there is a positive trend in the performance as the pretraining session progresses. This indicates that, as more data is used, clinical KB-BERT becomes better at incorporating and encoding the differences in the distribution of the clinical text and, as a consequence, it becomes better at performing the downstream tasks.

However, in the case of the Uncertainty multiclass classification task, this trend is not quite as clear: although the vast majority of checkpoints of clinical KB-BERT seem to benefit from the continued pretraining with in-domain data, it experiences a low spike towards the end of the epoch, recovering right at the end. In contrast, the performance of clinical KB-BERT in the general-domain downstream task seems to follow a steadily degrading trend as the pretraining epoch progresses, and does not show any clear signs of recovering.

Finally, to illustrate the differences between a general-domain corpus and a clinical-domain corpus, the KB-BERT tokenizer is used to process the texts in the PHI Corpus and the Web News Corpus, respectively. This tokenizer is a word piece tokenizer, as described by Schuster and Nakajima (2012), and is responsible for constructing the vocabulary – gradually building it from the character level and upwards – by maximizing the likelihood of the training data with respect to the vocabulary. The goal is to investigate how the sentences in the general-domain and clinical-domain corpora are split into tokens, subtokens, and character-level tokens. This is done by calculating the average sentence length, in terms of number of tokens, in the respective corpora when applying the KB-BERT tokenizer versus tokenization based on whitespace and regular expressions. As demonstrated in Figure 2, the clinical-domain corpus, after being preprocessed with the KB-BERT wordpiece tokenizer, leads to a larger increase in average sentence length compared to the general-domain corpus.

5 Discussion

As demonstrated by the experimental results, there is potentially much to be gained from continuing the pretraining process of an existing generic language model with in-domain data, confirming the findings of previous work. Adapting a generic language model to a specific domain by exploiting the availability of unlabeled in-domain data helps BERT to better capture the semantics of the target domain as reflected by differences in the underly-
ing distribution. This is highlighted, not only by improved performance on the clinical tasks, but also by the decreased performance on the general-domain task. These results allow us to better understand the reasons behind the improved performance in the target domain and is an aspect that is often overlooked in similar studies. It indicates that improvements yielded by clinical KB-BERT are not solely due to being pretrained on more data – irrespective of domain – but that the domain of the data used for pretraining is indeed an important factor.

It is interesting to observe that these improvements were yielded by continuing to pretrain the language model for only one epoch, and it is possible that further improvements could be obtained by continuing to pretrain on the in-domain data for several more epochs. Moreover, in contrast to similar studies, we also evaluate numerous checkpoints during the pretraining of the the clinical language model. An important observation is that the clinical KB-BERT outperforms the original KB-BERT on all three clinical NLP tasks after using only 20% of the in-domain data. This indicates that it may be worthwhile to adapt general language models and
make them domain-specific even in the absence of enormous amounts of in-domain data.

The general domain and the clinical domain differ primarily in the use of different vocabularies. The vocabulary of a newspaper article, or a work of literature, follows a different language distribution compared to a clinical note or a discharge summary. Clinical texts are typically written in a rather peculiar fashion and contain a large amount of technical terms, as well as (ad-hoc) acronyms and abbreviations, that are not as prevalent and may not even exist in the general domain. There may also be domain-conflicting homonyms, where a word has a completely different meaning in one domain compared to another. Due to these differences in vocabulary and frequency, the result of applying a generic language model’s tokenizer – in this case that of KB-BERT – to a clinical corpus is that the words are likely to be split into subwords, even potentially reaching a character-level split. This was indeed confirmed by the analysis presented in Figure 2. This, in turn, entails that the BERT model will use more relevant word-level token representations and more common subword token combinations for the general-domain corpus compared to the clinical-domain corpora, where, instead, there is likely to be a high contribution of subword or even character-level token representations. This impact of the tokenizer in turn implies that the major workload and information encoding falls onto this subset of subword and character-level representations during continued pretraining on in-domain data. This not only helps to explain the increased performance on the clinical tasks, but also potentially the performance degradation on the general-domain task since there is a potential mismatch between the representations that are more frequent in the general domain versus the ones that are more frequent – and updated during continued pretraining – in the clinical domain.

In future work, this challenge regarding tokenization can be addressed by pretraining a clinical language model from scratch, which would create a tokenizer and vocabulary based on the in-domain clinical data. As shown by previous work, this may lead to further improvements in performance on the clinical tasks. Another approach is to manually add specific tokens to the vocabulary of a pretrained model, as explored by Tai et al. (2020). An informed set of tokens could potentially be extracted by a new tokenizer specifically trained on the in-domain data, and in a later step, incorporate the set difference to the original tokenizer’s vocabulary.

Furthermore, we plan to continue pre-training the current clinical BERT model for more epochs in order to investigate whether this will lead to further improvements in performance, as well as training a new model with pseudonymized data with the aim to make this model publicly available.

Lastly, we also plan to explore and compare different transformer approaches, as well as different pretraining continuation setups, such as using specific parts of the dataset in the spirit of Gururangan et al. (2020). These could include more pretraining continuation setups, such as task-specific pretraining, where the unlabeled training set would be used during the pretraining for more epochs.

6 Conclusions

In this paper, we reported on the development of a clinical language model for Swedish – the first of its kind. The development of the domain-specific BERT model followed the common practice of continuing to train an existing generic language model, KB-BERT, with in-domain data. Compared to previous efforts to develop clinical language models for English, the model was trained using non-pseudonymized clinical data and, in contrast to previously reported results (Alsentzer et al., 2019), yielded improvements also on the de-identification sub-task of identifying protected health information in clinical text.

Furthermore, we carefully investigated the effect of further pretraining an existing language model with in-domain data and evaluated a number of checkpoints during the pretraining process on the downstream tasks. The results showed that continued pretraining with in-domain data yielded improvements on the in-domain tasks, but led to worse performance on a general-domain task, indicating that performance gains on the clinical NLP tasks can indeed be attributed to the domain-specificity rather than the sheer size of the additional pretraining data. Finally, these results further demonstrate the value of developing domain-specific and specialized language models.

Text Retrieval for Language Learners: Graded Vocabulary vs. Open Learner Model

Abstract

A text retrieval system for language learning returns reading materials at the appropriate difficulty level for the user. The system typically maintains a learner model on the user’s vocabulary knowledge, and identifies texts that best fit the model. As the user’s language proficiency increases, model updates are necessary to retrieve texts with the corresponding lexical complexity. We investigate an open learner model that allows user modification of its content, and evaluate its effectiveness with respect to the amount of user update effort. We compare this model with the graded approach, in which the system returns texts at the optimal grade. When the user makes at least half of the expected updates to the open learner model, simulation results show that it outperforms the graded approach in retrieving texts that fit user preference for new-word density.

1 Introduction

Since language learning requires extensive extra-curricular reading, learners can benefit from a text retrieval system that helps them identify suitable reading materials from a pool of candidate texts (Brown and Eskenazi, 2004; Miltsakaki, 2009; Lee, 2021). The suitability of a text may depend on multiple factors, including the user’s reading interests (Heilman et al., 2007b), and the degree of matching between its difficulty and the user’s proficiency. This paper investigates the use of an open learner model (OLM) to predict the latter.

By giving users more control over their learning, OLMs have been shown to foster users’ confidence and reflection on their progress (Bull and Kay, 2007). These benefits are especially important for long-term or life-long learning activities (Kay and Kummerfeld, 2019), such as foreign language learning. We evaluate the effectiveness of an editable OLM (Bull and Kay, 2010) — i.e., an OLM that allows the user not only to view but also to modify its content — for text retrieval for language learning. As their vocabulary expands, users can update the OLM so that the system continues to retrieve texts that are lexically challenging to them. Specifically, we address two research questions:

Text retrieval performance (Q1): How accurately can an OLM identify reading materials with the desired density of new vocabulary, as specified by the user?

User update effort (Q2): How frequently does the user need to edit the OLM in order to reap its benefits?

Most previous research in computer-assisted language learning measured text retrieval performance through holistic evaluation (Heilman et al., 2007a), or in terms of users’ overall learning outcomes (Hsu et al., 2013). In answering Q1, we will directly evaluate the density of new vocabulary in the retrieved texts. In addressing Q2, we will further consider how retrieval performance is affected by users’ vocabulary acquisition over time and the amount of user update effort.

The rest of the paper is organized as follows. After a review of previous work (Section 2), we define our text retrieval framework (Section 3). We then describe and motivate the user simulation (Section 4). Next, we present the OLM approach and the baseline graded approach (Section 5). Finally, we compare the performance of the OLM and the graded approach with respect to the amount of user update effort (Section 6).

2 Previous work

While text difficulty can be influenced by a variety of lexical, syntactic, semantic and discourse features, many text recommendation systems focus on vocabulary (Brown and Eskenazi, 2004; Hsu et al.,...
2013; Wu, 2016), likely due to the strong correlation between vocabulary difficulty and text difficulty (Heilman et al., 2007b; François and Fairon, 2012). Our study will similarly adopt vocabulary difficulty as the text retrieval criterion.

Various approaches have been proposed for matching language learners with reading materials at a suitable level of lexical difficulty. The graded approach, also known as the leveling approach, places users and documents on a common scale, such as school grades (Mitsakaki and Trout, 2008; Collins-Thompson et al., 2011). The system performs automatic readability assessment on each document and labels it with a grade to reflect its difficulty. This approach may not be able to capture individual learning patterns, however, as users are pigeon-holed into pre-defined grades.

As an alternative, the adaptive approach identifies user traits and preferences, and then adjusts the pedagogical content in the system to optimize learning outcomes (Brusilovsky, 2012; Vandewaetere et al., 2011). In the context of text retrieval for language learning, the system typically maintains a learner model on the user’s linguistic proficiency, and then returns texts that best fit the model. The learner model may be estimated through user updates (Lee, 2021); formal assessment such as cloze items (Heilman et al., 2010); complex word identification models trained on vocabulary self-assessment by the user (Yeung and Lee, 2018); time log and click history patterns (Hokamp et al., 2014); as well as dictionary and translation queries by the user (Wu, 2016), among other non-invasive methods.

One disadvantage of the graded approach is the “jump” in difficulty when promoting the user from one grade to the next. The adaptive approach can potentially provide more fine-grained adjustments by gradually raising the vocabulary difficulty in the retrieved texts. To the best of our knowledge, there has not been any direct, quantitative comparison between these two approaches during a period of vocabulary acquisition by the user. This paper aims to fill in this gap.

3 Text retrieval framework

After motivating the use of vocabulary difficulty as the retrieval criterion (Section 3.1), we describe its implementation in the learner model (Section 3.2) and its application in the retrieval model (Section 3.3).

3.1 Retrieval criterion

The ideal text should have an appropriate amount of new vocabulary, so that it stretches the reader’s competence without hindering comprehension. We quantify vocabulary difficulty by new-word density (Holley, 1973) (NWD), i.e., the percentage of words in the text that are new for the user. This metric is more straightforward to interpret and more transparent than grades, since users can easily examine the basis of retrieval results.

The system aims to return texts at a Target NWD that is specified by the user. The user thus has the freedom to set a relatively high Target NWD, for example, to maximize vocabulary acquisition, or set a relatively low one for leisure reading without dictionary look-ups.

3.2 Learner model

A language learner knows only a limited number of words in the foreign language. For each user $u$, we refer to this set of words as his or her vocabulary set, denoted as $\text{voc}(u) = \{w_1, \ldots, w_n\}$. Although nuances in lexical knowledge may be more precisely expressed with a real-number score (Yimam et al., 2018) or on a Likert scale (Ehara et al., 2012; Shardlow et al., 2021), we opted for the simpler known/unknown distinction to enable an intuitive interpretation of the NWD metric.

Since the system does not know the ground-truth vocabulary set $\text{voc}(u)$, the learner model needs to make an estimation $\hat{\text{voc}}(u)$ for each user $u$. It can be effective to use automatic methods to re-estimate the vocabulary set as the user acquires new vocabulary (Section 2). However, we choose to base our evaluation on manual edits to an open learner model (OLM). This methodology has the advantage of being agnostic to the update algorithm, which may include any combination of manual and automatic methods, and may vary from one text retrieval system to another. Our results will therefore not be tied to any particular algorithm, but rather measure text retrieval performance with respect to varying amounts of valid updates (Section 5.1).

3.3 Retrieval model

The NWD of a document varies according to the user’s vocabulary set. Formally, given a document $d$ with $D$ words, say $d = [w_1, \ldots, w_D]$, its Actual
NWD for user $u$ is:

$$\frac{1}{D} \sum_{i=1}^{D} \text{new}_u(w_i)$$

(1)

where $\text{new}_u(w) = 0$ if the word $w \in \text{voc}(u)$, and $\text{new}_u(w) = 1$ otherwise.

Again, since the system has no access to the ground truth $\text{voc}(u)$, it must use $\text{voc}(\hat{u})$ to compute an Estimated NWD. The retrieval model returns the text whose Estimated NWD is closest to and not exceeding the Target NWD as specified by the user (Section 3.1).

4 Methodology

After motivating the advantages of using a simulation to compare the open learner model (OLM) and the graded vocabulary approach (Section 4.1), we give details on the simulation set-up (Section 4.2) and implementation details (Section 4.3) and define the evaluation metrics (Section 4.4).

4.1 Human subjects vs. user simulation

In the context of this study, text retrieval performance can be influenced by two variables: the Target NWD (Section 3.1) and the frequency of user update to the learner model (Section 3.2). It is therefore helpful to consider multiple configurations of these two variables.

There are a number of trade-offs between a user study and a user simulation. In the former, the subjects would need to perform text searches over a sufficiently long period of time to allow for substantial vocabulary acquisition. Throughout this period, they would need to read the retrieved texts and exhaustively annotate the unknown words therein, while experimenting with various update frequencies. This design has the advantage of providing authentic human data on vocabulary acquisition. However, it would introduce confounding factors such as differences among the subjects’ proficiency levels, ability to work with the user interface, and diligence in updating the learner model. These factors are difficult to control for but can significantly influence the experimental results.

A user simulation can facilitate a more rigorous comparison by keeping these factors constant. It can also cheaply evaluate a large number of text searches, with no constraint on the length of the experimental period. The main disadvantage is that the users’ vocabulary acquisition would need to be prescribed rather than empirically observed.

This issue can be partially mitigated by consulting vocabulary lists, such as the widely used *Hanyu Shuiping Kaoshi* (HSK), which were crafted by experts with support from empirical data to reflect typical language learners (Hanban, 2014).

Given our research goals, we feel that the overall advantages of a simulation outweigh its disadvantages. Our simulation will be able to evaluate over 6K recommended documents in various experimental settings, a set of data points that is an order of magnitude larger than what we would have been able to gather from human subjects.

4.2 Simulation set-up

We simulated a user who searches for extracurricular reading materials for learning Chinese as a foreign language. We ran the simulation three times, with the Target NWD parameter set to $m\%$ NWD, for $m = \{20, 30, 40\}$.

**Text retrieval.** At times $i = 1, \ldots, k$, the user performs a text search to obtain documents whose Estimated NWD is closest to and not exceeding $m\%$ (Section 3.3). The user reads the top-ranked document that he or she has not yet read, and updates the OLM while reading (Section 5.1). Let $d_i$ represent the document read by the user at the $i$th search.

**Vocabulary acquisition.** Between two consecutive searches, the user learns a number of new words. Let $u_i$ represent the user at the $i$th search, and let $W_i$ represent the set of new words learned between the $i$th and $(i + 1)$th searches. The user’s vocabulary set expands during this period as follows:

$$\text{voc}(u_{i+1}) \leftarrow \text{voc}(u_i) \cup W_i$$

(2)

4.3 Simulation implementation

Let $V_l$ denote the accumulative set of words in the HSK graded vocabulary lists up to level $l$, for $l = 1, \ldots, 6$. We set $\text{voc}(u_0) = V_5$ and $\text{voc}(u_6) = V_6$. This means that the user initially knows all the words listed up to HSK level 5, and then learns the words at level 6 during the simulation period.

We set a uniform learning rate at $|W_l| = 6$, meaning that six words are learned between two searches. The acquisition order is in reverse of word frequency in Chinese Wikipedia.

4.4 Evaluation metrics

We use two metrics to evaluate text retrieval performance:
NWD Error The difference between the Actual NWD of \( d_i \) and the Estimated NWD of \( d_i \). This metric measures how much the estimated difficulty of the recommended document deviates from the ground truth. Recall that Estimated NWD is computed according to the estimated vocabulary set \( \text{voc}(\hat{u}_i) \), while Actual NWD is based on \( \text{voc}(u_i) \). These two figures differ whenever new words learned by the user appear in \( d_i \) but have not been updated in the learner model.

NWD Gap The difference between the Actual NWD of \( d_i \) and the Target NWD (Section 3.1). This metric expresses the discrepancy between the actual difficulty of the recommended document and the difficulty requested by the user.

5 Approach

As users learn new words, a document’s new-word density (NWD) decreases. Periodic updates to the vocabulary set and re-estimation of the NWD of candidate documents are therefore necessary to ensure that the retrieved texts remain adequately challenging. We compare two approaches for this task.

5.1 Open learner model (OLM) approach

In the OLM approach, users are expected to manually update the vocabulary set described in Section 3.2. Hence, user update frequency crucially affects retrieval performance. If a user reports all newly acquired word to the OLM before using the text retrieval system, there would be no NWD Error. In practice, the user will likely update these words only after he or she encounters them when reading a recommended document \( d_i \). At the time of search, the newly learned words would remain outside the vocabulary set and contribute to the NWD Error. We experimented with two update frequencies:

**Full Update** This frequency models the conscientious user who updates all words (that require update) when he or she reads the top-ranked documents \( d_i \). Hence, following the \( i \)th search, the vocabulary set is updated as follows:

\[
\text{voc}(\hat{u}_{i+1}) \leftarrow \text{voc}(\hat{u}_i) \cup \left( d_i \cap \text{voc}(u_i) \right)
\]  

**Occasional Update** This models the more casual or conservative user who performs update on only half of the words in \( d_i \) that require update. In this more realistic scenario, newly learned words may remain excluded from the vocabulary set \( \text{voc}(\hat{u}_i) \) even after the user has read them in multiple documents.

5.2 Graded Approach

Akin to a graded reader, the graded approach relies on the user to choose his or her grade, and assigns the vocabulary list corresponding to that grade as the vocabulary set. To create a strong baseline, we assume that the user always chooses the optimal grade. More formally, at time \( i \), the graded approach uses the vocabulary list \( V_\ell \) that achieves the highest F-measure for the ground-truth vocabulary set \( \text{voc}(u_i) \). In our case, then, the graded approach uses \( V_6 \) in the first half of simulation, and then switches to \( V_6 \) at the optimal time, when the user’s lexical knowledge becomes closer to level 6.

This set-up gives the graded approach several advantages over the OLM. The graded approach not only selects the optimal grade, but also “knows” the words that the user will be learning in the simulation (namely, those in \( V_6 \)). The OLM, in contrast, has no access to \( V_6 \) and relies only on user updates. Our simulation result will gauge the amount of user update necessary to reap the benefits of OLM over the graded approach.

6 Results

We conducted the simulation with a database of 1923K Chinese Wikipedia entries and 29K short essays.\(^1\) We performed automatic word segmentation on all documents with the Stanford CoreNLP parser (Manning et al., 2014). We now present a chronological analysis of the simulation (Section 6.1), and then examine the overall experimental results (Section 6.2).

6.1 Chronological analysis

Figure 1 plots the Actual NWD of the top-ranked documents \( d_i \) over the course of the simulation, with the Target NWD set to 20%.

**OLM approach (Full Update).** Throughout the simulation, the model retrieved documents whose Actual NWD was relatively close to the 20% target, with the NWD Gap never exceeding 2%. The

\(^1\)The short essays were downloaded from the website duanmeiwen.com
Actual NWD was consistently below the target because the user would not update the status of newly learned words until he or she reads them in $d_i$.

**Graded approach.** In contrast, the NWD Gap for the graded approach reached a maximum of 5%. The Actual NWD of the recommended documents was initially close to the 20% target. With the vocabulary set kept constant at HSK level 5 during the first half of the simulation, the user’s vocabulary acquisition led to a widening of the NWD Gap, up to 5% towards the middle of the simulation. At this point, with the promotion of the user to level 6, the NWD spiked to as high as 24.0%. The Actual NWD then gradually converged back to the 20% target towards the end of the simulation.

### 6.2 Overall results

Table 1 reports the average NWD Gap and NWD Error over the entire simulation. The OLM outperformed the graded approach at both update frequencies (full and occasional) and at all three targets (20%, 30%, 40%). We first analyze the results at 20% Target NWD, and then examine the effects of higher targets.

**Target NWD at 20%**. The OLM achieved the smallest NWD Gap with Full Update, at only 0.55% below the target. Aided by incremental adjustment to the vocabulary set, it more accurately re-estimated the user’s current vocabulary competence, which in turn led to better NWD estimation.

Occasional Update made the OLM more prone to over-estimate the difficulty of the documents, and hence produced a larger gap (0.84%). The graded approach incurred the largest NWD Gap, with an average of 1.69%. The gap was largest when the user was half-way between levels 5 and 6, since it was forced to choose one of the two and could not offer a middle ground.

In terms of NWD Error, the OLM also outperformed the graded approach at both update frequencies. The OLM was able to retrieve documents whose NWD more closely fits the user’s target.

**Effects of higher Target NWD.** At higher NWDs, a larger pool of candidate documents can

</table>

Table 1: New-word density (NWD) Gap and NWD Error of the top-ranked documents returned by the graded approach and the open learner model (OLM)
fit the search criteria. In general, a document with more difficult words exposes the OLM to more chances of failing to recognize the user has learned those words. As a result, the higher the Target NWD, the larger the NWD Gap, i.e., the farther the recommended documents fell short of the target. For the OLM with Full Update, NWD Gap increased from 0.55% (Target=20%) to 0.84% (Target=30%) and 1.07% (Target=40%). A similar increase can be observed in the Occasional Update setting. These experimental results suggest that text retrieval is more challenging when the user requests documents with more advanced vocabulary.

7 Conclusions

Automatic text retrieval supports language learners in self-directed reading and independent learning. A major challenge in this task is to match learners with different capabilities to texts with appropriate vocabulary complexity.

We have evaluated an open learner model (OLM) that allows users to update their individual progress in vocabulary acquisition. We compared this model to the graded approach, where the system recommends texts to users at the optimal grade. We conducted a simulation of a learner of Chinese as a foreign language who uses the retrieval system during a period of vocabulary acquisition. Results show that the OLM outperforms the graded approach in retrieving texts at a range of target NWDs. When the user makes at least half of the expected updates, the OLM’s fine-grained, incremental adjustment yields superior retrieval performance.

We believe these results can help inform the design of text retrieval systems for language learners. In future work, we intend to further improve retrieval quality by extending the OLM beyond vocabulary to other dimensions of text difficulty, such as syntactic and semantic complexity.

Transforming Multi-Conditioned Generation from Meaning Representation

Joosung Lee
Kakao Enterprise Corp., South Korea
rung.joo@kakaoenterprise.com

Abstract

Our study focuses on language generation by considering various information representing the meaning of utterances as multiple conditions of generation. Generating an utterance from a Meaning representation (MR) usually passes two steps: sentence planning and surface realization. However, we propose a simple one-stage framework to generate utterances directly from MR. Our model is based on GPT2 and generates utterances with flat conditions on slot and value pairs, which does not need to determine the structure of the sentence. We evaluate several systems in the E2E dataset with 6 automatic metrics. Our system is a simple method, but it demonstrates comparable performance to previous systems in automated metrics. In addition, using only 10% of the dataset without any other techniques, our model achieves comparable performance, and shows the possibility of performing zero-shot generation and expanding to other datasets.

1 Introduction

In many conversation systems, generating sentences with specific information is useful. For example, it can be used in chatbot systems or spoken dialogue systems to generate utterances that contain meaning representations (MRs) corresponding to a user’s query. In order to train the NLG system that reflects this variety of information, a large amount of labeled data is required. At the 2017 E2E challenge (Dušek et al., 2019), a large dataset was released, which consisted of pairs of MRs representing restaurant reviews and corresponding utterances. Table 1 shows an example. MRs can be regarded as the multi-conditions type of utterance generation, which consists of slots and values, and the corresponding utterances are references written by humans. We focus on training the model to generate utterances directly from MRs.

Many of the previous NLG research are a two-stage approach through sentence planning and surface realization. Sentence planning determines the overall sentence structure and surface realization is the process of flattening the sentence structure. In recent studies (Konstas and Lapata, 2013; Dušek and Jurčiček, 2016; Juraska et al., 2018), these two stages are processed at once by learning end-to-end without aligned data with a neural network.

When generating sentences from an input (flat or structured MR), there are a template-based approach and a neural network-based approach. Smiley et al. (2018); Puzikov and Gurevych (2018); Wiseman et al. (2018) generate sentences based on template. The template method is to obtain the structural sets of sentences corresponding to MRs from training data and apply the template appropriate to the test data to generate the sentences. In Smiley et al. (2018); Puzikov and Gurevych (2018), a template is formed based on rules, and Wiseman et al. (2018) learns the template structure of a sentence as a neural network.

There is also a way to generate a natural language with a neural network without using a template. Dušek and Jurčiček (2016); Smiley et al. (2018); Puzikov and Gurevych (2018); Juraska et al. (2018); Elder et al. (2019); Gehrmann et al. (2018) are sequence-to-sequence models of encoders and decoders, which have a one-stage framework, and

</tbody>
</table>

Table 1: An example of an E2E dataset consists of pairs of a MR and an utterance.
Dušek and Jurčíček (2016) is the model used by E2E challenge organizers. In Balakrishnan et al. (2019), the encoder and decoder model converts flat MRs to structure MRs, and outputs the sentence through constrained decoding.

Template and neural network methods each have advantages and disadvantages. The template method guarantees a certain performance but limits the diversity and possibilities of the output. The neural network method generally performs better than the template method, but requires a lot of data and has limitations in the naturalness and semantical correctness of sentences (Nayak et al., 2017).

We propose a novel approach using the Transformer decoder as a simple one-stage framework. In our model, GPT2-small (Radford et al., 2019) is the backbone, and \((s_i, v_i)\) pairs of the meaning representation are put into multiple conditions to generate a sentence. In the previous works (Juraska et al., 2018; Balakrishnan et al., 2019; Smiley et al., 2018; Puzikov and Gurevych, 2018; Dušek and Jurčíček, 2016), when receiving the meaning representation as input, the value is delexicalized. Specifically, all values corresponding to the same slot are delexicalized to a placeholder so that unseen inputs can be processed. However, Nayak et al. (2017); Juraska et al. (2018) report that delexicalization often leads to inappropriate behavior in scenarios. For example, the word "cheap" can be reflected in the utterance that matches the value of "less than $20". Also, when food[Italian] is given as slot[value], "Italian food" is an appropriate phrase in a generated utterance, but in the case of food[fast food], "fast food food" is an incorrect phrase. Additionally, the combination of eatType[coffee shop] and food[Italian] is rather weird, and the combination of name[The Rice Boat] and area[riverside] is appropriate, so delexicalization doesn’t fully utilize the characteristics of tokens. We, therefore, treat the slot as a special token and the value as a regular token of vocabulary without delexicalization in the training. Nevertheless, in testing for unseen values, the model generates appropriate utterances and is described in Section 4.3. Our method is considered as generating a sentence as a simple one-stage framework directly from flat MRs.

Our model is tested on the E2E dataset. In addition to the evaluation metrics used in the E2E challenge, the systems are evaluated with BERTScore (Zhang* et al., 2020). Our approach shows the best performance in BLEU, METEOR, and BERTScore and competitive performance in other metrics. By leveraging the pre-trained model GPT2, we quickly converge the model with only a few epochs and generate fluent utterances without considering the structure of the sentence. In addition, even if only 10% of the training data is used, it achieves performance comparable to previous systems.

2 Related Work

In many NLP tasks, the Transformer-based (Vaswani et al., 2017) models have recently shown good performance. Gehrmann et al. (2018) is a previous work using the Transformer encoder and decoder in the E2E task. BERT (Devlin et al., 2019) composed only of the Transformer encoder is used a lot in NLU tasks, and GPT (Radford et al., 2019) composed only of the Transformer decoder is used a lot in NLG tasks. These models are trained as large-scale open-domain corpora. By leveraging pre-trained models trained on large datasets and applying them to downstream tasks, many NLP tasks achieve better performance.

The generation of utterances from MRs is quite similar to machine translation, one of the sequence-to-sequence tasks. Also, in terms of generating sentences with certain restrictions, it is similar to style transfer (Logeswaran et al., 2018; Lample et al., 2019; Lee, 2020), which is one of sequence+condition-to-sequence tasks. However, the generation of utterances from MRs is not exactly the same as the above tasks because of the condition-to-sequence perspective. Since the E2E task does not have a given sequence as the input of the model, we approach the sentence generation using only the decoder without sequence encoding. We choose a language model of the Transformer decoder that performs better than LSTM and uses the pre-trained model GPT2 as a backbone.

3 Our Approach

3.1 Problem Statement

E2E dataset The domain of the E2E dataset is a restaurant and consists of \(D = \{(M_1, u_1), \cdots, (M_n, u_n)\}\). \(M_i\) is the MR and contains the (slot, value) pair, \((s_i, v_i)\), and \(u_i\) is the corresponding utterance. There are \(8\) types of slots, and the value corresponding to each slot has various numbers (2 to 34). Statistics of the overall dataset are shown in Table 2.
### Table 2: Statistics of E2E dataset provided by Dušek et al. (2020).

<table>

<td>26.76</td>
<td></td>
</tr>
</tbody>
</table>

The goal of the task is to generate a $u_i$ by reflecting $M_i$. $s_i$ is the concept of a given category of conditions, and $v_i$ is an item that should actually be reflected in utterance generation. Since utterances can also reflect values as synonyms, changing them to a single placeholder is considered a risk that the processing of input and output will not work properly. In model training, not only delexicalization but also preprocessing of special data such as Smiley et al. (2018) is not performed, and the model is expected to learn about tokens and phrases with different inputs and outputs such as synonyms.

### 3.2 Pre-trained Model: GPT2-small

Our system uses GPT2-small model as a backbone to generate utterances and is illustrated in Figure 1. GPT2 is an unsupervised pre-trained model with large-scale open-domain corpora of unlabeled text. GPT2 uses only the Transformer decoder and generates sentences from left to right autoregressively without an encoder. GPT2-small has 768-dimensional embedding size, 12 heads, and 12 layers, so the total number of parameters is 117M. Our system has the advantage of starting from knowing the token distribution by using the pre-trained model as the initial state.

### 3.3 Generation

As conditions of an utterance generation, $(s_i, v_i)$ pairs of a flat MR are given, slots are treated as special tokens. Specifically, the tokens for slots and start are added to vocabulary, and the regular tokens in vocabulary are used for values and end. In order to distinguish between special tokens and regular tokens, special tokens are changed to $<$SPECIAL TOKEN$>$ to form vocabulary. Inputs are given by concatenating the given $(s_i, v_i)$ pairs in order (e.g. $<$name$>$, Giraffe, $<$eatType$>$, pub, ...). We use $<$name$>$, $<$eatType$>$, $<$food$>$, $<$priceRange$>$, $<$customer rating$>$, $<$area$>$, $<$familyFriendly$>$, $<$near$>$ in the fixed order of slots as formed in the E2E dataset, and do not put slots not in the given MR as input. Our system generates utterances by considering the MR as multi-conditions of generation. Through training end-to-end Multi-Conditioned generation, we hope that the model find out the role of a MR.

Transformer Decoder is autoregressively unidirectional from left to right, so the model only sees the previous tokens:

$$\alpha_i = \text{TransformerDecoder}(u_1^{i:k}, \langle \text{start} \rangle, s_i, v_i)$$

where $u_1^{i:k}$ denotes tokens up to $k$th tokens of $u_i$, $\alpha_i$ is the output of the Transformer Decoder, $k \times h$ tensor, and $h$ is the hidden embedding dimension of the decoder.

To predict the token of the next step $(k + 1)$, multiply the $k$th-vector $\alpha_i^k$ by matrix $M$ as follows:

$$u_i^{k+1} = \text{argmax}(M(\alpha_i^k))$$

where $M$ is a randomly initialized matrix.

Because our system is a one-stage framework that generates utterance directly from flat MRs, sentence planning and surface realization are not considered separately. Our approach shows strong results in 4.2 without additional techniques such as delexicalization, data augmentation, and extra datasets. When testing, it is possible to deal with unseen values by delexicalization, which is described in detail in Section 4.3.

### 3.4 Training

We experiment using one V100 16GB GPU in Linux environment on an AWS server. Our system is end-to-end trained with the AdamW (Loshchilov and Hutter, 2019) optimizer for 5 epochs. The initial value of the learning rate is 2e-5 and is adjusted with a linear scheduler. The model is trained so that the output at the current step $(k)$ predicts the token of the next step $(k + 1)$ and the loss of the objective function is calculated as:

$$L(\theta) = - \sum_{(M_i, v_i) \in D} \log p(u^1_i | s_i, v_i) + \sum_{k=1} \log p(u_i^{k+1} | u_i^{1:k}, s_i, v_i) + \log p(\langle \text{end} \rangle | u_i^{1:k}, s_i, v_i)$$

where $u_i^k$ is the $k$th tokens of $u_i$ and $\langle \text{S}\rangle$, $\langle \text{E}\rangle$ are start, end token respectively. Since the ground truth given in the dataset is only utterance, the outputs before $\langle \text{S}\rangle$ is entered cannot be used for loss calculation.

During training time, tokens are generated by applying teacher-forcing, and tokens are generated by self-feeding during testing time.
Figure 1: Our structure has GPT2 backbone based on the Transformer decoder. Blue tokens are special tokens that are newly added to the vocabulary. The model autoregressively starts to generate utterance from when the \texttt{<START>} token is received as input, and ends when the \texttt{<endoftext>} token is output.

4 Experiments

We use the model provided by HuggingFace \footnote{https://huggingface.co/gpt2} to make it easy to use the pre-trained GPT2 trained by OpenAI.

4.1 Evaluation Metrics

We use the five automatic evaluation metrics used in the E2E Challenge, BLEU (Papineni et al., 2002), NIST (Lin and Och, 2004), METEOR (Denkowski and Lavie, 2014), ROUGE (Lin, 2004) and CIDEr (Vedantam et al., 2015), equally as the basis. Evaluation scripts are provided by challenge organizers \footnote{https://github.com/tuetschek/e2e-metrics}. We additionally calculate the similarity F1 scores of the two sentences using the BERTscore of RoBERTa model (Liu et al., 2020) provided by the library \footnote{https://pypi.org/project/bert-score/}. The two sentences entered in the BERTscore library are the generated utterances and human references. The BERTScore metric is task agnostic and, unlike previous metrics, uses importance weighting between contextual embedding. Therefore, it is a common metric that calculates a better correlation by solving the disadvantages of the previous metric. BERTScore is measured only for the systems that provided the output for the test dataset.

4.2 Results

Table 3 shows the experimental results of our system and comparison systems. The first section is our model \textit{Multi-Conditioned Transformer}, which consists of the Transformer decoder.

4.2.1 Compared Systems

TGen (Dušek and Jurčiček, 2016) is the baseline tested by the E2E challenge organizer. SeqGen (Smiley et al., 2018) is the system that participated in the challenge, and Slug2Slug (Juraska et al., 2018) is the system that won the E2E challenge. Slug2Slug improves performance by learning the surface realization model as additional data and ensemble the three models. Model-T (Puzikov and Gurevych, 2018) and TempleGen (Smiley et al., 2018) are rule-based systems using templates. NTemp + AR (autoregressive) (Wiseman et al., 2018) is a hidden semi-markov model (HSMM) decoder that learns the structure of a template. Template-based systems guarantee a certain quality and fluency of natural language generation, but overall performance is lower than neural networks. Dot-copy and Transformer (Gehrmann et al., 2018) are methods of learning the structure of a template with a neural encoder and decoder. The hyperparameter $K$ of these two systems indicates the number of models to be diverse ensembling. TripAdvisor (Elder et al., 2019) follows a two-stage approach: (1) content selection at the system input to generate a symbol intermediate representation and (2) generating utterance. Each stage proceeds with the structure of a neural encoder and decoder and improves the performance of the model with additional data.

4.2.2 Automatic Evaluation

The performance of our system and the comparison systems are shown in Table 3. In these systems, Multi-Conditioned Transformer achieves the best performance in BLEU, METEOR, and BERTScore, and the second-best in NIST. Our system also shows competitive performance compared to previous systems in ROUGE and CIDEr metrics. We experimented with at least 3 random seeds and observe that our model always reaches similar performance.

"No pre-trained" is a model trained from scratch and the rest are the same except for initialization. If our model is trained without the pre-trained tech-

4.2.3 Human Evaluation

Human evaluation is performed for quality and naturalness as in Dušek et al. (2020); Juraska et al. (2018), and the results are shown in Table 5. Quality is a score for grammatical correctness and whether generated utterance properly reflects given MRs. Naturalness is a rating of the possibility that utterance is written by a native speaker, regardless of the MRs. We randomly sampled 200 samples from our test set and hired 3 workers from Amazon Mechanical Turk 4 to rate them on a scale of 1(bad)-5(good). Slug2Slug is a system that ranked first and second in quality and naturalness, respectively, in the E2E challenge. In human evaluation, our model shows better than baseline TGen and Slug2Slug.

---

4https://www.mturk.com/
4.2.4 Utterance Generation

Table 4 shows the output of the systems. As with BERTscore calculations, other comparative systems with no output provided cannot verify the utterances. When there are three \((s_i, v_i)\) pairs, there is no difference between our system and previous systems. However, as the number of pairs increases, the possible sentence structures vary, so different systems output different utterances. Test data with many pairs is considered to make a difference in automatic evaluation performance. Since our system is based on the Transformer, it can be more robust and general to long-term sequences than LSTM-based systems.

4.2.5 Training with Less Data

The 2nd and 3rd rows of Table 3 are the results of fine-tuning our model by sampling only a small amount of training dataset. For small training data, 10% and 30% of the entire training dataset are randomly sampled. Our model is trained and averaged by performing random sampling three times in consideration of the possibility that the performance of the model may vary according to the statistics of the randomly sampled dataset. We found that the performance of our model was similar even with random sampling. Our system shows a similar level of performance with a small standard deviation according to the sampled data.

As the sampling of the training data of the system increases, the performance of the system improves. However, if we use more than 50% of the training data through many experiments, our system has little improvement in performance. Our approach can leverage the pre-trained language model to take advantage of the background knowledge of sentence generation. Therefore, it is difficult to expect a linear relationship between increasing the number of training data and increasing performance. However, with the effect of background knowledge, our system, which was trained by sampling 10% of the training data, shows performance comparable to previous systems. The performance of the model trained by sampling 30% of the data is similar to that of the Slug2Slug, the system that won the E2E challenge. Building our system with only 30% of the training data and showing good results demonstrates the effectiveness of using the pre-trained model. If a better pre-trained model is used as the backbone, we hope to build an effective model with less data.

4.3 Generation from Unseen Values

Our model is not trained on unseen values, so it can have weaknesses in real applications. Therefore, we introduce a zero-shot generation method through Sim-Delexicalization. Table 6 shows an example of this experiment. The value of \(<\text{familyFriendly}>\) is not treated as unseen value because it only has \((\text{yes or no})\). Our system generates proper utterance through the following two steps for zero-shot generation.

1. **Sim-Delexicalization:** The given unseen values are replaced with similar values among the lists of value corresponding to the same slot. In the first example of Table 6, "Green Man" is replaced by "Blue Man" and "2.1 out of 5" is replaced by "3 out of 5". In the second example we observe that expensive is replaced by high. Also, taking into account the grammatical aspect, if an unseen value containing "the" in the \(<\text{name}>\) and \(<\text{near}>\) slots are given, the value list containing "the" is limited as a candidate (and vice versa). There can be several ways to find similar tokens, but we use BERTscore to select the value with the highest score.

2. **Relexicalization:** Replaced values are changed back to unseen values in generated utterances. "Green Man" is deciphered as "Blue Man" and other values proceed as well.

The generated utterances are of appropriate quality from a human perspective. In the previous study, unlike delexicalization of unseen values to one placeholder, we have the difference of converting to similar values. Changing to one placeholder in the test also has the same risk as in training above, so we used the existing list of values to change it to an appropriate value each time. In other words, our system can generate utterances that are suitably customized for a given \((s_i, v_i)\). Rather than using only BERTscore, it may be helpful to find similar words using word embedding techniques such as Glove (Pennington et al., 2014) and FastText (Bojanowski et al., 2017) but this will be left for further study.

4.4 Experiments on a Different Dataset

Our paper focuses on the E2E dataset, but for the possibility of scaling, we do a simple experiment in the WebNLG challenge task (Colin et al., 2016) similar to the E2E dataset with the same approach. The WebNLG dataset is collected from DBpedia, and the train, development, and test datasets are
Table 6: Zero-shot generation from unseen values. Given unseen values, the system generates an utterance subject to delexicalization of unseen values to similar seen values.

Table 7: Example of the WebNLG dataset. In one sample, the category is fixed as Airport, and multiple values corresponding to (subject, property, object) can be given.

Table 8: Comparison of systems evaluated with the WebNLG dataset. It was evaluated using the same library as the E2E dataset.

6940, 872, and 1862, respectively, and examples are shown in Table 7. It is significantly smaller than the E2E dataset, and MRs consisting of values corresponding to four (category, subject, property, object) slots are given as a condition. In other words, unlike E2E, the WebNLG dataset has 4 fixed slots, but multiple values can be given.

Table 8 shows the experimental results, and the three comparison systems that participated in the challenge (Gardent et al., 2017) are as follows: (1) The baseline is a neural system trained with OpenNMT. (2) Melbourne shows the best score for all automatic evaluations in the WebNLG dataset, and MRs consisting of values corresponding to four (category, subject, property, object) slots are given as a condition. In other words, unlike E2E, the WebNLG dataset has 4 fixed slots, but multiple values can be given.

Table 8 shows the experimental results, and the three comparison systems that participated in the challenge (Gardent et al., 2017) are as follows: (1) The baseline is a neural system trained with OpenNMT. (2) Melbourne shows the best score for all automatic evaluations in the challenge with an end-to-end LSTM with attention model. Performance is improved by preprocessing entity tagging by collecting information from DBPedia. (3) UPF-FORGe (Mille et al., 2017) is a grammar-based NLG system and has the highest score in human evaluation through rule-based graph-transducers for syntactization.

The systems are evaluated in the same way as the E2E dataset and our system is better than the baseline but slightly worse than the best systems in many metrics. However, our system shows meaningful results in BERTscore and is a simple method that utilizes a pre-trained model without any rule definition, preprocessing, or other datasets. If we preprocess the data like the comparison systems above, our model can expect better performance.

4.5 Analysis
Section 4.3 experimentally demonstrates that our approach is capable of zero-shot generation, a situation not found in the training. The system is trained to generate appropriate utterances for \((s_i, v_i)\) without the delexicalization. Therefore, there is no need to take the ambiguous risk of replacing unseen values with a single delexicalization of placeholders. Instead we introduce sim-delexicalization, which allows the system to reflect unseen values.

The two-stage framework needs to reveal the structure of the sentence, so it is difficult to solve as the number of \((s_i, v_i)\) pairs increases. However, our approach is easily extensible for more pairs. In the WebNLG dataset, we show that it is possible to extend multiple values as well. Since only slots are replaced with special tokens and values are used as regular tokens, our system can be trained to learn the utterance corresponding to MRs without limiting the number of pairs.

We also conducted experiments using a larger backbone model, GPT2-large, but the change in performance is small.

5 Conclusion
This paper presents a simple one-stage approach to generating natural utterances from flat MRs. Our system uses a pre-trained model language model to improve the performance of the system and shows that it is better than the system that won the challenge in human evaluation. Even if our model is trained with only a small amount of sampling data due to the leveraging effect, it is comparable to the previous models. Our approach is simple, efficient, easy to extend to multiple MRs (i.e. WebNLG), and enables zero-shot generation without additional data through sim-delexicalization.

Abstract

We present a neural-network-driven model for annotating frustration intensity in customer support tweets, based on representing tweet texts using a bag-of-words encoding after processing with subword segmentation together with non-lexical features. The model was evaluated on tweets in English and Latvian languages, focusing on aspects beyond the pure bag-of-words representations used in previous research. The experimental results show that the model can be successfully applied for texts in a non-English language, and that adding non-lexical features to tweet representations significantly improves performance, while subword segmentation has a moderate but positive effect on model accuracy. Our code and training data are publicly available¹.

1 Introduction

Dramatically increasing data storage and processing capacities have resulted in an explosion of available data, and of potential uses for the many kinds of knowledge or insights that could theoretically be extracted from that data. The development of Web 2.0 has created unprecedented amounts of text, and, in recent decades, images and videos. But the sheer volume of the available data is problematic due to a shortage of human resources (time and attention) available for analyzing or even just browsing through it all, as described in (Verma et al, 2016). From the very start, as soon as machine learning techniques appeared, they were immediately applied to text analysis. Neural networks have proven particularly suitable for such tasks, but to learn to approximate human judgements, these methods generally need a large amount of manually annotated training data to obtain a viable model. Creating such corpora is a very time-consuming task, especially if it has to be done from scratch. For languages with a relatively low number of speakers, such as Latvian, this is a particularly pressing problem, because of the small number of textual corpora available, so that researchers generally need to create their own datasets.

Much of the information of importance to be captured from the Internet is by its nature related to emotions. Recommendation systems, conversational “chat bots”, automated customer support assistants, various tools for analyzing, monitoring or enhancing personal well-being or mental health, not to mention systems for targeting or crafting advertising or marketing messages — all can benefit from understanding the emotional state of the recipient or sender of a given message. But recognition of emotions in text generally requires considerable investment of human resources; and is difficult to automate in principle. Perception of emotions is largely subjective, and the emotions perceived from the same source by different people differ. Further, in written communication, and especially communication in social networks, the words alone do not capture all of the emotional information available in the message. For example, the emotional tone of a sentence may vary depending on whether it was followed by period as the absence of periods is a characteristic feature of internet jargon usage, as shown in (Khalifa, 2020), which may carry a different emotional charge.

In this work, we propose the method for automatic annotation of the emotional charge found in text with the help of non-lexical means of expression — typographical marks, emojis and

¹ Source code is available at
https://github.com/Lynx1981/dfrustration/
likewise. In addition, to be able to do so for Latvian, we propose an annotated dataset that was used for model training and its results.

2 Background and Related Works

As machine learning methods, and neural networks, in particular, have developed over the past couple of decades, they naturally started to be applied to recognizing emotions, especially following the demonstrated successes of neural networks in image recognition as in (Giacinto et al., 2016). Emotion recognition in speech, as the easier task, began to appear as early as 2000 in (Nicholson et al., 2020). We begin to see published research on the recognition of emotions in text only beginning with (Alm et al., 2005). The majority of works focus on the classification of text according to its predominant emotion, which means that the text or part of the text was classified as containing one of the basic emotions. The most commonly used is Ekman’s emotion classification scheme, described in (Ekman, 1992), which contains six basic emotions: anger, fear, sadness, disgust, surprise, and joy — either in the standard way, or with various extensions, such as in (Yao et al., 2014), or reductions, as in (Lee and Wang, 2015).

Another model used to classify emotions, in two variants, is the Russell circumplex model, described in (Russell and Mehrabian, 1977), which is a two- or three-factor model where each emotion is represented in a two-dimensional (valence-arousal) or three-dimensional space, with axes of dominance, valence and arousal. Although there are numerous works that use these emotion classification models — for example, the three-factor model used in (Parthasaraty and Busso, 2017) and the two-factor model in (Yu et al., 2016) — these are not as common as works using a categorical list of basic emotions.

As computing power and data grew, the classification of emotions began to shift from a purely qualitative to a more quantitative approach: the intensity of emotions, not just the presence of specific emotions in the text, began to be studied. Some authors even create automatic tools for classifying emotions with intensity, for example the Weka package presented in (Bravo-Maquez et al., 2019) for four emotions (anger, fear, joy and sadness), or another opensource emotion computing framework presented in (Duppada and Hiray, 2017) for the same four emotions.

Interestingly, however, none of these classifications include frustration, or dissatisfaction, in the list of emotions, even if the emotion itself is well known to everyone and plays an important role, for example, in assessing quality of service in (Stauss et al., 2005). In customer service, however, ‘dissatisfaction’ is typically used instead of the word ‘frustration’, but this does not change the content of the term. There are very few works on annotating frustration, and they are relatively old, for example, (Klein et al., 2002) and (Hone, 2006), where the authors discussed the possibility of reducing human frustration in dialogue with the help of an emotional or empathic agent. In (Kapoor et al., 2007), the authors achieved good results in identifying frustration, but they used a complex multimodal system that measured the physical parameters of human (in their case, student) behavior, such as the pressure on the chair and the speed of the mouse. In short, the recognition of frustration from text has not been adequately studied. A recent paper (Hu et al., 2018) is a relatively rare example in which intensities for eight differing emotional “tones” (anxious, frustrated, impolite, passionate, polite, sad, satisfied, and empathetic) were annotated; however, the goals and methods of this work and ours were significantly different: while we examine the effect of words and non-lexical means of expression on perceived frustration, they look for correlations between user and support worker emotional tones; also, their approach uses a seq2seq (“sequence to sequence”) neural model, while we employ a model based on an architecturally simpler, fully-connected feedforward neural classification network.

The works we have mentioned have one feature in common: the classification of emotions in them is based on the analysis of words, or lexical means of expression. Several studies have been devoted to compiling lexicons, such as (Staiano and Guerini, 2014) and (Strapparava and Valitutti, 2004), but we have not been able to find a lexicon of non-lexical features. (Aman and Szpakowicz, 2007) mentions the use of non-lexical means of expression for the classification of emotions (using Ekman’s scheme) but does not give a list or description of these means. With the growing popularity of Twitter as a source of data, several works are making use of emojis, like (Wood and Ruder, 2016) or hashtags, like (Das and Bandyopadhyay, 2010). The article (Mohammad...
and Kiritchenko, 2015) is devoted to the construction of a hashtag lexicon for the automatic classification of emotions, however, there is one problem with their use: most Twitter messages do not contain any hashtags, at least in the domain of customer support conversations. Textual features such as the use of exclamation and question marks were used in (Hasan et al., 2014), and message length in (Roberts et al., 2012). The use of non-lexical (and non-linguistic) means of expression for the classification and intensity of emotions is much more developed for voice communication. An example is (Hautasaari, 2019), where both non-lexical features such as speaking speed or number and length of pauses, and non-linguistic features such as inhalation and exhalation are used to classify emotions into eight classes.

Attempts to use other linguistic features, such as the ratio of sentence parts to each other, like in (Devillers and Vidrascu, 2006) or the number of word separators or word separator sequences as in (Perikos and Hatzilygeroudis, 2016) in addition to a basic bag-of-words representation, are being made, but a systematic review and study of such features is still lacking.

3 Preceding Work

We use two gauge points for appraising the performance of our model: first is the baseline accuracy, obtained by always predicting the most frequent ground-truth rating, and second — the results obtained by an equivalent model based solely on lexical features and not employing any sort of input processing. A paper by (Zuters and Leonova, 2020) presented such a model for predicting frustration intensity level based on lexical features only. There, the authors employed a fully connected feedforward neural network with 64 hidden units. This network took as input a bag-of-words representation of the input text, using a subset vocabulary constructed during the training phase. In order to construct this, for every word in the dataset that was encountered in more than 2 entries, the following statistics were calculated: the average value of frustration intensity of the entries this word was found in, and the standard deviation of this value. Entries that were annotated as not rated (“n”) or missing a rating value were ignored. The standard deviation is a main criterion for constructing the bag-of-words “best words” vocabulary, based on reasoning that the lower the standard deviation of the frustration rating, the more characteristic the specific word is for the given frustration intensity.

</tr>
</tbody>
</table>

Table 1: Statistical metrics of different forms of the word “offer”.

Table 1 provides an excerpt from such a vocabulary: for each word, the following numbers are provided: the number of occurrences of the word in the dataset, the average value and the standard deviation of this value.

For each set of training data, a vocabulary was constructed, and then used for preprocessing each input entry for calculating predictions. The output of the model was a value from 0 to 4, representing the predicted frustration intensity. The performance of this model is used as a baseline for comparison.

4 Model

Here, we propose a new model that uses as input a set of features based on non-lexical means of expression in addition to the basic bag-of-words representation, and also employs subword segmentation for input preprocessing. By adopting

![Figure 1: Model schema.](image-url)
these techniques, we demonstrate a significant improvement in prediction accuracy, as discussed in detail in the Results section. A schematic of the model is given in Figure 1.

It can be seen that a user message in the model is used to construct two types of features: lexicon-based and non-lexical means of expression-based. We use the same method of lexicon construction as developed for the baseline model which was described in the Previous Work section. However, the new model differs in that it applies subword segmentation of the user message prior to constructing the bag-of-words representation (which thus becomes a ‘bag-of-subword-units’), and it also adds features to the model input based on a range of non-lexical means of expression. We next discuss these in detail.

4.1 Non-Lexical Means of Expression

While there is no shortage of research based on annotating emotions on the basis of lexical means of expression, and considerable effort has been dedicated to developing lexicons and word embeddings to improve the results, non-lexical means of expressions are used but very sparingly. It is true that in text-based social media — as opposed to, for example, in personal conversations — non-verbal signs of emotion such as intonation or facial expressions are naturally absent, and thus mostly lexical means are used for emotion identification from text. However, people creatively use the means available to compensate, at least partially, for the absence of such non-verbal means. To this end, built-in and homemade emoticons, or "smileys", sometimes composed of typographic marks, as well as typographic marks themselves (e.g. quotes for sarcasm), and also hashtags and the like, are very commonly used.

(Mohammad and Bravo-Marques, 2017) showed that hashtags consistently increase the perceived intensity of emotions in Twitter messages in English, which suggests that making use of these and other non-lexical means of expression to improve automatic annotation has promise. We also would like to mention that not all emojis are used equally by all users. Some appear situationally and play an illustrative role by commenting the text in the form of an image. However, emoticons are not the only means of expression used to express emotions in a text. Traditional forms are also used, such as punctuation marks of all kinds, and conversational features such as two-, three- or more -fold repetition of letters, as well as more Internet-specific ones such as uppercase writing, among others.

4.2 Feature Selection

In the dataset we have constructed, we have identified a number of non-lexical means of expression (NLME), for each of which we calculated the correlation with the median human-annotated level of frustration. The correlation served as a selection criterion for selecting NLME for further feature construction. The original correlation table can be found in the accompanying GitHub repository, along with the other source files. Contrary to our expectations, we found that means of expressions such as hashtags do not possess predictive value for the level of frustration.

The same is true for emoticons expressing seemingly positive feelings, such as smiling, laughing faces and similar. Having looked more closely at the examples containing such emoticons, we concluded that the most likely reason for the absence of such correlation is that these are used to denote sarcasm as often as not. An interesting fact is that, while the tendency is preserved for self-made emoticons constructed from typographic marks, such as “(-:”, it is less pronounced. The final list of selected features looks as follows:

- Message length
- Number of exclamation marks
- Number of exclamation marks normalized in relation to the message length
- Number of question marks
- Number of dots
- Number of commas
- Number of quotation marks (single, double, and reversed quotes)
- Number of uppercase words of length 5 and more
- Number of repeated letter “a” sequences
- Number of Twitter built-in emojis
After having selected the promising features, we tested different combinations of those and found the following. Firstly, there is no single feature dominantly responsible for the improved performance. The best feature, namely, the number of exclamation marks, gave only 46.8% accuracy. Secondly, exclusion of the worst features, whose inclusion individually gives worse results than the model without any NLME features at all (quotes, repeating letters, negative smileys made of typographic marks, presence of a picture in the message), also decreases performance by about 0.5%. This means that all the listed features are necessary to achieve the maximal performance.

### 4.3 Segmentation

Another technique that we employed in order to improve performance is preprocessing of the input data with a subword segmentation tool. The reasoning behind this is that Latvian is closer to being a synthetic language than an analytical one, and thus each word is present in the dataset in a multitude of forms — differing for every combination of case, number, gender, and other grammatical categories.

To alleviate this effect, segmentation has been successfully employed in machine translation field. Table 2 shows the top ten entries from the word dictionary, illustrating the principle.

As the vocabulary for subsequent frustration level annotation is constructed automatically based on the distribution of the ratings for specific words, segmentation should facilitate classifying the same words in different grammatical forms together, potentially improving prediction accuracy. It also allows to unify a number of forms under a single entry, reducing data sparsity. As we analyzed these entries in comparison with the whole-word dictionary, we saw, that: 1) brand names (“lg”, “mac”) and unchanged (“nov.”, “neierobežots”) words preserved their place on top; one entry (“-isku”) is a word ending that couldn’t have been in an unsegmented dictionary; two (“publisk-”, “pagāj-”) are new developments — they originally appeared as whole words less than three times and were thus previously ignored, but are now included by virtue of serving as a root form for multiple related word-forms; and, finally, the remaining three (“izmēģin-”, “piezvan-” and “neiet”) were reranked, for similar reasons. The improvements in performance due to subword segmentation are discussed in the Results section.

### 4.4 Additional Processing

In addition to subword segmentation, we also explored other input preparation methods. Specifically, removing diacritical marks in original entries in order to unify spelling variations differing only in their presence or absence, and replacing abbreviations for time, speed and other units of measure, as well as popular sources of spelling variations, with their full forms. The effect of these two methods, even applied cumulatively, was found to be disputable at best and provided, no real improvement of the model accuracy.

### 5 Dataset

In this work, we have used a completely new Latvian dataset, developed specifically for the purpose of testing the performance of our proposed frustration annotation model against the old one used as a gauge point. Following the example of many other recent researchers, we selected Twitter

as a data source of choice. Four major Latvian internet and telecommunication service provider accounts were chosen for collecting conversations of users with customer support representatives. Those accounts are: (@mans_tet), (@mans_LMT), (@Bitelv) and (@tele2Latvija), which belong to companies Tet, LMT, Bite and Tele2, respectively. To provide for not just the possibility of appraising a frustration level at a certain moment of time, but also to allow studying the dynamics of frustration changes from one user turn to the next, the selected conversations contain no less than two user turns, with at least one customer support turn between those. As a turn we consider a sequence of messages that belong to one party in the conversation (not interrupted by any other users’ messages). An essential criterion was that the dialogs should be in Latvian, as obtaining a dataset in Latvian was the primary goal of collecting this dataset of tweets. The conversations were collected manually, in order to ensure that the criteria are met and that eligible conversations were not excluded just because another user replied to a tweet from the conversation, if such intervention did not actually affect the initial dialog. The resulting dataset consists of 283 dialogs with 688 user turns and 531 customer support representative turns. Of those 688 user turns, 9% had a median frustration value of 0, 19% of 1, 31% of 2, 30% of 3 and, finally, 11% of 4. The resulting collection was post-processed and saved in a unified and anonymized format, as described in the Experimental Setup section.

Each user’s turn in the dataset is followed by three values, representing the level of frustration assigned to this turn by three independent annotators. Each value represents a frustration level measured on a scale of 0 to 4, or can be “n” if the annotator judged that a level of frustration could not be determined from the text of the user message, for example, in case of the user simply stating their address. A final option is a missing value, for example if the text was in a language other than Latvian or could not be understood by an annotator for some other reason.

For English, in order for the results to be comparable with the baseline, we have employed the same dataset that was used in (Zuters and Leonova, 2020). The dataset represents a small subset of the Kaggle Customer Support dataset, where approximately 400 consistent dialogues between a support and a user were isolated and annotated for frustration by three independent annotators on the scale of 0..4. In total, this dataset contained 843 user turns, of which 18% had median frustration value of 0, 15% of 1, 28% of 2, 27% of 3 and 11% of 4. Thus, the baseline accuracy of the most frequent value was 31% for Latvian and 28% for English, and the most frequent frustration values were 2 and 3, respectively.

6 Experimental Setup

The model was implemented on Python as a neural network with RELU activation function and a softmax layer. It is using the following metaparameters: number of hidden units, number of epochs. The model, using both non-lexical and lexical means of expression, whether it was using subword segmentation of the input text or not, was trained on the same set of data.

We tested the model on different vocabulary sizes, fixing the number of epochs as 100 and the number of hidden units as 64, and found that the tendency of vocabulary sizes 50 and 500 to underperform has been preserved. We further explored the effect of hyperparameter changes, and also some additional input processing methods. We tried different network sizes (number of hidden units in the dense feedforward layer), including 32, 128, and 256, and concluded that 32 hidden units were not sufficient, while 128 and 256 gave suboptimal results with 0.75%, 0.5% and 1.5% decline in accuracy, respectively.

The model takes as its input a file with a collection of dialogs between users and customer support representatives in an anonymized format. Information such as Twitter user ids and message ids were removed from the dialogs, and any included sensitive information such as e-mail or customer number, is replaced with generic placeholders, following the example of the Kaggle Customer Support dataset. All user messages in the dataset are tagged with either “USER:” or “SUPP:” to denote whether they belong to a client/user or to the company’s customer support representative, respectively. Consecutive messages coming from a single party are joined together, forming a single “turn” — a sequence of messages uninterrupted by another party, so that the model works under the assumption that each two consecutive messages in a dialog belong to the different parties. For all experiments reported here, we use a single value per turn, calculated as a median of three ratings given by the annotators, which allows keeping the
aggregated annotation value as an integer, thus enabling us to perform classification rather than regression. The number of occurrences of each of the median ratings for values 0 to 4 is [59, 131, 210, 205, 83], respectively, with 2 being the most frequent rating with 210 instances.

To determine the optimal selection of features, used in the model, we have used a two-step process. To appraise the performance of the NLME features, for comparison we used the model with bag-of-words input features only. Figure 2 provides its principal schema of operation.

In the first step, we identified all potential features in the dataset and calculated a correlation table with the median annotated value, leaving only those that had at least a weak correlation. In the second step, we have run the model with a different combination of those features. First, we have used none and all the features for a benchmark, and then tested every feature in isolation to verify that no single feature would give a comparable accuracy. Since none did, we next tried to exclude features that in isolation gave worse results than a model using bag-of-words only. However, the removal of underperforming features (those which in isolation give results below the performance of the bag-of-words-only model) resulted in decreasing the overall performance by 0.4% (z-score = 1.32).

For segmentation of Latvian text, we have applied a GenSeg tool, described in (Zuters and Strazds, 2019) to preprocess the dialog file, so that the input now consisted of the messages in an already segmented form, leaving the rest of the process exactly as before — so that the run of the model on segmented versus unsegmented data differed only in the input file. Having fixed the metaparameters at 64 hidden units and vocabulary size 100, we found that subword segmentation improved the resulting model accuracy by 1.25% (z-score = -4.02).

Table 3 summarizes the results for the most prominent configurations of the features. It can be seen that using the combination of the best features increases the accuracy by 1.5% compared to using the single best feature, while adding the underperforming features improves the result by another 0.4%.

Using input preprocessed with the GenSeg segmentation tool gives the highest performance, yielding a total 49% accuracy, which is an 8% improvement over the old model, of which 1.25% can be attributed to the subword segmentation.

Table 3: Prediction results for the NLME model in comparison with different configurations (for Latvian). C1 - NLME model with all features, C2 - NLME model without subpar features, C3 - NLME model with all features and no segmentation, C4 - NLME model with a single best feature, RM – reference model, BM – baseline model.

7 Results

As our goal was to test improvements on Latvian data, and additionally adapt the original model to the specific challenges of the Latvian language, we created a reference point for comparison by training the baseline neural model using our Latvian language dataset. As discussed in the Preceding Work section, we defined a first baseline for prediction as the accuracy achieved by always assigning the most frequent annotation value in the corpus. However, different from the English dataset, the most frequent value in the Latvian dataset is 2 (with a distribution of values [59, 131, 210, 205, 83]), and the corresponding baseline accuracy is 30.5%. The baseline neural model uses 64 hidden units, vocabulary size 100 and a bag-of-words input representation.
Diacritics removal and unification of abbreviations did not have any discernible effect on the model performance. The best results are achieved using 64 hidden units and vocabulary size 100. Summarizing the results of our experiments, we can conclude that using our proposed model for prediction of frustration intensity significantly increases the accuracy of predictions.

8 Conclusions

In this paper, we have proposed a new neural network-based model for frustration intensity prediction for customer messages in the context of conversations with customer support representatives, as well as a new dataset of such conversations in Latvian, used to train and evaluate the model performance. A baseline model used for comparison employs a bag-of-words representation as input, constructed on the basis of vocabulary that is dynamically built during the training phase. The words selected for inclusion in the vocabulary are the ones that have the least standard deviation for annotated frustration intensity values. Our proposed method differs, first and most importantly, by including also features constructed on the basis of non-lexical means of expression, and, secondly, by performing close-to-morphological segmentation as a preprocessing step to make vocabulary construction more coherent. We also examined a few other methods of input processing, namely, removal of diacritics, and unifying popular variations in spelling, but these did not yield any improvements in results, even when used together.

Performance was assessed by performing a leave-one-out cross exhaustive cross-validation, that is, by computing accuracy (as percentage of correct predictions) obtained after training the model on all data except one entry using this one entry for prediction, and repeating this process for all the entries in turn, averaged across five runs. We compare against a similar neural model that only uses lexical features as input. While such a model achieves a 10% improvement over the baseline accuracy obtained by always predicting the median frustration rating of the dataset, our proposed model achieves an improvement in accuracy of 18% over the baseline and 8% over the old model. We have conducted ablation studies to evaluate the contribution attributable to input preprocessing using close-to-morphological segmentation, and also adjusted hyperparameters, and found that the segmentation is responsible for approximately 1.25% of the improvement.

In addition, we have presented a new dataset in Latvian, that contains dialogs between users and customer support specialists. The dataset in total has 283 dialogs with 688 user turns and 531 customer support representative turns, with each dialog containing no less than two user turns separated by a support representative turn, and with all user turns manually annotated for frustration intensity level. This dataset was used for training and assessing the reference neural network-based model for frustration prediction and its improved version.

System Combination for Grammatical Error Correction
Based on Integer Programming

Ruixi Lin Hwee Tou Ng
Department of Computer Science
National University of Singapore
{ruixi,nght}@comp.nus.edu.sg

Abstract

In this paper, we propose a system combination method for grammatical error correction (GEC), based on nonlinear integer programming (IP). Our method optimizes a novel $F$ score objective based on error types, and combines multiple end-to-end GEC systems. The proposed IP approach optimizes the selection of a single best system for each grammatical error type present in the data. Experiments of the IP approach on combining state-of-the-art standalone GEC systems show that the combined system outperforms all standalone systems. It improves $F_{0.5}$ score by 3.61% when combining the two best participating systems in the BEA 2019 shared task, and achieves $F_{0.5}$ score of 73.08%. We also perform experiments to compare our IP approach with another state-of-the-art system combination method for GEC, demonstrating IP’s competitive combination capability.

1 Introduction

Grammatical Error Correction (GEC) is the task of detecting and correcting grammatical errors of all types present in sentences in an essay, and generating a corrected essay (Ng et al., 2014).

Most of the latest GEC systems rely on pre-training with synthetic data and fine-tuning with task-specific data, and employ deep neural networks with attention mechanisms (Bryant et al., 2019). Single GEC systems can be highly effective in capturing a wide range of grammatical error types (Ng et al., 2014), but each individual system differs in its strengths and weaknesses in correcting certain error types, and the differences could result from the synthetic data used in pre-training a GEC system (Bryant et al., 2019). Two main categories of synthetic data generation approaches have been introduced, including directly injecting noise into grammatically correct sentences according to error distributions (Zhao et al., 2019; Choe et al., 2019), or by back-translation (Sennrich et al., 2016; Xie et al., 2018; Kiyono et al., 2019). While both categories could help a system achieve a high recall across many error types, it is hard to obtain a single uniform GEC system that is good at correcting all error types.

Presented with this difficulty and the strengths of individual systems, combining single GEC systems is thus a promising and efficient way to further improve precision and recall. Creating an ensemble of multiple systems is a common approach when it comes to combining multiple models, and the work of Junczys-Dowmunt et al. (2018) has shown its effectiveness when combining single GEC models with different random initializations and configurations. However, this mode of combination requires altering the component systems to achieve a tight integration.

In contrast, we focus on combination methods that need to consider only the outputs of individual systems. State-of-the-art system combination approaches working in this manner include Susanto et al. (2014) and Kantor et al. (2019). The approach in Susanto et al. (2014) adopts the MEMT system combination technique of Heafield and Lavie (2010) and learns a combined corrected sentence which is made up of different parts of multiple system outputs. The work by Kantor et al. (2019) has proposed a system combination approach based on convex optimization. It treats single GEC systems as black boxes, rounding system weights to 0 or 1, and iteratively combines two systems at a time.

In this paper, we propose a novel system combination method based on nonlinear integer programming (IP). Our method optimizes an $F$ score objective based on error types, and combines multiple component GEC systems simultaneously with binary selection variables. In Section 2, we present related work on system combination for GEC. Then, our proposed IP approach is described in detail in Section 3. We present experimental setup and
results in Section 4, provide analysis of results in Section 5, and conclude in Section 6. Our source code is available at https://github.com/nusnlp/gec_ip.

2 Related Work

System combination approaches for GEC are based on pipelining, confusion networks, error types, or optimization. Pipelining approaches, such as the CAMB system (Felice et al., 2014), adopt a pipeline of simpler to more complex GEC systems for correction, but they suffer from error propagation. Confusion networks, especially the MEMT approach for GEC (Susanto et al., 2014), learn the optimal word choice at a sentence location via a decoding scheme. The error type-based approaches aim at edit selection per error type and per system. The LAIX system (Li et al., 2019) employs a confidence table and a rule-based conflict solver to select the optimal edits from component systems. Past work using integer linear programming (ILP) for GEC includes (Rozovskaya and Roth, 2013; Wu and Ng, 2013). Moving on to using optimization-based selection variables, the IBM approach (Kantor et al., 2019) combines edits for a pair of systems at a time, based on error types and subsets of corrections. Continuous selection variables are learned by maximizing the subset-based \( F_{0.5} \) objective. The IBM approach is most related to our proposed IP approach, and we highlight the key differences in Section 3.3.

3 System Combination

We combine systems based on the strengths of individual systems in terms of error types, and optimize directly the \( F \) score evaluation metric (van Rijsbergen, 1974) to obtain error type-based selection variables for each system. Compared to Kantor et al. (2019), we make several major changes to achieve good precision and recall while making the combination more efficient. An overview of our proposed IP approach is illustrated in Figure 1.

3.1 An Integer Programming-Based Approach

First, we observe that the selection variables learned by convex optimization in Kantor et al. (2019) are rounded to their nearest integers, either 0 or 1, for simplicity. This approximation of continuous variables raises the question of why binary variables were not directly used in the first place. A more direct solution is to adopt binary variables. Let

\[
x_{ij} = \begin{cases} 
1 & \text{if } S_i \text{ is used to correct } T_j \\
0 & \text{otherwise}
\end{cases}
\]

where \( S_i \) refers to system \( i \) in a set of \( M \) systems \( S = \{ S_1, \ldots, S_M \} \) and \( T_j \) refers to error type \( j \) in a set of \( N \) error types \( T = \{ T_1, \ldots, T_N \} \). Taking \( F \) score, the evaluation metric of GEC systems, as our objective function to maximize, we can formulate the GEC system combination problem as a nonlinear 0-1 integer programming (IP) problem as follows:

\[
\max F_\alpha(X) = \frac{(1 + \alpha^2) \cdot TP_{sum}}{(1 + \alpha^2) \cdot TP_{sum} + FP_{sum} + \alpha^2 \cdot FN_{sum}}
\]

s.t.

\[
\sum_{i \in S} x_{ij} = 1, \forall j \in T \tag{1}
\]

\[
x_{ij} \in \{0,1\}, \forall i \in S, j \in T \tag{2}
\]

where

\[
TP_{sum} = \sum_{i \in S} \sum_{j \in T} \lambda_{ij}^{TP} x_{ij} \tag{3}
\]

\[
FP_{sum} = \sum_{i \in S} \sum_{j \in T} \lambda_{ij}^{FP} x_{ij} \tag{4}
\]

\[
FN_{sum} = \sum_{i \in S} \sum_{j \in T} \lambda_{ij}^{FN} x_{ij} \tag{5}
\]

Equation (1) imposes the constraint that each error type is corrected by exactly one system. Equation (2) is the integer constraint, resulting in a 0-1 integer programming model. In Equations (3), (4), and (5), \( \lambda_{ij}^{TP} \), \( \lambda_{ij}^{FP} \), and \( \lambda_{ij}^{FN} \) respectively denote the true positive count, false positive count, and false negative count for system \( i \) and error type \( j \). In this paper, we set \( \alpha = 0.5 \) and optimize \( F_{0.5} \), the standard evaluation metric in GEC.

Moreover, the combination method in Kantor et al. (2019) uses the intersection of the edits of multiple systems, which can be too sparse to be useful when many systems are combined. Their iterative combination approach may alleviate the sparsity problem, but high computational cost is incurred when the number of component systems is large, due to the inherent combinatorial explosion of finding the optimal order of combination. In contrast, our approach requires no subset splitting, and optimizes all component systems simultaneously as indicated in Equations (3), (4), and (5).
3.2 Combination Procedure

The input to the IP approach is $M$ corrected sentences (of the same ungrammatical sentence) given by GEC systems $S_1, \ldots, S_M$. The output is a corrected sentence, after applying edit selection. The combination procedure consists of an optimization step followed by a correction (inference) step. Details are as follows.

**Optimization Step.** We compute the true positive, false positive, and false negative counts for each error type and component system on a training dataset. Utilizing these counts, the 0-1 integer programming model defined in Section 3.1 is solved using the commercial optimization software LINGO10.0\(^1\) to compute the optimal solutions for $x_{ij}$. In LINGO10.0, we adopt the INLP (integer nonlinear programming) model. For the experiments in this paper, the runtime for the LINGO solver to compute an optimal solution is 2 to 10 seconds.

**Correction Step.** During correction (inference), the system applies an edit (by system $i$ to correct an error of type $j$) to an input sentence if $x_{ij} = 1$ as determined by the LINGO solver. Conflicts of candidate edits from multiple systems (under different error types) can occur in the same location in a sentence. In other words, although a single system is used for each error type, a conflict can occur when two systems perceive an error in the same location to be of different error types, causing the location to have multiple candidate edits. When this happens, we set IP to randomly choose a candidate edit.

3.3 Key Differences from the IBM approach

Since the IBM approach (Kantor et al., 2019) is the most related work, we summarize the key differences of our IP approach from the IBM approach.

1. The IP approach directly combines all systems at once, as opposed to iteratively combining two systems at a time in the IBM approach, where the order of combination affects the outcome and there is a need to search for the best order of combination. In contrast, our approach avoids the problem of searching for the best order of combination.

2. Binary (0-1) integer selection variables are directly used, in contrast to approximation by integers in the IBM approach.

3. In the IP approach, we avoid having to perform subset splitting during optimization, in contrast to the IBM approach. For subset splitting, corrections from two systems are split into an intersection subset and subsets containing per system-only corrections, which can result in data sparsity.

\(^1\)https://www.lindo.com/index.php/products/lingo-and-optimization-modeling
4 Experiments

4.1 Component Systems

To apply the IP combination method on GEC, we choose three state-of-the-art GEC systems as component systems. They are the systems UEdin-MS (Grundkiewicz et al., 2019) and Kakao (Choe et al., 2019) (the top two systems from the restricted track of the BEA 2019 shared task), as well as Tohoku (Kiyono et al., 2019).

The three GEC systems share interesting commonalities and exhibit salient differences. The major commonalities are the use of the Transformer Big architecture (Vaswani et al., 2017) (the Kakao system uses a variant, the copy-augmented Transformer (Zhao et al., 2019)), pre-training on 40M to 100M synthetic parallel data, ensemble of multiple models, and re-ranking. They differ in the synthetic data generation methods, the monolingual sources, the implementation of the architecture, and re-ranking features. These characteristics lead to individual strengths in correcting different types of errors, allowing room for improvements via system combination.

4.2 Training and Evaluation

We use the official BEA 2019 shared task datasets for training and evaluation. We learn our selection variable values based on the output sentences of the component systems on the official validation set. At inference time, we apply combination on the output sentences of the component systems on the official blind test set of BEA 2019. The resulting output sentences are sent to the shared task leaderboard for evaluation, where $P$, $R$, and $F_{0.5}$ scores are the evaluation metrics. The official scorer is the ERRANT evaluation toolkit v2.0.0 (Bryant et al., 2017).

4.3 Experimental Results

Besides our proposed IP method, we compare with the MEMT-based system combination approach for GEC. We follow the work of Susanto et al. (2014) to use the open source MEMT toolkit (Heafield and Lavie, 2010) for experiments.

MEMT system combination performs two major steps to combine edits: pairwise alignment and confusion network decoding with feature weight tuning. Pairwise alignment is first performed using METEOR (Banerjee and Lavie, 2005) to form a search space for combination. The alignment recognizes exact matches, words with the same stem, synonyms defined in WordNet, and unigram paraphrases. Then a confusion network is formed on top of the aligned sentences and beam search decoding is used to form hypotheses. During beam search, scoring of partial hypotheses is performed by a set of features, including hypothesis length to be normalized, log probability from a language model, n-gram backoff from the language model, and matched n-grams between the sentences generated by the component systems and the hypothesis. Tuning of feature weights is performed using ZMERT (Och, 2003), optimized for the BLEU metric. We report the average score of three runs of each MEMT combination.

The scores for the component systems and the IP combination approach are reported in Table 1, and the scores for the MEMT approach are reported in Table 2. All combination scores using the IP method are higher than the individual systems’ scores. The best IP score is achieved by combining UEdin-MS and Kakao (1+2), and the $F_{0.5}$ score is 73.08%, which is 3.61% higher than that of the best individual component system UEdin-MS. Comparing IP with MEMT, the average $F_{0.5}$ score across all combinations of IP is 72.36%, and that for MEMT is 71.42%, so the average $F_{0.5}$ score of IP is 0.94% higher than that of MEMT. The IBM approach (Kantor et al., 2019) reported $F_{0.5}$ score of 73.18% when combining the component systems UEdin-MS and Kakao (1+2). Overall, the performance of IP is thus comparable to other state-of-the-art combination approaches.

Table 1: Scores (%) of the component systems and the IP combination approach on the BEA 2019 blind test set.
## 5 Analysis of Results

We analyze how much the combined system using the IP approach improves over individual component systems, on a per-sentence basis. Since reference edits are unavailable for the blind test set, we base our analysis on the BEA 2019 validation set and split it into two halves: the first half for training and the second half for testing. For each input sentence, we compare the $F_{0.5}$ scores of its output sentences generated by Kakao, UEdin-MS, and the system obtained by IP combination of both. We assign each output sentence $s$ into one of two classes, based on whether (1) the $F_{0.5}$ scores of $s$ are identical in Kakao and UEdin-MS; or (2) the $F_{0.5}$ scores of $s$ are different.

The findings are summarized as follows. Of the 2,192 test sentences, there are 1,503 sentences where Kakao and UEdin-MS have the same $F_{0.5}$ score. For these sentences, the IP approach achieves the same or higher $F_{0.5}$ score on 1,501 sentences. The $F_{0.5}$ score of IP on these 1,501 sentences is 0.4% higher than each individual system. For the remaining 689 sentences that either Kakao or UEdin-MS performs better, 503 out of 689 sentences benefit from IP combination, with an increase of 11.58% in the overall $F_{0.5}$ score on the 503 sentences compared to the average $F_{0.5}$ score of Kakao and UEdin-MS. This analysis shows that the component systems benefit from the IP combination approach on a per-sentence basis.

## 6 Conclusion

In this paper, we have proposed a system combination approach for GEC based on nonlinear integer programming, which combines all systems at once. The use of binary selection variables is simpler and more direct, compared to using continuous variables then rounding them. The best $F_{0.5}$ score achieved is 73.08% on the BEA 2019 test set.

Abstract

The Semantic Verbal Fluency Task (SVF) is an efficient and minimally invasive speech-based screening tool for Mild Cognitive Impairment (MCI). In the SVF, testees have to produce as many words for a given semantic category as possible within 60 seconds. State-of-the-art approaches for automatic evaluation of the SVF employ word embeddings to analyze semantic similarities in these word sequences. While these approaches have proven promising in a variety of test languages, the small amount of data available for any given language limits the performance. In this paper, we for the first time investigate multilingual learning approaches for MCI classification from the SVF in order to combat data scarcity. To allow for cross-language generalisation, these approaches either rely on translation to a shared language, or make use of several distinct word embeddings. In evaluations on a multilingual corpus of older French, Dutch, and German participants (Controls=66, MCI=66), we show that our multilingual approaches clearly improve over single-language baselines.

1 Introduction

Mild Cognitive Impairment (MCI) is a medical condition (Petersen et al., 2014) that often precedes Alzheimer’s Disease (AD). The development of cost-effective and scaleable screening approaches for MCI is crucial for the early treatment and management of AD (Dubois et al., 2016). The Semantic Verbal Fluency Task (SVF) is a promising screening approach as it combines a time-efficient testing procedure with the possibility of remote and automatic evaluation (Tröger et al., 2018). In this task, the testee is asked to name as many words as possible from a given semantic category (e.g. animals) in a given time (e.g. 60-seconds). Traditionally, the number of named within-category items is used to detect cognitive impairment. However, recent research has shown that in-depth analysis of the underlying cognitive strategies used for the SVF (e.g. semantic memory retrieval, executive control) enables a more fine-grained differential diagnosis (Tröger et al., 2019).

To harness the diagnostic power of the SVF, current automatic evaluation approaches identify semantic clusters in the participants’ word sequences, based on semantic word embeddings (Woods et al., 2016; Linz et al., 2017b; Paula et al., 2018). As the word embeddings used in these approaches are language-specific, training diagnostic machine learning approaches for target languages with small available datasets of SVF tests is challenging. Despite the potential of improving MCI classification by training on larger, multilingual data, all existing approaches for automatic MCI diagnosis are trained and evaluated on data from a single language.
In this paper, we for the first time investigate multilingual learning approaches for MCI screening from the SVF. To train a joint model that generalises across test languages we evaluate two approaches: (1) translation to a common language, and (2) the application of several distinct embedding resources to the same SVF productions. In line with the state of the art (Paula et al., 2018), we evaluate qualitative embedding-based approaches through an extrinsic quantitative downstream NLP application (Wang et al., 2018): classification between controls (HC) versus MCI from qualitative SVF features. In evaluations on French, Dutch, and German corpora we show clear improvements of the multilingual learning approaches over the single-language baselines. Our results show that the the performance of classical single-language, single-embedding approaches heavily depends on the combination of embedding and language, hindering generalizability. In contrast, by extracting features from several embeddings simultaneously and training over several languages, we achieve improved and more consistent classification performances across several test languages.

2 Related Work

Our work is related to clinical Evaluation, semantic word embeddings, as well as the automatic qualitative evaluation of verbal fluency tasks.

2.1 Clinical Evaluation

During an SVF trial, a person is asked to name as many words from a semantic category (e.g. animals) as they can in one minute. The person’s response is then scored as the number of unique words named excluding any repetitions. Typically, this word count is then used to determine if the person shows signs of cognitive impairment.

In addition to the word count, qualitative measures to evaluate underlying strategy—clustering and switching—have been proposed (Troyer et al., 1997). For this evaluation, consecutive words that have a discernible semantic relationship are considered to be in a cluster. For instance, in the SVF response “cat, dog, whale, dolphin...”, “Cat” and “dog” are common pets whereas “whale” and “dolphin” are marine mammals. The process of going from one cluster to the next is called switching.

Computing these additional metrics by hand is time-consuming and subjective. This has lead to developing automated methods of clustering and switching based on distributional semantics, or semantic word embeddings (Linz et al., 2017a; Clark et al., 2016).

2.2 Semantic Word Embeddings

Semantic word embeddings map words to a vector space encoding their semantic meaning. Words with high semantic similarity are mapped to vectors close in this semantic space, semantically dissimilar words to distant vectors. These semantic vectors are learned through a variety of algorithms on any large corpora of text with two main varieties of embeddings: contextual and non-contextual (Miaschi and Dell’Orletta, 2020). In a non-contextual word embedding, the vector representation is static, whereas, in a contextual embedding, the surrounding words are considered. For example, if we had 'cutting paper' and 'cutting class', a non-contextual word embedding would assign the same vector to 'cutting' in both phrases whereas a contextual embedding would take into account the difference of meaning.

Given the nature of the verbal fluency task, a non-contextual list of animals, this paper focuses on using different types of non-contextual word embeddings to investigate how to model a persistent underlying cognitive structure while combining data from multiple languages. To keep results comparable and reproducible, pre-trained publicly available models that are available in a range of languages are investigated namely, FastText (Bojanowski et al., 2016a), Spacy (Honnibal et al., 2020), and Wikipedia2Vec (Yamada et al., 2020a).

As semantic vectors are learned from large amounts of text corpora (usually Wikipedia and OSCAR common crawl), embedding quality heavily depends on the quantity of the available training data. While French, German and Dutch are relatively well-supported Indo-European languages, they are at a large disadvantage in comparison to English model resources. For instance, Wikipedia offers 6,317,662 articles for English but much fewer for French(2,337,481), German(2,586,965) or Dutch(2,058,488)1.

This presents a trade-off for approaching multilingual learning with semantic embeddings for clinical applications between maintaining the nuance of verbal fluency response in its native language or translating the response to English to take advantage of larger resources. In this paper, we

1https://en.wikipedia.org/wiki/List_of_WikipediasDetails_table
investigate both scenarios of multilingual machine learning for clinical models.

2.3 Automatic Qualitative Evaluation of VF Tasks

Verma and Howard (2012) showed that pathological semantic organization of speech is an effective proxy for underlying cognitive impairment in early AD—MCI. As a result, MCI screening from the SVF has leveraged a variety of computational models of semantic coherence across many languages. Early approaches for automatic semantic modeling of the SVF relied on classic co-occurrence measures for capturing AD-related semantic SVF markers (Clark et al., 2016; Pakhomov et al., 2012), graph-based measures (Lerner et al., 2009), or employed latent semantic analysis (Pakhomov and Hemmy, 2014; Pakhomov et al., 2015).

Most recently, semantic word embeddings have been used for automatic evaluation of verbal fluency tasks, including the SVF (Linz et al., 2017b; Paula et al., 2018; Kim et al., 2019; Lindsay et al., 2021a). For MCI screening, encouraging results were obtained with a variety of semantic NLP resources including word2vec (Linz et al., 2017b; König et al., 2018), WordNet (Paula et al., 2018), and Wikipedia backlink vector space models (Kim et al., 2019); Paula et al. (2018) and Linz et al. (2017a) reported classification performances of AUC 0.71 with a random forest classifier and F1 0.77 with a support vector machine, respectively.

While the type of embedding was found to significantly influence classification performance (Linz et al., 2017b; Paula et al., 2018), an approach combining different embedding types was not presented. Similarly, studied languages include French (Linz et al., 2017a), Korean (Kim et al., 2019), English (Pakhomov and Hemmy, 2014) and Brazilian Portuguese (Paula et al., 2018), but to our knowledge, no multilingual classification was investigated.

We argue that by extracting qualitative SVF features with multiple language-specific resources, we can train machine learning models across languages. Overcoming the issue of small clinical data sets and possibly building more robust models that generalize cognitive impairment that is not language-specific.

3 Methodology

3.1 Data

This study included SVF data from clinical datasets in three languages; French collected at Nice Institut Claude Pompidou Memory Clinic in France; German collected at the University Medical Centre Freiburg, Germany; and Dutch from Maastricht University Clinic, Netherlands. All participants performed a 60-second SVF for the category “animals” in their native language—in addition to a battery of cognitive tests—administered by a clinician. The recordings were manually corrected according to the CHAT protocol (MacWhinney, 1991; Karakostas et al., 2017; Tröger et al., 2017).

For all corpora, participants were excluded if they presented with comorbidities (e.g. apathy or depression). To control for confounding cognitive factors, samples from healthy controls (HC) and those with mild cognitive impairment (MCI) were matched for age and education in each language using the MatchIt package in R (Ho et al., 2011). The resulting demographic information for each corpus is listed in Table 1. A Wilcoxon non-parametric test is reported to check for differences in age and education between HC and MCI. All described studies were approved by national ethical committees and conform to the Declaration of Helsinki.

3.2 Embedding Resources

As the SVF does not evaluate language abilities but rather underlying processes of executive function and memory, we made use of non-contextual word embeddings. To keep results comparable and generalizable for future studies, we used pretrained mod-
Figure 1: Overview of our Multi-Embedding Multilingual Learning framework. The training data consists of SVF productions with MCI labels in different languages (French, German, Dutch). For each training sample, features are extracted using multiple embedding resources (FastText, Spacy, Wiki2Vec). With this training data, we learn a SVM classifier that is able to predict MCI versus HC at test time on SVF productions from any of the three languages.

3.3 Clustering-Based Features

The implementation for determining clusters using semantic embeddings followed Linz et al. (2017a). Each participant’s SVF production was transcribed and preprocessed into a sequence of only animal words represented by $a_1, ..., a_n$. A base threshold $T_p$ is determined for each participant $p$ by averaging the semantic similarity between all pairs of animal words in $p$’s production.

$$T_p = \frac{1}{n(n-1)} \sum_{i,j=1 \ldots n, i \neq j} sim(a_i, a_j)$$

Semantic similarity $sim$ was measured by the cosine distance between semantic embedding vectors $e_i$ extracted from words $a_i$, i.e. $sim(a_i, a_j) = \cos(e_i, e_j)$. Clusters were determined by comparing the semantic similarity of consecutive words $sim(a_i, a_{i+1})$ in the production to $T_p$. If the consecutive words were more similar than the base similarity threshold they were considered to belong to the same cluster. If the consecutive words were less similar than the base similarity threshold they introduced a cluster boundary, also referred to as a switch.

Based on the clusters obtained from a given participant with a given embedding, we computed the following features based on Linz et al. (2017a):

- **Mean cluster size** computed as the average number of words in a cluster.
- **Number of switches** calculated as the number of clusters minus 1.
- **Mean cluster distance** computed as the average semantic distance between all words in a cluster.
- **Mean switch distance** as the average semantic distance between centroids of adjacent clusters.

3.4 Multilingual Approaches

To combine multilingual data, we investigate two approaches. Section 3.4.1 proposes a method using available language-specific resources for each language and the section 3.4.2 translates all of the data to a common language, English.
3.4.1 Untranslated Multilingual, Multi-Embedding Approach
The central idea underlying the untranslated multilingual, multi-embedding approach is to maximize the available clinical data by using generalizable semantic features that robustly model cognitive impairment. To mitigate the possibility of fluctuating performance between language and embedding type, we propose using multiple embeddings for untranslated, multilingual data.

3.4.2 Translated to Common Language Approach
An alternative way to make use of training data from several source languages is to translate all SVF productions to a common language prior to feature extraction. We follow the methodology in (Paula et al., 2018) and translate all SVF productions to English before extracting word embeddings. For translation we first used Google translation API
\(^2\) and then manually checked and post-edited any words where the source word was identical to the target word. Due to privacy restrictions on medical data, a set of all mentioned animal names was extracted from the transcripts and a look-up dictionary was created mapping the animals of each language to its English equivalent.

3.5 Classification Experiments
From each of the French, Dutch and German productions as well as their English translations, the four described clustering-based features are extracted using each respective embedding resource.

3.5.1 Multilingual, Multi-embedding (ML-ME)
Figure 1 gives an overview of the multilingual, multi-embedding framework. For both the untranslated and translated approaches, the four features of underlying cognition are extracted. Each of the features vectors are concatenated into a single feature vector. This is the new representation of the SVF production that is then used to train the model and predict a label of HC or MCI.

3.5.2 Baseline Comparisons
Single Language, Single Embedding (SL-SE)
To test how well each embedding resource models each language, we trained on each combination of language and embedding resource individually.

Multilingual, Single Embedding (ML-SE)
To investigate how each embedding resource behaves in a multilingual training scenario, we trained a separate model for each embedding resource using all the language corpora.

3.5.3 Out-of-Vocabulary (OOV) Rate
In addition to the classification experiments, the out of vocabulary rate for each language for each embedding is considered. This is used as a quality control test to ensure words are not being dropped from the transcript when the features are being computed. The OOV rate is calculated as the unique number of word that are not in the semantic model divided by total produced animal words.

3.6 Evaluation
In line with previous work (König et al., 2018), classification was performed by a Support Vector Machine (SVM) with Radial Basis Function kernel implemented in sci-kit learn\(^3\) (Pedregosa et al., 2011), using default parameters for \(\gamma\) and \(C\). To maximize the amount of available data, testing for each model was done via leave-one-out cross-validation. Model performance was measured as area under the receiver operator curve (AUC). In the multilingual cases, a language-specific AUC was reported, where the multilingual model is evaluated separately on each target language. To compare the multilingual methods to the other approaches, AUC scores were averaged across the languages.

To nullify the effects of random initialization of the SVM optimization, we averaged AUC values obtained from 50 random initializations. To further test quality of the word embeddings, the rate of out of vocabulary words (OOV Rate) was reported as the percentage of words that did not have an embedding vector in the specific model.

4 Results
All results described in Section 3.6 are in Table 2 and Table 3. Table 2 displays the OOV rate analysis and Table 3 contains classification results.

A baseline was created using single language, single embedding (SL-SE) classifications. In the untranslated approach, Dutch had the lowest average across embeddings with an average AUC of 0.29, then French with 0.58, and finally German with 0.55. Similarly, Dutch had the lowest value (average AUC=0.38) across resources in the

Table 3: Averaged AUC results for the Multilingual, Multi-embedding model and Baseline approaches. Single Embedding (SE), Multi-embedding (ME), Single Language (SL), Multilingual (ML), Average (AVG), Out of Vocabulary (OOV). Cross-Language AVG is the average AUC performance for the values in the row.

translated approach, then German (0.41) and finally French (0.50). No single embedding type showed consistent best performances. In the untranslated approach, French and Dutch performed best with Spacy, and German performed best with FastText. In the translated approach, French and German achieved their best performance with English Wiki2Vec embeddings, whereas the Dutch data worked best with FastText embeddings. The overall finding from the SL-SE baseline showed that no single embedding type performed best over the setting.

In a next step, we combine the datasets to create a multilingual training scenario for each of the embedding types (ML-SE). In both approaches, every classification improves with the multilingual data with the exception of the French Wiki2Vec embeddings in the untranslated case. To make more meaningful comparisons to the SL-SE and ML-SE cases, we aggregate over the languages for each embedding type and report a cross-language average (shown in the table as Lang AVG). We then compare the cross language averages in the single language and multilingual scenarios. In both the untranslated and translated scenarios we see overall improvement. In the untranslated case, we see an average improvement of 12 AUC points, with the largest improvement coming from Wiki2Vec (16 AUC points). In the translated case, using the combined data, we see an average improvement of almost 15 AUC points.

In the case of the untranslated data, we see the largest overall improvement in the multilingual, multi-embedding scenario. Averaging over the cross language averages (Lang AVG) of the ML-SE scenario produces an AUC of 0.60, while the ML-ME average reaches an AUC of 0.66. For the ML-ME scenarios in the translated case, by averaging across the ML-SE models we achieve a comparable AUC of 0.58 which is outperformed by the ML-ME model (0.62). However, in the translated case, the best results are produced in the multilingual scenario using Wiki2Vec embeddings (0.64).

In addition to the classification analysis, we investigated the Out-of-Vocabulary (OOV) rate for each of the embeddings in each of the languages as a form of quality control. The results in Table 2 show that our embeddings were suited for the task. Overall, we had no OOV words for French, English and surprisingly Dutch. However, German animals seem to be lacking from models of equivalent size. This could also be due to language-specific differences in morphology.

5 Discussion

In this study we investigate two different methods of combining multilingual data to build clinical models to distinguish between healthy controls and early signs of Alzheimer’s Disease (MCI); untranslated and translated.

While the multi-embedding method is best for when data is kept multilingual, if the data is translated and no longer in need of multilingual re-
sources, a single embedding type did emerge with the best performance, Wiki2Vec. Given this, in the case where a common language (especially English) can be achieved, according to our data, it may be best to find and use one embedding type.

In addition, we found that embedding type does make a difference in classification performance. Therefore, caution should be used when deciding on semantic resources. For instance, in the untranslated case, if we were to build a multilingual model and only use Spacy emebeddings, we would have relatively good performing classifier in French and German but the Dutch classification would not exceed chance performance. While combining embeddings may not yield the best results for each individual language, it results in the most uniform improvement in a multilingual—versus translated—setting.

However, translating the data to English, drastically improved Dutch performance, specifically with the Wiki2Vec models. Speculatively, the improved overall performance of the English translations with Wiki2Vec could be due to the backlink model where relationships are modeled through linked wikipedia page, situating Wiki2Vec to be very useful in modelling these semantic relationships from a cognitive standpoint in verbal Fluency tasks. However, based on these results, it seems that these relationships are mainly found in the English Wiki2Vec model, most likely due to the large discrepancy in the amount of available training data between the languages.

Beyond just the brand of embedding, there are pros and cons that come with each the untranslated and translated approach. By translating the data to English, we introduce possible errors based on how the data is translated. In this study, we chose to combine an automatic approach with a manual post-editing step, making the translated approach not fully automatic. From a clinical perspective, we do not know if the previous work on cognition applies to data that is translated to another language and then assessed. However, from a computational standpoint, if a reliable translation service for the source language to English exists, using the monolith of English resources presents as a reliable and effective alternative.

There are many challenges that arise when trying to concatenate data from multiple sources, thus specific caution should be taken on how to model data that has health implications. Our investigation of the two approaches (untranslated and translated) shows that SVF speech data can be combined to achieve results comparable to previous models. As no unified benchmark exists for HC vs. MCI detection from the SVF, our results can only cautiously be compared with previous work. However, we noticed that our best results from our best models for French(0.66), German(0.68) and Dutch (0.69) are in line with reported AUC values for French (0.76 (König et al., 2018)) and Spanish (0.75 (Paula et al., 2018)). It is worth noting, that these results are achieved without using the overall word count, which typically the strongest indicator for MCI detection from the SVF task.

6 Conclusion

Using multilingual cognitive data in both a untranslated multilingual, multi-embedding approach and translated to a common language approach improved classification over single language baselines.

This is promising not only for the feasibility of increasing the size of small clinical datasets in quick and cost-effective way, but it also opens the door for methodology on how we can use multilingual data to build more robust understanding of underlying cognitive conditions (Lindsay et al., 2021b; Fraser et al., 2019).

Future work should look at exploratory analysis for the compatibility of features computed from translated transcripts in the current clinical understanding. This could present translation as a viable option for low-resource languages, or taking advantage of larger resources, while still presenting explainable clinical solutions and improved classification performance. While the languages in this study are all in the same language family, this methodology should be tested with data from different language families to test for robustness of the solution.

As such, our proposed methodology provides insight into the effect of NLP resources for classifications on cognition as well as a tentative solution to the problem of combining multiple clinical datasets. This addresses the issue of small clinical data sets as well as opens the door for building robust models of cognition for clinically actionable solutions leveraging multilingual data, paving the way towards reaching the societal goal of cost-effective early AD detection.

Abstract
This paper presents an automatic method to evaluate the naturalness of natural language generation in dialogue systems. While this task was previously rendered through expensive and time-consuming human labor, we present this novel task of automatic naturalness evaluation of generated language. By fine-tuning the BERT model, our proposed naturalness evaluation method shows robust results and outperforms the baselines: support vector machines, bi-directional LSTMs, and BLEURT. In addition, the training speed and evaluation performance of naturalness model are improved by transfer learning from quality and informativeness linguistic knowledge.

1 Introduction
With the increasing popularity of virtual assistants such as Alexa or Siri, users have a higher demand for conducting natural conversations. They would like to chat with these assistants more naturally—maybe even like talking to a real human being. One of the key questions arising from this, though, is how to measure the naturalness of the generated language. In the past, native speakers judged the quality of the generated language by answering questions like “is this utterance natural?” or “could it have been produced by a native speaker?” to rate the naturalness (Novikova et al., 2016). However, this approach heavily depends on manual effort and is impractical for broader use. On the other hand, the widely used automatic metrics for evaluating language generation, like BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005), rely on word overlap mechanism and compare the generated sentence to one or more human-created reference sentences (Stent et al., 2005), but cannot directly reflect naturalness information.

Likert scale ratings are generally used in human evaluation. The Figure 1 shows an example of 6-point Likert scale rating on naturalness of a sentence. In general, the human evaluation items (naturalness, coherence, etc.) are hard explainable objectively and native speakers purely rely on their underlying criteria to judge the performance of generated language without any specified rules. To alleviate the manual effort previously needed, the goal of this paper is to render the task of assessing the naturalness of generated language as an automatic reference-based classification problem having each Likert scale rating representing one class. To our knowledge, we are the first to propose this task and present an approach evaluating naturalness of generation through fine-tuning a pre-trained Language Model (LM).

The contribution of this paper is two-fold: a pre-trained BERT model is fine-tuned to estimate the naturalness of a generated sentence based on a reference sentence. Three baselines are proposed for robust performance comparison: a support vector machine (SVM) baseline using bag-of-words (BoW) vectors for input representation, a bi-directional Long Short Term Memory (LSTM) neural network, and the pre-trained BLEURT model (Sellam et al., 2020). Second, based on the positive correlation between naturalness and other annotated information: quality and informativeness of the generated sentence, the proposed method is extended to leverage this additional information through transfer learning. And the learning speed and estimation performance of naturalness evaluation model is significantly increased.

The remainder of this paper is structured as fol-
Section 2 introduces the related works. In Section 3, our proposed approach for BERT-based naturalness estimation is presented. In Section 4, the experiment setups are covered, which include fine-tuning BERT, comparison against the baselines, and transfer learning. Section 5 describes the experiments results. The last Section 6 draws conclusions and outlines future work.

2 Related Work

With the development of Natural Language Generation (NLG) applications and their benchmark datasets, evaluation of NLG systems has become increasingly important. Generally, multiple automatic metrics are used in parallel to evaluate the performance of language generation, such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) or ROUGE (Lin, 2004). However, Chaganty et al. (2018) demonstrated that the existing automatic metrics have poor instance-level correlation with mean human judgment and that they assign bad scores to many good quality responses.

Since automatic metrics still fall short of replicating human decisions (Krahmer and Theune, 2010; Reiter, 2018), many NLG papers include some form of human evaluation. For example, Hashimoto et al. (2019) report that 20 out of 26 generation papers published at ACL2018 presented human evaluation results for showing their robust performance comparison. Celikyilmaz et al. (2020) and Gatt and Krahmer (2018) also highlighted that human evaluation is commonly viewed as the best reliable way to evaluate NLG systems, but come with many issues, such as costly and time consuming and human judgement bias. And more importantly, the evaluation results from human efforts are not always repeatable (Belz and Reiter, 2006). Dusek et al. (2017) previously attempted to predict quality ratings of generated language by using Recurrent Neural Network (RNN) with the help of the Meaning Representations (MRs) and showed promising performance. However, our work is more focused on naturalness evaluation and based on the gold reference. In order to relieve the human labor, we propose a reference-based method for naturalness evaluation by utilizing neural network to learn the complicated linguistic relationship from sentences. And this work can be easily extended to other human evaluation criteria (coherence, quality, etc...), if the corresponding human evaluation data is available.

In recent years, with huge success of pre-trained LMs (Devlin et al., 2019; Radford et al., 2018), many machine learned metrics for evaluating generation are proposed. Especially the pre-trained BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2019) shows its superiority in this field. Shimanaka et al. (2019) presented automatic machine translation evaluation by using BERT and achieved the best performance in segment-level metrics tasks on the WMT17 dataset for all to-English language pairs. Zhang et al. (2019) proposed an automatic evaluation metric for text generation based on pre-trained BERT contextual embeddings: BERTScore. BERTScore computes the similarity of two sentences as a sum of cosine similarities between their tokens’ embeddings. And Zhang et al. (2019) showed BERTScore correlates better with human judgments and provides stronger model selection performance than existing metrics. Sellam et al. (2020) presented BLEURT, which continually pre-trained BERT on synthetic data and then fine-tuned on task-specific ratings. And Sellam et al. (2020) demonstrated BLEURT can model human assessment with superior accuracy. Given the superiority of BERT, we also apply the pre-trained BERT for our proposed naturalness evaluation on generated language.

3 Naturalness Evaluation Using BERT

The task of estimation the naturalness of a generated sentence is framed as a classification task. Two sentences are used as input: the candidate sentence to be scored and a reference sentence. The naturalness score is derived through fine-tuning a pre-trained BERT (Devlin et al., 2019) model. The main architecture of BERT uses the encoder of a Transformer (Vaswani et al., 2017), which is an advanced encoder-decoder architecture leveraging the attention mechanism. Considering that the input may be sentence pairs in several tasks, technical innovation Next Sentence Prediction (NSP) helps BERT to learn the relationship between sentence pairs by receiving pairs of sentences as input and separating them with [SEP] token to learn predicting if the second sentence is the subsequent sentence in the original document. To do so, a [CLS] token is added at the beginning for every input to learn the meaning of the entire input. Exactly because of these specific characters, eleven NLP tasks
in Devlin et al. (2019) obtained new state-of-the-art results by fine-tuning BERT.

Figure 2 shows the fine-tuning structure for naturalness estimation with a candidate sentence (sys_ref) and a reference sentence (orig_ref) as input. Example for a sys_ref and orig_ref is shown in Table 1. In accordance to the NSP task, representing both sentences on the input side is achieved by separating them with the [SEP] token. As can be seen in Figure 2, an additional [CLS] token is inserted at the beginning of the first sentence. The final output of the [CLS] token, which is called pooled_output, forms a representation of the entire input. Then a linear layer with softmax activation is added to the top of pooled_output to predict the probability of sentence-level naturalness label. To our knowledge, we are the first to fine-tune BERT to learn the abstract naturalness linguistic information and demonstrate the robust performance of this method.

4 Experimental Setup

In this section, the experiment procedure including the pre-processing of the used data is introduced. First, BERT is fine-tuned for naturalness estimation and then compared it with the baselines. Furthermore, external knowledge is added demonstrating the impact on naturalness estimation through transfer learning.

4.1 Dataset Preprocessing

The dataset\(^1\) (Novikova et al., 2017) comprises textual dialog responses produced by three data-driven NLG systems over three different domains. The three NLG systems are respectively RNNLG\(^2\), TGen\(^3\) and LOLS\(^4\). The applied domains are SF Hotel and SF Restaurant (Wen et al., 2015).

$$\text{sys}_{\text{ref}}: \text{zuni cafe, is expensive.} \quad \text{orig}_{\text{ref}}: \text{how about zuni cafe, an expensive one?}$$

which provide information about hotels and restaurants in San Francisco, and BAGEL (Mairesse et al., 2010) that provides information about restaurants in Cambridge. Human annotations on naturalness, quality, and informativeness were collected for each NLG-produced text on a 6-point Likert scale by asking the annotator “could the utterance have been produced by a native speaker?”, “How do you judge the overall quality of the utterance in terms of its grammatical correctness and fluency?”, “Does the utterance provide all the useful information from the meaning representation?”, respectively.

Table 1 shows an annotation example of the data. The sentence pair input comprises sys_ref and orig_ref. The sys_ref presents the output of each of the above-mentioned three NLG systems, one at a time, while orig_ref denotes human written references from the original data. The judges (1, 2, 3) represent the three human raters. The naturalness score is our target label. In addition to the naturalness score, the informativeness score and the quality score are utilised in transfer learning experiments to improve naturalness estimation as introduced in Section 4.4. To derive a single label for each sentence pair, the median of the individual annotations is used. The Table 2 shows the distribution of the final processed data, which includes 11,353 samples. And we randomly split the data into train/dev/test with 80%/10%/10%.

4.2 Fine-tuning BERT

During fine-tuning, the entire pre-trained BERT model is optimised end-to-end. The output of token [CLS]: the pooled_output, is further fed to a linear layer with softmax activation function with parameters $W \in \mathbb{R}^{K \times H}$, where $H$ is the dimension of the hidden state vectors and $K$ is the number of classes. In this paper, we applied English uncased BERT-Base model\(^5\), which has 12 layers, 768 hidden states and 12 heads, for the naturalness classification. So $H$ is 768 and $K$ is 6 in our experiment.

Figure 2: Fine-tuning BERT architecture for naturalness estimation

All hyper-parameters are tuned to our dataset. The batch size is 256 and the number of epochs is 25. Adam (Kingma and Ba, 2014) is used for optimization to minimize the cross-entropy with an initial learning rate of 5e-3.

4.3 Baselines

As this is a novel task, there is no available existing baseline for us to compare. Hence, we apply the following three baselines for performance comparison in order to show the robustness of our proposed method.

**BoW + SVM:** We firstly introduce a SVM classifier using BoW representation as baseline. The SVM (Suykens and Vandewalle, 1999) is a discriminative classifier formally defined by a separating hyperplane and is widely used for classification task because of significant accuracy with less computation power. The BoW model (Zhang et al., 2010) is a text representation that counts the occurrence of words within a document. The BoW approach is very simple and flexible, and can be used for extracting word features from documents. These numerical BoW vector features are used as input to a SVM with linear kernel having hyper-parameters $C = 1.0$ and $\gamma$ set to ’auto’.

**Bi-LSTM:** We also introduce the bidirectional LSTM (Bi-LSTM) with one layer for naturalness evaluation as baseline. The Bi-LSTM layer has the same hidden size as fine-tuning BERT, i.e., 768, and the output is forward to one linear layer with softmax function for naturalness classification. We almost remain the same hyper-parameters setting as BERT for Bi-LSTM training, i.e., 256 batch size, 25 epochs and 5e-3 initial learning rate. We restrict the number of LSTM-layers to one because multiple layers resulted in very slow training speed, as the LSTM cannot be trained in parallel, and worse performance.

**BLEURT:** In order to establish robust performance comparison, we also apply a pre-trained model for naturalness evaluation as the third baseline: BLEURT (Sellam et al., 2020), which is a machine learned automatic metric for text generation. BLEURT continually pre-trained BERT (Devlin et al., 2019) with a large number of synthetic reference-candidate pairs on several lexical- and semantic-level supervision tasks and then fine-tuned on multiple human ratings. Sellam et al. (2020) published multiple versions of BLEURT in the official repository, which includes BLEURT-tiny, BLEURT-base and BLEURT-large. More information could be found in the link. (Sellam et al., 2020) demonstrated that BLEURT is much closer to human annotation and also recommended to fine-tune the pre-trained BLEURT for custom applications. Hence, we apply the BLEURT-tiny in this work for naturalness classification by adding one additional linear layer with softmax function. We also tried the recommended BLEURT-base model for naturalness evaluation, however, it directly resulted in worse performance in our case.

4.4 Fine-tuning BERT plus Transfer Learning

Analysing the correlation of the naturalness scores with the respective quality and informative scores using Spearman rank correlation coefficient (Hauke and Kossowski, 2011) shows the positive results. The spearman’s correlation between naturalness and quality is $\rho = 0.60$ and between naturalness and informativeness is $\rho = 0.45$. Hence, this positive correlation is further leveraged through transfer learning (Pan and Yang, 2009) using the same BERT-based setup. The procedure is as follows: first, the BERT model is fine-tuned to quality (or in-
formativeness, respectively), and then this already fine-tuned model is continually fine-tuned once more using the naturalness score as target.

5 Results and Discussion

The results of our proposed approach (BERT) for estimating the naturalness of a generated sentence given an additional reference are depicted in Table 3. In addition to the baselines: BoW + SVM and Bi-LSTM and BLEURT, the majority class accuracy is also shown. It is calculated as the proportion of the majority class (naturalness score 6) resulting in $\frac{4669}{11353} = 0.41$. BERT + TLI and BERT + TLQ represent the Transfer Learning results from Informativeness (TLI) and Quality (TLQ) respectively.

The results in Table 3 show that all BERT-based approaches outperform the baselines for classifying the naturalness of a generated sentence achieving a higher overall accuracy.

Even though the data set is imbalanced as shown in Table 2, Madabushi et al. (2019) indicate that BERT is capable of handling imbalanced classes with no additional data augmentation, which is also confirmed in our work. The Table 4 shows the accuracy of different naturalness score on our proposed model BERT with test data. Even if the data is seriously imbalanced, every naturalness class has comparative accuracy.

Given the imbalanced data set, the macro F1 score, recall and precision are also computed to show the robustness of our proposed approach. Moreover, through the transfer of quality (or informativeness) knowledge to naturalness training, the performance of naturalness estimation is further improved and training speed has also been greatly promoted. Figure 3 shows that the naturalness training based on transfer learning is faster and tends to be stable after only 5 epochs. Table 3 shows that transferring knowledge from quality results in the highest improvement on naturalness estimation. This is also consistent with the Spearman correlation of the naturalness scores and quality scores which is higher than the correlation of the naturalness scores and informativeness scores.

The Table 3 shows that using the BLEURT model for naturalness evaluation results in the worst performance even though BLEURT was already pre-trained on multiple tasks. The possible reason is that the BLEURT was pre-trained with multiple automatic metrics, hence, it has no superiority in our naturalness classification task.

6 Conclusion and Future Work

In this paper, we proposed a novel task of automatically estimating the naturalness for task-oriented generation based on a human reference. We proposed a robust estimation approach by fine-tuning the pre-trained BERT model which outperforms an SVM classifier, Bi-LSTM, fine-tuned BLEURT and majority class accuracy. Taking advantage of the positive correlation of naturalness on quality (or informativeness), we successfully improved the naturalness training speed and estimation performance through transfer learning.

This work sheds light on research towards naturalness evaluation by neural network learning. The final goal of our work is to relieve the human labors from naturalness evaluation task and realize the automatic naturalness evaluation for dialogue generation. Hence, we will firstly collect more human evaluation data for future work. Because the human evaluation data, which is already shared and public on the internet, is very limited. With more collected human evaluation data, we are also interested in the performance of our proposed method on other

Abstract

Being able to accurately perform Question Difficulty Estimation (QDE) can improve the accuracy of students’ assessment and better their learning experience. Traditional approaches to QDE are either subjective or introduce a long delay before new questions can be used to assess students. Thus, recent work proposed machine learning-based approaches to overcome these limitations. They use questions of known difficulty to train models capable of inferring the difficulty of questions from their text. Once trained, they can be used to perform QDE of newly created questions. Existing approaches employ supervised models which are domain-dependent and require a large dataset of questions of known difficulty for training. Therefore, they cannot be used if such a dataset is not available (e.g. for new courses on an e-learning platform). In this work, we experiment with the possibility of performing QDE from text in an unsupervised manner. Specifically, we use the uncertainty of calibrated question answering models as a proxy of human-perceived difficulty. Our experiments show promising results, suggesting that model uncertainty could be successfully leveraged to perform QDE from text, reducing both costs and elapsed time.

1 Introduction

Question Difficulty Estimation (QDE), also known as “question calibration”, is a crucial task in education. In Computerized Adaptive Testing (Linden et al., 2000), for instance, students are shown questions that are suitable for their skill level. When a question is miscalibrated (i.e. its difficulty has been erroneously estimated), it can be either too hard or too easy for a student, which would negatively affect their learning outcome (Wang, 2014). If the questions are too hard, students might get frustrated and lose motivation; if they are too easy, students are not adequately challenged (Papousek et al., 2016). In either case, their learning experience is worse than if the questions were of appropriate difficulty, which, especially in the context of large-scale online courses, gives rise to the methods of automated difficulty estimation.

Traditionally, QDE is performed either i) manually (Attali et al., 2014) or ii) with pretesting (Lane et al., 2015). Manual calibration involves one (or more) human experts labelling the question by selecting a numerical value representing its difficulty, a method that is subjective and not scalable. Meanwhile, pretesting involves deploying the new question in an exam as if it was a standard exam question, but without using it to assess students and without telling them that there is a question under pretesting. The other questions of the exams are then used to actually assess the students, and their answers help to calibrate the question under pretesting. This approach indeed leads to an accurate calibration, but it introduces a long delay between the time of question creation and when the new question can be used to assess students. Besides, it requires the new questions to be shown to students before being actually used for scoring them, which is undesirable.

Recent studies tried to address the limitations of the traditional approaches by performing QDE with Natural Language Processing (NLP) techniques (Ha et al., 2019; Qiu et al., 2019; Benedetto et al., 2020b, 2021; Xue et al., 2020; Huang et al., 2017). They are all based upon the same general idea: starting from a set of calibrated questions, we train a supervised machine learning model to infer the difficulty of questions from their text. Once the model is trained, it is used to calibrate newly-generated questions, overcoming (or at least reducing) the need for pretesting and manual calibration. Although these techniques were proposed to enable an immediate calibration of new questions, they
have two major limitations due to their supervised manner: i) they require thousands of calibrated questions as a training set, and ii) they cannot perform cross-domain QDE. In other words, the training questions must assess the same topics as the new questions, which the model will later be used on, thus limiting its applicability (e.g. when introducing new courses in an e-learning platform). These limitations are intrinsic to such approaches and cannot be addressed by improving the accuracy of the models.

In this work, we explore an approach that is a total shift in the paradigm of QDE from text and which could potentially overcome both limitations. The intuition is to build an end-to-end Question Answering (QA) model that answers Multiple Choice Questions (MCQs) and use its uncertainty (which can be interpreted as representing the machine-perceived difficulty) as a proxy for human-perceived difficulty, which is the final target of the estimation. Previous research already hypothesized that there might be a relation between human-perceived difficulty and machine-perceived difficulty (Ha et al., 2019), but leveraged the machine-perceived difficulty as a feature for a supervised model, thus facing the same limitations as the approaches to QDE from text mentioned above. On the contrary, the approach we propose here performs QDE by leveraging the confidence of a trained QA model: specifically, we compute the variance of the probability distribution over the possible answer choices of the MCQ under calibration. Crucially, this approach is model agnostic and can be used on any QA model that outputs scores for the possible choices of an MCQ. Architecture-wise, in this study, we experiment with Transformers (Vaswani et al., 2017) for QA. In order to understand how well the proposed approach performs with different QA models, we use three different Transformers: BERT (Devlin et al., 2019), DistilBERT (Sanh et al., 2019), and XLNet (Yang et al., 2019). We choose them because they offer variety and differ in sizes, and were all demonstrated to perform well in several language understanding tasks.

However, large neural classification models tend to be overconfident in their predictions (Desai and Durrett, 2020), which might hinder the possibility of using their uncertainty as a proxy for question difficulty. In order to understand whether this is really an issue for unsupervised QDE from text and to explore possible solutions, we also experiment with calibrated QA models. Calibrating a model involves aligning the posterior probabilities with the empirical likelihoods (Guo et al., 2017). For instance, if we consider all the predictions for which a model has the confidence of 75%, the true accuracy must be 75% if the model is perfectly calibrated. We remark here that calibration and accuracy are not directly related: in fact, a model might be accurate but not calibrated or, on the other hand, not very accurate but well-calibrated. Calibration can be intuitively interpreted as the “awareness” of the model of its capabilities. In practice, several techniques can be used for calibrating neural models, and they will be discussed in Section 3. For simplicity and computational reasons, we use the ensembling technique.

We experiment on the large question-answering dataset RACE (Lai et al., 2017) to assess the QDE capabilities of the proposed approach. Specifically, we evaluate it on the task of pairwise difficulty prediction: given a pair of questions from RACE, the objective is to indicate which question of the pair is more difficult. As the gold standard for the difficulty, we use i) the difficulty level available in RACE and ii) additional human labels obtained with crowd-sourcing. The experimental results are promising and suggest that the proposed approach could be used to perform QDE from text in an unsupervised manner leveraging the uncertainty of QA models. We also show that choosing the underlying QA model is not straightforward, and the best results are obtained leveraging models that are both accurate and calibrated.

Our contributions are as follows: i) we propose an unsupervised way for QDE from text that does not require answer logs or question difficulty labels, only the text of the MCQ and the possible choices, ii) we experiment with modern Transformer-based architectures to demonstrate the viability of the proposed approach.

We share our code publicly1.

2 Related Work

The earliest research about QDE from text focused on MCQs, using bag-of-words and the similarities between question, correct choice, and distractors (incorrect choices) for the estimation (Alsubait et al., 2013; Ha and Yaneva, 2018; Kurdi et al., 2016; V and Puligundla, 2015). However, they are

1https://bit.ly/3b4tPLN
generally outperformed by the more recent models, which are based on machine learning techniques.

Ha et al. (2019) introduced a model to estimate from a question text its correctness, which is defined as the fraction of students who correctly answered the question. This model was trained using question texts and a large dataset of medical documents (i.e., books, papers). Similarly, the model proposed by Qiu et al. (2019) is trained on a dataset of medical documents and question texts to estimate the wrongness of newly generated questions. Benedetto et al. (2020b,a) proposed R2DE, a model that estimates the difficulty of newly generated MCQs, using as input only the text of the questions and the text of the possible choices, without any additional data. Xue et al. (2020) explored the effects of transfer learning for question calibration from text. Specifically, the authors fine-tune pre-trained ELMo embeddings (Peters et al., 2018) for the task of response time prediction and subsequently perform a second fine-tuning for the task of QDE. Lastly, Huang et al. (2017) propose a neural model for the estimation of the difficulty of reading comprehension questions.

From a high-level perspective, all these models are based on the same idea: the real question difficulty (obtained either with pretesting or manual calibration) is used as the target value for training a supervised machine learning model that performs QDE from text for newly generated questions. The downside of this approach is that it can work only as long as the new questions belong to the same domain as the training questions. Moreover, such models need a large number of calibrated questions for training, which might be too costly to obtain, especially for smaller institutions. (Wang et al., 2014) employs a pairwise difficulty comparison scheme similar to the one we will, but they still require the user responses for the algorithm to work, same as (Narayanan et al., 2017).

Motivated by this, in this work, we explore the possibility of completely shifting the paradigm for the task of QDE from text. The proposed approach leverages the uncertainty of a QA model as a proxy for question difficulty and uses this model-perceived difficulty to calibrate newly generated questions. This unsupervised approach does not require ground truth difficulty labels, but only the text of the questions and, in the case of MCQs, of the possible answer choices.

3 Calibration of Neural Models

Several techniques exist to calibrate neural network classifiers. The most popular ones are the following: i) vanilla: maximum softmax probability, which usually does not lead to calibrated classifiers (Hendrycks and Gimpel, 2017). ii) Temperature scaling: a posterior calibration technique using a validation set (Guo et al., 2017; Desai and Durrett, 2020). iii) Bayesian deep learning, which requires alterations to the training procedure and is computationally expensive. iv) Ensembles: consists in independently training $M$ models on the entire dataset using different random initializations (Lakshminarayanan et al., 2017) or dropout (Gal and Ghahramani, 2016; Srivastava et al., 2015) and averaging their predictions.

Focusing on pre-trained Transformers, previous research (Desai and Durrett, 2020) showed that pre-trained BERT is fairly well-calibrated for in-domain tasks, but it is miscalibrated for out-of-domain tasks. To the best of our knowledge, no previous research experimented with the calibration of DistilBERT and XLNet.

In this work, we use deep ensembles with $M$ equal to 3, since we observed that this approach led to fairly well-calibrated models for all the Transformer architectures under evaluation. Additionally, we also experimented with ensembles made of the combination of models with different architectures (e.g., BERT with XLNet, etc.).

Considering the metrics existing to evaluate model calibration, one of the most commonly used approaches is the Expected Calibration Error (ECE) (Naeini et al., 2015), which compares the confidence and the accuracy of the model. More precisely, it defines miscalibration as the difference in expectation between confidence and accuracy. Thus, ECE approximates the miscalibration by partitioning the predictions in a number $M$ of bins and averaging the difference between the accuracy and confidence obtained in each bin.

4 Models

The approach proposed in this paper leverages the confidence of a QA model to perform QDE for MCQs in an unsupervised manner. Specifically, it leverages the output scores, one for each possible answer choice, produced by the model for each question, and the only requirement is that such output scores represent a probability distribution (i.e., they sum to 1, such as the softmax scores of
a neural network). We experiment here on MCQ with four possible choices, but the approach can be easily scaled to MCQ with different numbers of answer choices. It is important to note that this approach to unsupervised QDE from text is “QA model agnostic”, in the sense that it does not need any information about the underlying model but only the scores produced by it. We leverage the softmax scores produced by the underlying QA model to measure the model-perceived question difficulty, which is considered a proxy for human-perceived difficulty. In practice, we convert the raw softmax scores of each question into a single numerical value by computing their variance. We assume that larger values of variance indicate easier questions (since it means that the model is more certain in the estimation).

We also experimented with some alternatives, but they were generally outperformed by using the score variance (although the difference was not major). Specifically, we also experimented with: i) keeping only the highest softmax score, and ii) computing the difference between the highest and the second-highest softmax score.

In order to understand how the proposed approach performs with softmax scores from different underlying QA models, we experiment with three Transformer models: i) BERT (Devlin et al., 2019), ii) DistilBERT (Sanh et al., 2019), and iii) XLNet (Yang et al., 2019). The details of each architecture are beyond the scope of this research; we refer to the original papers for their description. For our study, it is essential to know that they are all publicly available neural network models, which are pre-trained on several language understanding tasks, and that they can be fine-tuned for different downstream tasks with minimal changes to the architecture. Precisely, in this study, we add a multiple-choice classification layer on top of each original model, which is a common task in the literature. The three models have diverse sizes and architectures, even though DistilBERT is strongly related to BERT since it is obtained from it by using knowledge distillation (Hinton et al., 2015) to reduce the number of hidden layers.

We implement all the models with the HuggingFace transformers library (Wolf et al., 2019), using in all cases the pre-trained base-cased version. We fine-tune them using Google Colab GPUs. The parameter configuration for the QA models is taken from the literature; the specific values are shown in Table 1. The table also shows, for each model, the accuracy we obtain in the QA task on RACE, which is in line with previously reported results.

As suggested by (Lakshminarayanan et al., 2017), we ensemble models to reduce miscalibration. In practice, we proceed as follows. First, we i) train five instances for each architecture (i.e. BERT, DistilBERT, XLNet), and each instance is trained on the entire training dataset (randomly shuffled), with a different random initialization. Then, we ii) pick the three best performing instances of each architecture, considering the test accuracy on the QA task. Lastly, we iii) build the ensembles by averaging (separately for each test question) the softmax scores produced by the three instances of each architecture so that each of the four answer options is assigned a single score from 0 to 1. These scores indicate the probability (according to the model) of each option being correct. In addition to building an ensemble for each architecture, we also build “hybrid” ensembles in the same way but averaging the predictions of instances of different architectures.

## 5 Data

In this study, we use the reading comprehension RACE dataset\(^2\) and two datasets derived from it, which contain pairs of questions and a label indicating which question of the pair is more difficult. The entire RACE dataset is used to train the QA models, while the two other datasets are used for the experiments on QDE from text.

### 5.1 RACE

The original RACE dataset contains 25,000 passages in English from middle and high school reading comprehension exams, with four MCQ associated with each text (100,000 questions in total). All the questions are MCQ with four possible choices (see an example in Figure 1). The questions are

designed to require more extensive reasoning skills than other QA datasets such as SQuaD (Rajpurkar et al., 2016) and differ in reasoning types required to answer them. For example, they cover passage summarization and attitude analysis, which means that the answer cannot always be extracted directly from the passage. As a result, neural methods have a significant performance gap compared to humans: 66.7% (with XLNet-base) and 94.5% accuracy, respectively. The questions can be separated into two types based on their syntax: interrogative or cloze. Interrogative questions are the ones that end with a question mark, while cloze questions contain a gap that has to be filled in.

5.2 PairRACE HM

For constructing this dataset, we use the level label available in RACE, which indicates the level of examination (high or middle) of each question. Specifically, we use level as an indication of question difficulty and prepare 2,062,096 pairs of question, such that each pair contains one middle question and one high question (related to different passages). This dataset is then used to evaluate the proposed approach in the task of pairwise difficulty estimation: basically, given a pair of question, we check whether the proposed approach labels the high question as being the more difficult one.

5.3 PairRACE CS

The level label does not contain a numerical estimation of question difficulty, and there is no way of knowing how much harder the high questions are. Therefore, we also build a dataset to evaluate how well the proposed approach performs at a more focused level difficulty estimation, which differentiates the difficulty of the question within the middle level and within the high level. Such fine-grained information about the difficulty is not available in RACE; thus we manually annotate a subset of the question pairs by crowd-sourcing on the Amazon Mechanical Turk platform.

First, 80 pairs of questions from the test set were randomly chosen (both questions in each pair have the same level and correspond to the same passage, with 77 unique passages used in total). An annotator was then presented with a passage and a pair of questions, along with their answer options, and asked to identify the more difficult question. Each question was first labelled by two of the authors (with Cohen’s kappa of 0.30) and then passed to turkers. The only condition imposed on turkers was to be native English speakers. Each question was answered by one crowd-worker; thus, in combination with our labels, we obtained three labels per question pair. To encourage a thoughtful approach, we added an obligatory field in which we asked the turkers to provide a brief motivation for their choice. An example reasoning is the following: “Question 1 requires you to think beyond the passage content, to extrapolate and predict the next step, while 2 just asks to give a title to the content.” There were multiple recurring indicators of how humans estimate difficulty. As expected, the questions which require searching for a named entity or finding a simple fact statement are considered simpler, while summarising information or giving a title is more challenging. The text’s location contributes as well – it is easier to answer the question if the cue can be found in the first or the last sentences of the passage. Ultimately, the Fleiss’ kappa agreement was 0.21, which is “fair”, according to guidelines by (Landis and Koch, 1977). Still, we recognise the possible issues with a relatively low agreement, and, in the experimental evaluation, we separately consider the performance on the question pairs with full agreement.

6 Experiments

The goal of our experiments is to perform unsupervised QDE from text, using only the softmax scores produced by QA models. More precisely, we do not estimate directly question difficulty but evaluate the proposed approach on the task of pairwise difficulty prediction: given a pair of questions, the task consists in identifying the one that is more difficult. The manual labels are obtained, also within the pairwise comparison framework. This way,
we investigate i) whether the machine uncertainty leads to a notion of difficulty that aligns well with the human one – which is represented by the level and the crowdsourced labels – and ii) whether it can be useful in practical applications when logs of answers or calibrated questions are not available for training.

### 6.1 Evaluating QA accuracy and calibration

Before actually evaluating the proposed approach on the task of pairwise difficulty prediction, we evaluate the QA accuracy and the calibration of the underlying models to explore the relations between these and the accuracy in the task of pairwise difficulty prediction. Results are shown in Table 2.

For QA, we use accuracy as a metric (the higher, the better), while for calibration, we use Expected Calibration Error (ECE, the lower, the better). It should be noted that ECE is used to diagnose whether the model’s confidence can be a reliable proxy for difficulty or not.

For each underlying model (i.e. BERT, DistilBERT, XLNet), we present the results for three single instances and the calibrated ensemble. The single instances are identified by a number, which is the random seed used during training. While the specific value of the random seed is not meaningful in itself for this analysis, we use it to distinguish between different instances of the same architecture. Ensembles are indicated by “E”.

As for the QA accuracy, we can see that, considering the same architecture (e.g. BERT) the accuracy of the ensembles is generally better than the single models, both on the eval dataset and the test dataset. However, this is not true for the “hybrid” ensembles, which perform worse than the model they are obtained from.

Similar results can also be seen for model calibration: ensembles generally have lower ECE, meaning that they are better calibrated. Indeed, BERT (E) has an ECE of 0.10, while the average of the single models is over 0.14, and XLNet (E) has an ECE of 0.11, the average of the single instances being 0.15. This trend is not as visible for DistilBERT, as the ensemble model has an ECE only slightly higher than the average of the single instances (0.07 compared to 0.06).

### 6.2 Pairwise difficulty prediction

Given as input a question pair, the unsupervised pairwise difficulty prediction task consists of predicting which question of the pair is more difficult. We evaluate the proposed approach using different underlying models (both single instances and calibrated ensembles), and compare it with three baselines based on ELMo (Peters et al., 2018). It should be noted that internally there is no difference indicated between comprehension and knowledge questions and each model is thus evaluated on the same subset.

i) ELMo\(_C\) (comprehension): we calculate the cosine distance between the ELMo embeddings of the question and of the passage; the question with the larger distance is labelled as more difficult.

ii) ELMo\(_K\) (knowledge): we calculate the average distance between the correct answer option and the distractors; the more difficult question has the lowest distance. This is a standard approach in the literature (Alsubait et al., 2013; Kurdi et al., 2016).

iii) ELMo\(_{QA}\): a QA model built upon ELMo. Given a passage and an MCQ, it selects the answer by picking the choice which has the lowest cosine distance to the passage. It produces one score for each possible choice, and we use our approach directly on these scores (after normalization).

As introduced in Section 4, the proposed ap-
Table 3 presents the results obtained on PairRACE_HM and PairRACE_CS, using accuracy as evaluation metric. Each row shows the results for a different model, and we can identify three groups: the baselines, the single instances, and the ensembles.

### 6.2.1 High vs middle (PairRACE_HM)

The columns on the left present the results obtained using the `level` label as ground truth difficulty. We separately present the accuracy i) on all the question pairs and ii) on the pairs in which both questions were Correctly Answered (CA) by the QA models; \( n \) is the number of question pairs.

Considering all the pairs, we can see that the proposed approach consistently performs at least as well as the baselines, both when using the single models and when using the ensembles, although the improvement is not major. The only exceptions are DistilBERT (3) and DistilBERT-XLNet (E).

Interestingly, if we compare Table 3 and Table 2, we can see that there is no clear correspondence between the accuracy in the QA task and the accuracy in pairwise difficulty prediction or between the ECE and the accuracy in pairwise difficulty prediction. For instance, DistilBERT (3) has the lowest (i.e. best) ECE, but it is outperformed by all the ensembles (except the hybrid ones) in the pairwise difficulty prediction task. This suggests that the calibration of the QA model is not the only factor to take into consideration when using its uncertainty for QDE and that its QA accuracy also has an important role.

Comparing the accuracy of the ensembles and the single models, we observe that there is no appar-
ent improvement in using calibrated ensembles. It is especially noticeable when considering only the questions that the models correctly answered. However, in a real-world unsupervised scenario, the true difficulty labels are not available for choosing the best performing model with cross-validation, and neither the accuracy in the QA task nor the ECE is sufficient to pick the best performing model. Therefore, we argue that the usage of calibrated ensembles is a better solution as it allows to avoid the oscillations of single instances (e.g. from 0.56 to 0.60 of the single DistilBERT models against the 0.58 of the ensemble). However, this is true only for ensembles of models with the same architecture. Hybrid ensembles did not lead to better performance; thus, we argue that they should not be used for the task of unsupervised QDE from text.

6.2.2 Crowdsourced labels (PairRACE_CS)

Moving to the right side of the table, we consider the crowdsourced difficulty as ground truth, and we present the results separately for i) the whole dataset, ii) the pairs of questions with Total Agreement between human annotators (TA), and iii) the pairs of questions with Total Agreement and Correctly Answered by each model (TA & CA).

The most crucial difference is that the best performing model, in this case, is ELMO_C. It means that leveraging the similarity between the provided document and the questions might be a good alternative to using the uncertainty of the QA models for comprehension MCQ. This is reasonable since the goal of comprehension questions is to find the answer to the question in the accompanying passage. However, this is not in agreement with the results obtained on PairRACE_HM. Also, we have to consider that PairRACE_CS is made of only 80 question pairs (37 when considering only the ones with total agreement) while PairRACE_HM contains 2M pairs; therefore the performance of ELMO_C is worth of further exploration. Moreover, BERT (E) and XLNet (E) clearly outperform ELMO_K and ELMO_QA, suggesting that indeed the uncertainty of accurate and calibrated QA models can be beneficial for QDE of knowledge questions (which are not provided with an accompanying passage that contains the answer).

Differently from the previous experiment, the performance of DistilBERT (E) here is clearly worse than the other ensembles (it is even worse than random), thus suggesting that – being a smaller model – they are not capable of modelling the questions as well as BERT (E) and XLNet (E).

Except for these two differences, the rest of the findings is fairly similar to PairRACE_HM, and the ensembles generally outperform the single instances of the same architecture. Crucially, the accuracy of all ensemble models (except the hybrid ones) is higher for pairs with the total agreement, thus supporting the claim that the uncertainty of QA models could really be used for unsupervised QDE from text. It is also interesting to remark that this is not always the case for the single instances of Transformers, which sometimes have worse accuracy on the pairs with total agreement. This, once again, suggests that calibrated ensembles are more suitable for unsupervised QDE from text.

Considering the pairs with the total agreement and containing questions correctly answered by the QA models (shown in column TA & CA^3), we can see that the correctness of the QA model does not seem to have a significant impact on the accuracy. However, there are only a few question pairs of this type; therefore we cannot perform any relevant observations.

7 Conclusions

The results of this research support the idea that it is possible to estimate the human-perceived difficulty of exam questions via the uncertainty scores produced by Question Answering (QA) neural networks. The advantage of the approach we propose is that it is possible to predict the relative difficulty of questions across different domains without needing any calibrated questions or logs of students’ answers. For training the QA model, it is sufficient to have access to i) the corpus of questions and (possibly) ii) the learning materials.

As a practical guideline, both the QA accuracy and the calibration seem to impact the accuracy of QDE. Therefore we believe that it is better to use calibrated models which are powerful enough to reach decent performance in the QA task (e.g. the BERT and XLNet ensembles used here).

Future work will focus on exploring whether improving the calibration of the QA models (e.g. increasing the number of models in the ensemble or using Bayesian neural networks) would lead to improved results in unsupervised QDE from text and will analyze the effects of combining raw softmax scores with different techniques. Weighing the

---

^3We do not show the accuracy unless there are at least 10 question pairs correctly answered.
scores by the accuracy of each intervening model is a way to explore whether hybrid ensembles can still improve the performance, but we leave the implementation of this approach for another study.

Another natural progression of this work is to leverage question-specific information, such as the reasoning type required to answer it, or the question format (e.g., cloze items vs interrogative items). Using the text of the possible choices might improve the accuracy, which makes it an interesting modification to explore in future studies. Further experimental investigations are also needed to use the proposed approach for creating a difficulty ranking of questions.

Abstract

We present GeSERA, an open-source improved version of SERA for evaluating automatic extractive and abstractive summaries from the general domain. SERA is based on a search engine that compares candidate and reference summaries (called queries) against an information retrieval document base (called index). SERA was originally designed for the biomedical domain only, where it showed a better correlation with manual methods than the widely used lexical-based ROUGE method. In this paper, we take out SERA from the biomedical domain to the general one by adapting its content-based method to successfully evaluate summaries from the general domain. First, we improve the query reformulation strategy with POS Tags analysis of general-domain corpora. Second, we replace the biomedical index used in SERA with two article collections from AQUAINT-2 and Wikipedia. We conduct experiments with TAC2008, TAC2009, and CNNDM datasets. Results show that, in most cases, GeSERA achieves higher correlations with manual evaluation methods than SERA, while it reduces its gap with ROUGE for general-domain summary evaluation. GeSERA even surpasses ROUGE in two cases of TAC2009. Finally, we conduct extensive experiments on the impact of the index size on summary evaluation with SERA and GeSERA. Code and Wikipedia dataset are publicly available.

1 Introduction

Automatic summary evaluation is a challenging task in Natural Language Processing (NLP). Evaluation is usually done by humans, but manual evaluation is subjective, costly and time expensive (Lin and Hovy, 2002). Automatic evaluation methods (Lin, 2004a; Torres-Moreno et al., 2010; Zhao et al., 2019; Zhang et al., 2020) are an alternative to save time for users who extract the most relevant content from the web using Automatic Text Summarization systems (ATS). There exist two types of evaluation approaches: (1) manual evaluation methods like Pyramid (Nenkova and Passonneau, 2004) and Responsiveness, where human intervention is mandatory, and (2) automatic evaluation methods, where human intervention can be needed as a ground-truth reference (Lin, 2004a; Cohan and Goharian, 2016) or not (Torres-Moreno et al., 2010; Cabrera-Diego and Torres-Moreno, 2018).

Summary Evaluation by Relevance Analysis (SERA) (Cohan and Goharian, 2016) is an automatic evaluation method that partially relies on human references to evaluate abstractive summaries from the biomedical domain. It was proposed as an alternative to ROUGE (Lin, 2004a), the widely used automatic metric, that is based on lexical overlaps between candidate and reference summaries. ROUGE is unfair to evaluate abstractive summaries where the ATS paraphrases the text instead of just copying-pasting chunks of it (Cohan and Goharian, 2016).

SERA is based on content relevance and is fairer to evaluate abstractive summaries because it attributes high scores to summaries that are lexically different but semantically related. However, it surpasses ROUGE on the biomedical domain only. In this paper, we modify SERA to make it usable for generic collections. We propose the following contributions:

1. Implement an open-source version of SERA from scratch.
2. Propose GeSERA (General-domain SERA), an improved version of SERA that is domain-independent.
3. Conduct extensive experiments with two large indexes (AQUAINT-2 (Graff, 2002) and Wikipedia) and three summarization datasets.
These datasets are well-suited for general-domain and news abstractive summary evaluation. GeSERA achieves competitive results compared to a range of state-of-the-art evaluation approaches on both abstractive and extractive summaries.

4. Make the code and our Wikipedia dataset publicly available to help future researchers.

5. Conduct extensive experiments on the impact of the index size on summary evaluation with SERA and GeSERA.

2 Proposed approach

2.1 Baseline: SERA

SERA (Cohan and Goharian, 2016) is based on a content relevance between a candidate summary and its corresponding human-written reference summaries using information retrieval. SERA compares these summaries (called queries) against a set of documents from the same domain (called index), and compares the overlap of retrieved results. SERA refines queries in three different manners: (1) Raw text - only stop words and numbers are removed, (2) Noun phrases (NP) - only noun phrases are kept, and (3) Keywords (KW) - only unigrams, bigrams, and trigrams are kept.

SERA scores are computed with Equation 1:

\[
\text{SERA} = \frac{1}{M} \sum_{i=1}^{M} \frac{|R_C \cap R_{G_i}|}{|R_C|}
\]

where: \(R_C\) is the list of retrieved documents for the candidate summary \(C\), \(R_{G_i}\) is the ranked list of retrieved documents for the reference summary \(G_i\), and \(M\) is the number of reference summaries.

Another variant of SERA is called SERA-DIS. It takes the order of retrieved documents into consideration (Equation 2).

\[
\text{SERA – DIS} = \frac{1}{M \cdot D_{\text{max}}} \sum_{i=1}^{M} \left( \sum_{j=1}^{R_C} \sum_{k=1}^{R_{G_i}} X_{j,k} \right)
\]

\[
X_{j,k} = \begin{cases} 
1 & \text{if } R_C(j) = R_{G_i}(k) \\
0 & \text{otherwise}
\end{cases}
\]

where: \(R_C(j)\) is the \(j^{th}\) result in the ranked list \(R_C\), and \(D_{\text{max}}\) is the maximum achievable score used for normalization. In both SERA variants, retrieved results are truncated at 5 and 10 documents (hence the notations SERA-5 and SERA-10 in Section 3). Cohan and Goharian (2016) used articles from PubMed as an index, and summaries from TAC 2014 as queries.

The intuition behind SERA is that a summary context is represented by its most related articles. Thus, two summaries related to the same documents are semantically related, even if they are lexically different. Consequently, SERA is fairer to evaluate abstractive summaries contrarily to the lexical-based ROUGE. However, SERA suffers from a series of limitations: (1) the code is not open-source, (2) no information was provided concerning the subset of PubMed used as an index, and (3) PubMed is specialized in the biomedical domain only. The first two drawbacks make SERA unusable by the community, while the third restricts its usage to the biomedical domain.

2.2 GeSERA: General-domain SERA

We build on SERA merits and limitations to propose GeSERA, an open-source version of SERA that evaluates summaries from the general domain. Novelties of GeSERA are the index pool and query reformulation adapted to the evaluation of summaries from the general domain.

Index documents pool - Differently from SERA, GeSERA enables general-domain summary evaluation. It is thus necessary to replace the biomedical index used by Cohan and Goharian (2016) with a set of documents related to the general domain. We build many indexes using a variant number of articles from Wikipedia and AQUAINT-2. See Subsection 3.1 for more details.

Query reformulation (QR) - It improves retrieval process by removing unnecessary terms from the text. Therefore, we propose a different approach to refine queries in GeSERA that is better suited for general domain summaries.

According to Kieuvonggnam et al. (2020), nouns in generated summaries represent more accurately the information conveyed by the original abstracts than other POS tags. This study was conducted on Covid-19 medical texts and can explain why SERA achieved a higher correlation than ROUGE for the TAC 2014 biomedical dataset. We led an analysis that consists of analyzing Part-Of-Speech (POS) tags distribution

\[

\]

\[
\text{https://github.com/}
\]

\[
\text{JessicaLopezEspejel/GeSERA/}
\]

\[
\text{http://www.ncbi.nlm.nih.gov/pmc/}
\]
for PubMed (biomedical dataset built by Cohan et al. (2018)), AQUAINT-2 (news corpus), and Wikipedia (general domain encyclopedia). Figure 1 shows bar plots for percentages of nouns, verbs, adjectives (Adj.), prepositions (Prep.), and the total percentage of other tags (Others).

Figure 1: POS Tags distribution percentages for Wikipedia, AQUAINT-2, and PubMed datasets

Our analysis of three datasets which describe different domains confirms the observation of Kieuvongngam et al. (2020) for PubMed. However, it shows that the percentages of verbs and adjectives are higher in AQUAINT-2 and Wikipedia than in PubMed. Equally important, there is a remarkable absence of prepositions in Wikipedia and AQUAINT-2. Based on our analysis, we propose to reformulate queries in GeSERA by only keeping tokens tagged with nouns, verbs, and adjectives, the three most frequent tags in the news and general domain corpora.

Search engine - A semantic-based retrieval approach is crucial when handling abstractive summaries. In order to compare the queries against the index, a search engine is needed for information retrieval and scoring. We use the Whoosh4 search engine with the BM25F (Best Match 25 Model with Extension to Multiple Weighted Fields) ranking function (Zaragoza et al., 2004). This model is widely used for semantic search (Pérez-Agüera et al., 2010; Robertson and Zaragoza, 2009). It consists in weighting terms according to their field importance, combining them, and using the resulting pseudo-frequencies for ranking.

3 Experiments

SERA was developed in the context of scientific biomedical article summarization with the idea that its semantic specificity is particularly useful for this domain. We hypothesize that if we reformulate queries properly and change the index pool, SERA can assess summaries from other domains for both abstractive and extractive summarization. This hypothesis is based on the fact that SERA considers terms that are not lexically equivalent but are semantically related. We conduct extensive experiments on SERA and GeSERA to test our hypothesis.

3.1 Index datasets

The index is a key component of GeSERA approach insofar as it should describe the same domain as the queries. The number of documents in the index is also decisive as we will show in Subsection 4.1. We describe briefly query and index datasets hereafter and provide more information in Appendix B.

AQUAINT-2 (Graff, 2002) is a news corpus built from various sources. We vary the size of the index to include \( I = \{10000, 15000, 30000, 60000, 89760, 179520, 825148\} \) randomly-selected documents.

Wikipedia is a free encyclopedia that contains various information from the general domain. We vary the size of the index to include \( I = \{10000, 15000, 30000, 1778742\} \) randomly-selected documents.

3.2 Query datasets

Candidate and reference summaries from the news datasets TAC2008, TAC2009, and the CNN Daily Mail (CNNDM) version published by Bhandari et al. (2020) are used as queries.

TAC2008 (and TAC2009) are subsets of AQUAINT-2. They contain 5568 (4840) candidate summaries proposed by 58 (55) participants, and 384 (352) reference summaries, respectively. These datasets are designed for multi-document extractive summarization (one summary is shared by a set of documents).

CNN Daily Mail (Bhandari et al., 2020) is a news dataset, and is of great interest to us because it has candidate summaries obtained from both extractive and abstractive systems. It consists of 100 reference summaries, having each 25 candidate summaries generated by 11 extractive and 14 abstractive systems. It is designed for monodocument abstractive and extractive summarization (one summary for each document).
We compare GeSERA with some of the most influential evaluation metrics from the literature:

- **ROUGE** and **SERA** - two automatic evaluation approaches that rely on human intervention. ROUGE has many variants, but we only report the most popular ones: ROUGE-N ($N = \{1, 2\}$ is the n-gram size) and ROUGE-L (Longest Common Subsequence). For each variant, we report the F-score, Recall and Precision.

- **MoverScore** (Zhao et al., 2019) and **BERTScore** (Zhang et al., 2020) - two automatic evaluation approaches based on BERT.

- **JS-2** (Lin et al., 2006) - Jensen-Shannon divergence between bigram’s distribution of the candidate and reference summaries.

- **SummTriver** (ST) (Cabrera-Diego and Torres-Moreno, 2018) - based on trivergence, i.e. a composition ($T_c$) or multiplication ($T_m$) of Kullback-Leibler (KL), Jensen-Shannon (JS), and smoothed Jensen-Shannon (sJS) divergences. It does need a human reference.

- **FRESA** (Torres-Moreno et al., 2010) - an automatic evaluation method that do not rely on human intervention. It is based on Jensen-Shannon divergence and has four variants: unigrams (FRESA-1), bigrams (FRESA-2), trigrams (FRESA-3), and skip-grams (FRESA-4).

More information is in Section 5. Implementation details are in Appendix C.

### 4 Results and discussion

In Subsection 4.1, we vary the index size in SERA and GeSERA and study the variation of their performance on TAC datasets by averaging the score of all four manual annotators. Once we determine the best index size, we present in Subsection 4.2 the correlations using the best index size of each method.

#### 4.1 Impact of the index size on the performance of SERA and GeSERA

We first present the impact of the indexes size built from Wikipedia on SERA and GeSERA, then those built from AQUAINT-2.

**Wikipedia Index** - Figures 2-b and 2-d show Pearson correlations of SERA and GeSERA with Pyramid when indexing different values of $I$ from the Wikipedia dataset, and when using TAC2008 and TAC2009 as query datasets, respectively. Figures show that the best score (0.902) is obtained with SERA-DIS-NP-10 using $I = 30,000$ for TAC2008 while the best one (0.957) for TAC2009 is obtained with GeSERA-DIS-10 with $I = 10,000$. We thus use in Subsection 4.2 an index size $I = 30,000$ and $I = 10,000$ for TAC2008 and TAC2009, respectively. Surprisingly, the worst scores are obtained with $I = 1,778,742$, the largest and more diversified index size corresponding to all documents from our Wikipedia corpus.

**AQUAINT-2 Index** - Figures 2-a and 2-c show the Pearson correlation coefficients of SERA and GeSERA with Pyramid when indexing different values of $I$ from the AQUAINT-2 dataset, and when using TAC2008 and TAC2009 as query datasets. Similarly to Wikipedia, figures show that overall, the best results are obtained with small index sizes. The best score (0.928) was obtained with GeSERA-5 using $I = 15,000$ for TAC2008, while the best one (0.947) for TAC2009 is obtained with both SERA-DIS-NP-10 and GeSERA-DIS-5 using $I = 179,520$. Note that results with $I = 10,000$ are comparable with those obtained with $I = 179,520$ for TAC2009. We thus use in Subsection 4.2 an index size $I = 15,000$ and $I = 179,520$ for TAC2008 and TAC2009, respectively. Once again, the lowest results are obtained with the full AQUAINT-2 corpus corresponding to $I = 825,148$. 

---

864
Figure 2: Pearson correlation coefficients using TAC2008 and TAC2009 as queries, and AQUAINT-2 and Wikipedia as indexes. Best viewed in color.

4.2 Comparison of GeSERA with the SoTA
We use the best index sizes from Subsection 4.1 to report the detailed results with the best variants of each method from Subsection 3.3. More results are reported in Appendix D.

4.2.1 TAC2008 query dataset
Table 1-up shows correlations of the best variants of SERA, GeSERA, ROUGE, SummTriver (ST) and FRESA with two manual evaluation approaches: Pyramid and Responsiveness. Note that for SERA and GeSERA, we fix the query dataset TAC2008, while we vary the index between AQUAINT-2 and Wikipedia.

AQUAINT-2 Index - Results show that GeSERA-5 achieves the best scores among all variants of SERA and GeSERA for both Pyramid and Responsiveness. SERA-5 is the best variant of SERA for Pyramid with Pearson and Spearman, while SERA-NP-10 provides better results for Pyramid with Kendall, and Responsiveness with all correlation measures. GeSERA-5 surpasses the two best variants of SERA by 0.015 (Pearson), 0.016 (Spearman), and 0.021 (Kendall) points for Pyramid, and by 0.02, 0.027, and 0.031 points for Responsiveness. The gains are higher for Responsiveness, and for Kendall correlations.

Wikipedia Index - Results show that GeSERA-10 is the best variant of GeSERA for Pyramid with all correlation metrics used. GeSERA-DIS-10 gets the best scores for Responsiveness with Pearson and Kendall. Alternatively, the best SERA variant is SERA-DIS-NP-10 for Pyramid with all correlation measures, and with Responsiveness for Spearman and Kendall measures. Interestingly, when using queries from TAC2008 with Wikipedia, GeSERA does not outperform SERA neither for Pyramid, not for Responsiveness.

Table 1: Correlations on TAC2008 and TAC2009 datasets, in terms of Pearson, Spearman and Kendall, of automatic evaluation methods with Pyramid and Responsiveness. The best first (red), second (blue) and third (black) score of each column are in bold.
While ROUGE-2-R and ROUGE-3-F provide the best results for all correlation measures on TAC2008, GeSERA and SERA largely outperform the scores of SummTriver and FRESA with both Pyramid and Responsiveness. In the case of GeSERA-5, it achieves higher correlations than ST-JS-Tm, the best variant of SummTriver, by 0.039, 0.097, and 0.117 for Pyramid, and 0.049, 0.053, and 0.055 for Responsiveness. Finally, FRESA baseline achieves the lowest correlation scores in all configurations. The performance of SummTriver and FRESA is not surprising insofar as they do not rely on any human reference.

4.2.2 TAC2009 query dataset

Table 1 shows correlation coefficients of SERA, GeSERA, ROUGE, SummTriver and FRESA with two manual evaluation approaches: Pyramid and Responsiveness. Once again, we fix the query dataset TAC2009, while we vary the index between AQUAINT-2 and Wikipedia.

AQUAINT-2 Index - ROUGE provides the highest scores against SERA and GeSERA when we index documents from AQUAINT-2. Importantly, GeSERA-DIS-5 and GeSERA-5 achieve higher correlations than SERA with Pyramid and Responsiveness, respectively. Note that the scores of SERA vary more between its variants, while results of GeSERA are more stable and the best ones are obtained with only two of its variants. This finding highlights the robustness of our approach against variations of configurations.

Wikipedia Index - SERA and GeSERA outperform ROUGE against the Pyramid manual method in terms of Pearson correlation when indexing documents from Wikipedia. The best correlations are obtained by GeSERA-DIS-10 and SERA-10 against Pyramid and Responsiveness, respectively. Interestingly, for TAC2009, GeSERA-DIS-10 achieves better Pearson correlation than ROUGE with Pyramid, and GeSERA-10 with Responsiveness. This finding proves the effectiveness of GeSERA to evaluate summaries from the general domain. Equally, GeSERA reduces the gap between SERA and ROUGE in most of other cases. SummTriver achieves reasonably good results in Table 1 even without the use of any human reference. This baseline is useful when human summaries are costly or hard to find. However, when such references are available, SummTriver does not take advantage of them, leading its correlation to be low compared to human-based evaluation approaches such as ROUGE and SERA.

FRESA shows the lowest scores among evaluation approaches tested here. It drops approximately from 0.1 to 0.3 point compared to the lowest results obtained by SERA. This is mainly because FRESA is based only on the divergence between the evaluated summary and its source documents, without including any comparison with summaries generated by other participants, as SummTriver does. Thus, FRESA is barely correlated with manual evaluation in many cases where the correlation gets so close to zero (for instance, FRESA-2 with TAC2009 using Kendall correlation). Note that SummTriver and FRESA have mostly negative correlations because they are based on a divergence measure which increases when the summary’s quality is low and decreases when its quality is high.

4.2.3 CNNDM query dataset

Based on results obtained in Subsection 4.1 regarding the effectiveness of SERA and GeSERA with small index sizes, we decided to index \( I = 10000 \) documents from Wikipedia to run the two methods on CNNDM.

</table>

Table 2: Correlation coefficients on CNNDM, in terms of Pearson, Spearman and Kendall, of multiple automatic evaluation methods with LitePyramid.

Table 2 shows that the highest correlations of ROUGE are obtained with ROUGE-2-R, followed by ROUGE-1-R. Globally, the highest correlations in ROUGE are obtained with the recall metric (ROUGE-R), followed by ROUGE-F, and finally by ROUGE-P. The following highest correlations are obtained with GeSERA-10. Once again, GeSERA surpasses all the SERA variants, and the state-of-the-art methods presented in this table.

866
Although SERA-KW-10 has the best score in terms of Pearson and Kendall, all SERA variants present very similar scores. Behind the SERA method, BERTScore and JS-2 measures present very similar scores. Meanwhile, MoverScore shows the lowest correlations. Results show the effectiveness of GeSERA to evaluate extractive and abstractive summaries since CNNDM contains both approaches.

5 Related work

Evaluation methods are fundamental techniques to assess if summaries generated by an automatic system capture the original document’s idea. Different evaluation methods have been developed in the last decade for the evaluation of automatically-generated summaries. There exist two types of evaluation methods: (1) manual evaluation methods and automatic evaluation methods. The first group of methods requires human intervention as ground-truth references. Pyramid (Nenkova and Passonneau, 2004) and Responsiveness are the most popular such methods. The second group of methods is divided itself into two subsets: (1) methods that need human intervention like ROUGE (Lin, 2004a) and SERA (Cohan and Goharian, 2016), and (2) methods that do not need any human reference like SummTriver (Cabrera-Diego and Torres-Moreno, 2018) and FRESA (Torres-Moreno et al., 2010).

The most popular automatic metric used by the community is ROUGE (Lin, 2004a). It needs reference summaries, and is based on their lexical overlaps with candidate summaries. That is why it is more useful to evaluate extractive summaries where chunks of the text are copied and pasted to form the summary. However, in the case of abstractive summaries where the ATS paraphrases the text with possibly new vocabulary, the ROUGE metric becomes unfair. To overcome this issue, researchers have been proposing in the last few years other automatic metrics to fairly evaluate both extractive and abstractive summaries.

The first type of automatic evaluation methods relies partially on human judgment as ROUGE does. The simplest method is Jensen-Shannon (JS-2) (Lin et al., 2006). It is based on the divergence between bi-gram’s distribution of candidate and reference summaries. More sophisticated systems include MoverScore (Zhao et al., 2019) that is based on fine-tuning the BERT model and combining contextualized representations with Earth Mover Distance (EMD) from (Rubner et al., 2000). BERTScore (Zhang et al., 2020) also is based on BERT model. Unlike ROUGE (Lin, 2004b), BERTScore makes use of contextual embeddings that are effective for paraphrase detection. Similarly to BERTScore, Semantic Similarity for Abstractive Summarization (SSAS) (Vadapalli et al., 2017) is based on semantic matching between candidate and reference summaries. The second type of automatic evaluation methods does not need any human intervention. For instance, FRamework for Evaluating Summaries Automatically (FRESA) (Torres-Moreno et al., 2010) is based on divergences among probability distributions between the summary to evaluate and its source document. Another well-known metric is SummTriver (Cabrera-Diego and Torres-Moreno, 2018). It is based on Trivergences between the summary to evaluate, its source document(s), and a set of summaries related to the same source document(s) but generated with other ATS systems.

6 Conclusion and perspectives

We introduced GeSERA, an open-source system for general-domain summary evaluation. We redefine query reformulation of SERA based on POS Tags analysis of datasets from different domains, and change the biomedical index with documents from AQUAINT-2 and Wikipedia. GeSERA achieves competitive results compared to state-of-the-art approaches. Overall, GeSERA surpasses SERA and reduces its gap with ROUGE, and in two cases, it even surpasses ROUGE, the lexical-based method. Unsurprisingly, the comparison with evaluation methods that do not rely on human references reveals a large gap in favor of GeSERA since it relies on human references while the others do not. Finally, extensive experiments show that the index size has a considerable effect on the performance of SERA and GeSERA that tend to perform better with small-size indexes. Our code is publicly available to facilitate reproducibility.

We will: (1) explore other variants of the search engine to know its impact on GeSERA, (2) propose a new version of GeSERA that does not rely on human intervention by exploiting information from the source text, (3) apply prepossessing on the index and search for other solutions to improve query reformulation, and (4) explore larger query datasets such as Multi-News (Fabbri et al., 2019).
References

A Introduction

In this appendix, we provide: (1) more details about evaluation datasets (Sec. B), (2) implementation details (Sec. C), and (3) detailed results of all tested approaches (Sec. D).

B Datasets details

- **AQUAINT-2** is a news corpus built from New York Times, Associated Press, and Xinhua News Agency. Indexes built from this corpus are balanced, except for the largest one ($I = 825, 148$), that contains all documents.

- **Wikipedia** is a free online encyclopedia from the general domain. The largest index ($I = 1, 778, 742$) contains all available documents.

- **TAC2008** (TAC2009) contains two sets. Each set contains 48 (44) topics. Each topic includes 10 documents and 4 reference summaries. Candidate summaries are proposed by 58 (55) participants, where each one provides a candidate summary per topic. In total, there are 960 (880) documents, 5568 (4840) candidate summaries, and 384 (352) reference summaries.

C Implementation details

SERA and GeSERA were implemented in Python. For information retrieval, we used the Okapi BM25F ranking function from Whoosh, a flexible and pure python search engine framework.

Table 4: Correlations on TAC2008 and TAC2009.
We used the authors’ public implementations to run ROUGE, SummTriver, and FRESA. The latter was basically designed for mono-document evaluation. Thus, we concatenated all the articles of the same topic to be able to run it on TAC.

To compute the correlations with LitePyramid of ROUGE, BERTScore, MoverScore, and JS-2 on the CNN Daily Mail dataset, we used the scores provided by Bhandari et al., 2020 in their GitHub repository\(^5\). Based on experiments on the TAC datasets in Subsection 4.3, we use an index size of \(I = 10,000\) in SERA and GeSERA.

For the sake of comparability, scores are averaged for each participant before computing the correlations with manual methods.

D More results

Table 3 and Table 4 provide more results on CN-NDM, TAC2008 and TAC2009 datasets. Both tables present variants of the evaluation metrics that we did not report in the main paper.

On the Interaction between Annotation Quality and Classifier Performance in Abusive Language Detection

Holly Lopez Long, Alexandra O’Neil, Sandra Kübler
Indiana University
Bloomington, IN, USA
{hdlopezl,aconeil,skuebler}@iu.edu

Abstract
Abusive language detection has become an important tool for the cultivation of safe online platforms. We investigate the interaction of annotation quality and classifier performance. We use a new, fine-grained annotation scheme that allows us to distinguish between abusive language and colloquial uses of profanity that are not meant to harm. Our results show a tendency of crowd workers to overuse the abusive class, which creates an unrealistic class balance and affects classification accuracy. We also investigate different methods of distinguishing between explicit and implicit abuse and show lexicon-based approaches either over- or under-estimate the proportion of explicit abuse in data sets.

1 Introduction
In recent years, annotation quality has come under closer scrutiny, especially for subjective classification tasks that rely on human judgement. Investigations of unintended bias in abusive language data sets have demonstrated that they are susceptible to sampling and annotation bias (Wiegand et al., 2019; Sap et al., 2019). Although this work provides some guidance for reducing the effects of unintended bias from sampling, it does not provide a clear path forward for mitigating annotation bias. As we need effective ways to curb online hate, we definitely need reliable data sets with high-quality annotations for abusive language detection.

In this paper, we compare annotations by untrained crowd workers with annotations by experts. Our examination demonstrates that labeling differences between crowd workers and experts change the class distribution in the data set and affect classifier performance. We also compare methods for determining explicit and implicit abuse in the data set, and how this affects the interpretation of machine learning experiments. Our paper is structured as follows: Sec. 2 explains our research questions, sec. 3 describes prior work on data sets, annotation procedures and quality, and classification schemes for abusive language, sec. 4 describes our data sets and methodology, sec. 5 discusses our insights into the interaction of annotation quality and classifier performance, and sec. 6 investigates the interaction of explicit and implicit abuse and the interpretation of results. We conclude in sec. 7.

2 Research Questions
We started our investigation by reviewing a random sample of 1000 posts from the Kaggle competition Jigsaw Unintended Bias in Toxicity Classification. Our initial inspection showed that many posts that were considered abusive by crowd annotators (wrt. the final classification used by the competition) were open to interpretation. The examples below show typical “abusive” posts where different interpretations are possible.

1. I do love Yataimura Maru’s ramen? It is a perfect food for Portland’s long winter. And PDX does kick a little ass.
2. Sorry to have to do this, but just to see if profanity filtering is enabled: fuck.
3. Took this as an opportunity to check back in on The Yard and the floorplans are finally up and they are ATROCIOUS.

The first example is a positive review of a ramen restaurant in Portland that also contains profanity. The second example also uses profanity, but is doing so as a part of a meta-comment about the filters used by the platform. Finally, the last post is a criticism of an apartment complex. Although an insult is used, it is directed toward an object and not
individuals. These examples show two common tendencies by crowd workers: interpreting profanity as abusive without considering the context and not distinguishing between insults and criticism directed at people and objects. These observations led us to our first research question:

**RQ1:** How does annotation quality affect characteristics of the data set and subsequently the performance of machine learning approaches? More specifically, we address the following questions:

**RQ1.1:** How does annotation quality affect the distribution of abusive and non-abusive posts?

**RQ1.2:** Based on a detailed annotation scheme that distinguishes varieties of non-abuse, how do crowdsourced and expert annotations differ?

**RQ1.3:** How do annotations by crowd workers and experts influence classification results?

We then turn to the issue of explicit vs. implicit abuse. It is generally accepted that explicit abuse is easier to detect automatically (Wiegand et al., 2019). However, the method that we use to determine whether a post is explicitly or implicitly abusive will result in different splits of the data, and different results of how well a classifier performs on either class. Explicit abuse is often identified via lexicons of abusive expressions. Automatically created lexicons, such as the one by Wiegand et al. (2018), have good coverage, but may overestimate the abusiveness of terms while manually curated lists, such as the one by Razo and Kübler (2020), are more reliable in their selection of abusive terms but may lack coverage. This leads to our second question:

**RQ2:** How does the method of identifying explicit abuse influence the distribution in the data set and subsequently the interpretation of the classifier’s performance?

### 3 Related Work

#### Data Sets and Their Development

There is an abundance of data sets available for abusive language detection, which represent a variety of approaches for annotating abusive content. While many data sets have relied on large pools of crowd sourced annotators (Zampieri et al., 2019), others have used experts (Waseem and Hovy, 2016). Crowdsourcing annotations is often an attractive option for developing abusive language data sets, since the process often requires a considerable amount of time and labor. The two largest data sets were created for Kaggle competitions: 1) The *Toxic Comment Classification Challenge*[^1], which contains 312,737 posts from Wikipedia Talkpages, and 2) the *Jigsaw Unintended Bias in Toxicity Classification* (see Section 4.1) with posts from the platform Civil Comments. Both data sets were annotated by crowd workers. However, using crowd workers can contribute to diminished annotation quality (Hsueh et al., 2009). Waseem (2016) found that amateur annotators were more likely to label a post as hate speech and expert annotations improved machine learning performance. Sap et al. (2019) showed amateur annotators more often labeled African American English posts as abusive, but that priming the amateur annotators for dialect and race reduced annotation bias.

#### Annotation Schemes

One way to maintain annotation quality is to create clear annotation guidelines with rich taxonomies (Vidgen and Derczynski, 2020). Many scholars have developed annotation schema and guidelines that describe different types of abuse in order to better characterize abusive content. Founta et al. (2018) evaluated 7 abuse categories (e.g., offensive, abusive, hateful, aggressive, cyberbullying, spam, and normal), which were then merged into four (e.g., abusive, hateful, spam, and normal) when they found overlap between categories. Zampieri et al. (2019) created a 3-tier scheme in which annotators decided whether a post was abusive, targeted, and whether the target was an individual, a group, or other. Davidson et al. (2017) distinguished hateful content from the casual use of profanity by creating three categories: hateful, offensive (but not hateful), and neither. Current methods overwhelmingly focus on the labeling of abusive posts, often at the expense of accuracy on non-abusive posts.

#### Investigating Unintended Bias

Recent work on abusive language detection has looked at sampling bias in the data. Sampling methods are required to increase the amount of abusive posts in data sets. However, the specific sampling methods used have been shown to create bias. Wiegand et al. (2019) document this bias. Razo and Kübler (2020) build on their work and find that the source of the text (Twitter, Wikepedia, etc.) has more influence on the bias of the data set than the sampling method.

4 Methodology

4.1 Data
We use subsets of the data set from the Kaggle competition Jigsaw Unintended Bias in Toxicity Classification with posts from the platform Civil Comments. For the Jigsaw challenge, each comment was annotated by several crowd workers and a mean annotation score of $\geq 0.5$ (range: 0.0–1.0) was considered abusive. From this data set, we use two sampling subsets by Razo and Kübler (2020): the first subset of the random boosted sampling sets (a random sample) and the first of the biased topic sampling sets (increasing the number of abusive posts by searching for controversial topics that tend to attract abuse)\(^3\).

4.2 Classifier Settings
For the machine learning experiments below, we follow similar procedures as Razo and Kübler (2020). As Razo and Kübler, we use SVMs, more specifically, the SVC class of Scikit-learn (Pedregosa et al., 2011) with the RBF kernel, the same parameter settings (e.g., $C=1000$, $\text{gamma}=0.001$), and word 1-3 grams for features. We also perform 5-fold cross validation. Unlike Razo and Kübler, we do not remove punctuation.

5 Investigating Annotation Quality
As discussed in section 2, a cursory inspection of the data sets showed that there was a considerable amount of posts that were annotated as abusive (based on Jigsaw’s definition of the challenge), which the expert annotators found questionable. This does not only mean that the classifier learns a model that is disposed towards classifying too many posts as abusive, it also raises the question of whether a more consistent annotation would improve classification results or make the task more difficult to learn (since profanity would have to be disambiguated between abusive and colloquial use). For this reason, we decided to re-annotate the abusive portions of the two data sets. We first present the new annotation scheme in section 5.1, then we describe the resulting changes to the data set in section 5.2 and on the classifier in section 5.3.

5.1 New Annotation Scheme
The new annotation scheme includes 8 categories: explicit, implicit, self-abusive, irony, colloquial, meta, argumentative, and non-abusive. The categories of explicit, implicit, and self-abuse are considered to be abusive, all other categories are non-abusive. These categories were developed using a grounded theory approach (Glaser and Strauss, 1967; Corbin and Strauss, 2014), where the researchers open-coded a small set of instances originally labeled abusive and then consolidated categories and refined definitions. During the open-coding stages, researchers focused on characteristics that non-experts erroneously consider abusive.

We created categories to capture the challenging nuances of language, such as discussions about abuse (meta) and argumentative statements that may be antagonistic to a particular idea or policy, but not abusive toward individuals. While many existing schemes focus on distinctions between different varieties of abuse (Founta et al., 2018), our scheme \(^4\) focuses on non-abusive instances including profanity, etc. The categories with examples are shown in Table 1. The last category is for posts that were originally labeled as non-abusive.

The category explicit describes posts that use insults, threats, ethnic/religious slurs, and/or ad hominem attacks. This included instances of cyberbullying (e.g., attacking people’s appearance/body shape) and other forms of overt hate based on attributes of their identity, such as religion, ethnicity, sexuality, disability, or socioeconomic class.

The category implicit is used to indicate that a post degrades individuals or groups of people by alluding to stereotypes or other insulting speech through indirect methods. These posts include the same stereotypes apparent in explicit abuse, but instead of being directly expressed, the abuse is implied in the post.

Self-abuse is used to label posts in which people direct the abuse against themselves. While it could be argued that people should have the right to abuse themselves, we group this category with the other abusive categories because certain types of self-abuse may result in a diminished sense of self-worth (cf. e.g., negative self-talk).

As posts can often belong to several categories, especially since posts are often longer than Twitter posts, we label each post with all applicable labels. However, for all machine learning experiments, we reduced the annotation automatically to a single label per post, either abusive or non-abusive, to keep

Table 1: Annotation categories and examples.

### Consistency with Prior Experiments

If a post contains any of the abusive categories, it is considered abusive. All posts that contain only non-abusive categories (i.e., irony, colloquial, meta, argumentative, non-abusive) are considered non-abusive. For the question on explicit vs. implicit abuse, we only examine instances considered explicit and/or implicit abuse but ignore the other categories.

### 5.2 Effect on Annotations

We first look at the effects of re-annotating the abusive posts from the original annotations, since we noticed previously a large number of false positives in the annotations. However, note that the annotation scheme can and should be applied to all posts. The two data sets were re-annotated by the first two authors, with each author being responsible for one data set. In order to ensure consistency, both annotators collected all posts that raised questions; these posts were discussed by all authors, and a consensus was reached.

When we compare the original annotations (by non-experts) with our expert annotations, we see the following trends: Although the overall agreement between expert and non-expert annotations remains high across both samples (95.3%), agreement is significantly lower (45.6%) when looking only at re-annotated instances. For the random boosted sampling set, labels between experts and non-experts only have an agreement of 46.9%. On the biased topic sampling data set, expert and non-expert annotations agree 44.7% of the time.

When looking at the distribution of labels in the re-annotated posts shown in Table 2, the large majority of disagreement between annotators are posts that the expert annotators consider argumentative instead of abusive, i.e., posts expressing criticism or disagreement, without targeting insults or criticism at individuals or groups of individuals.

### 5.3 Effect on Evaluation Results

Since the re-annotation has a significant impact on the annotations, and especially on the skewing between the abusive and non-abusive class, we expect

---

5 Since our annotation scheme differs from the crowd workers’, we could not compute inter-annotator agreement.
that they will also have a considerable effect on the difficulty of the task and consequently the classification quality. We investigate the general question of how exactly the re-annotation affects classification, and we focus on two specific questions: 1) How does the re-annotation affect the results of a classifier trained on the new gold standard? And 2) How does the new gold standard affect the evaluation of classifications trained on the original data from Razo and Kübler (2020)? In other words, is the classifier potentially more consistent than the crowd workers?

5.3.1 Evaluating a Retrained Classifier

To determine how the new annotation scheme affects classification accuracy, we train and test the SVM using the same parameter settings as Razo and Kübler (2020) (see section 4.2). We also use two of their data sets, but with the re-annotations of the original abusive posts.

The overall results show that the crowdsourced annotations are easier to learn; they result in higher scores across all evaluation measures than their expert annotation counterparts, regardless of sampling methods. For topic biased sampling, the macro-averaged F-score decreases from 62.45 for the crowdsourced annotations to 53.94 for the expert annotations. For random boosted sampling, the decrease is comparable, from 64.96 to 58.79. One of the reasons can be found in the class skewing: for both samples, the percentage of abusive posts in the sample decreases by about 5%. Thus, the skewing is even more extreme in the re-annotated data. However, the decrease in the classifier’s F-score is about twice as much, which leads us to the assumption that the simpler cases were moved from the abusive class to the non-abusive one. This may also have an effect on the distinction between explicit and implicit abuse, see section 6.

When looking more closely at the evaluation measures for abusive and non-abusive posts in Table 3, we observe that the re-annotation of the abusive posts leads to decreased precision and recall for abusive posts. For the topic biased sample, precision decreases from 70.04% to 54.22%; for the random boosted sampling, the decrease is from 65.83% to 47.00%. Recall is affected even more dramatically, it drops from 18.48% to 5.49% for topic biased sampling, and from 22.69% to 12.35% for random boosted sampling. However, at the same time, the re-annotation leads to an improvement of those same measures for non-abusive posts and more specifically to a considerable improvement of precision: For biased topic sampling, precision increases from 92.34% to 96.11% and for random boosted sampling from 93.55% to 96.63%. These changes are unsurprising given the changes in class skewing. Additionally, and more importantly, the task of identifying abusive posts has become more difficult. Of the 314 instances (across both data sets) where the classifier agrees with the crowdsourced annotation rather than the expert one, 78.37% are argumentative and not directed at people, 19.44% are meta comments about abuse, and 0.63% are colloquial use of profanity. Once these posts are labeled as non-abusive, the classifier basically needs to disambiguate between meta comments like, “...I have voted “not civil” on posts I deeply agree with but which call the other person “idiot” or some such.” and abusive comments such

</table>

Table 3: Precision, recall, and macro-averaged F for non-abusive and abusive posts for the retrained classifier.
The results of the re-evaluation in Table 4 show that the methods for determining explicit vs. implicit abuse result in very different distributions. The extended lexicon by Wiegand et al. (2018) results in the highest proportion of explicit abuse while the manually checked lexicon only groups 46.95% (topic) / 34.82% (random) of explicit posts. Our expert annotation and the Wiegand base lexicon result in similar proportions between 67.15% (random) and 79.74% (topic) of explicit abuse.

Since we now have expert annotations for the abusive posts, we can investigate how the distribution of explicit and implicit posts in the two gold standards differs from those based on the three lexicons. We compare the proportions of posts from each gold standard labeled as explicit and implicit abuse with the lexicon approaches used by Razo and Kübler (2020) and Wiegand et al. (2018). Table 5 shows the proportions in each data set.

Distributions of implicit and explicit abuse in Table 5 show that within the abusive category as defined by experts, the methods for determining explicit vs. implicit abuse result in very different distributions. The extended lexicon by Wiegand et al. (2018) results in the highest proportion of explicit abuse (92.80% (topic) and 91.55% (random)) explicitly abusive posts. Our expert annotation and the Wiegand base lexicon result in similar proportions between 67.15% (random) and 79.74% (topic) of explicit abuse while the manually checked lexicon only groups 46.95% (topic) / 34.82% (random) of the posts as explicit. These lower numbers are to be expected since the authors state that the manual lexicon is very small and thus has coverage issues.

However, the similarity in proportions raises the question whether the Wiegand base lexicon and the manual annotations choose the same posts, or just the same proportion of posts. We checked the overlap of posts that were labeled explicit or implicit by both (not shown in table). For the topic sample, 75.96% of explicit posts annotated by experts can be found in the posts extracted using the base lexicon. The random sample shares a smaller proportion of explicit posts (66.94%) than the topic sample. There is also a smaller proportion of overlap between annotations and the base lexicon among implicit posts. 24.90% of posts from the topic sample and 32.89% of posts from the random sample can be found in the implicit posts using the base lexicon method. This shows very clearly how different the samples of explicit and implicit abuse are based on the different methods.

### 5.3.2 Re-Evaluating Prior Results

To better understand the impact of annotation quality, we re-evaluate the classification results by Razo and Kübler (2020) on the two data sets, i.e., we contrast the two gold standards in evaluation. This means that we use the predictions of the classifier that was trained on the crowdsourced training data, and compare this to the new gold standard created by expert annotations.

The re-evaluation is performed on the subset of the original posts only (since those are re-annotated). Thus, precision for both categories and recall for non-abusive are meaningless, either 0.00 or 100.00 on the crowdsourced annotations. The results of the re-evaluation in Table 4 show that recall on the abusive class increases when evaluated against the expert annotations, from 18.48% to 22.07% for topic biased sampling and from 22.69% to 27.20% for random boosted sampling. This means that more of the posts that the classifier annotated as abusive are abusive based on the experts opinion. Thus, partly, the classifier is sensitive to distinctions that the crowd workers may have neglected. However, a look at precision of around 55% for both classes and both samples shows that the classifier creates many false positives and is still far from having learned the more conservative expert regularities.

### 6 Investigating Explicit vs. Implicit Abuse

Now we turn to the distinction between explicit and implicit abuse. It is generally accepted that explicit abuse is easier to detect than implicit abuse. However, making this distinction is not a simple task. In general, lexicons of abusive words are used to determine the explicitly abusive posts; a post is considered explicit abuse if one of the lexicon words occurs in the post. Wiegand et al. (2018) describe a method for automatically extending a base lexicon into a larger lexicon of abusive words. Their base list contains 551 words, their extended list 2,989 words. Razo and Kübler (2020) show that both the base and the extended lexicon cover a large proportion of posts that were labeled non-abusive by crowd workers. They manually checked the base lexicon and reduced it to 151 words.

</table>

Table 6: Effect of definitions of implicit and explicit categories on performance on the abusive class.

We then investigate how these different decisions affect classification results. For this, we use the same classification results from section 5.3, and we evaluate the subsets against our expert annotations. The subsets consist of only explicitly or implicitly abusive posts, based on either expert annotations or the base lexicon. The results are shown in Table 6. Since both precision and recall for the non-abusive class are 0.00 (and precision for the abusive class 100.00), we only report recall for the abusive class. A comparison of the recall results shows that there are differences between the expert annotation and the lexicon approach. However, for the two samples, they go in two different directions: For the topic biased sample and the explicit category, the classifier performs better based on the lexicon subset while for the random boosted sample, it performs better based on the expert annotations. The trends for implicit abuse also show this difference, but in the opposite direction. Part of this discrepancy is certainly due to the low overlap in the explicit/implicit subsets in the random sample. It is also clear that the definition of these categories has a significant influence on the interpretation, given the sizable differences in recall, thus requiring future work in this area.

7 Conclusion and Future Work

Our investigation illustrates the effect of diminished annotation quality on machine learning performance. Crowd workers and expert annotators disagreed on approximately a third of the posts originally labeled abusive. Disagreement often occurred with profanity and when targets were not individuals. The method for identifying implicit and explicit abuse leads to significant discrepancies between the explicit and implicit classes and affects evaluation.

Our work shows the need to improve annotation quality. This is only the tip of the iceberg, though. Verbal abuse can only be identified within a cultural context, but there exist so many different subcultures that any annotator, independent of their being sensitized to the nuances of abuse, may not be able to identify abuse if they are not part of that subculture. We will investigate using annotators with different backgrounds along with methods to distinguish between disagreement based on inattention or lack of sensitization from disagreement based on cultural backgrounds.

Abstract

In this paper, we present NEREL, a Russian dataset for named entity recognition and relation extraction. NEREL is significantly larger than existing Russian datasets: to date it contains 56K annotated named entities and 39K annotated relations. Its important difference from previous datasets is annotation of nested named entities, as well as relations within nested entities and at the discourse level. NEREL can facilitate development of novel models that can extract relations between nested named entities, as well as relations on both sentence and document levels. NEREL also contains the annotation of events involving named entities and their roles in the events. The NEREL collection is available via https://github.com/nerel-ds/NEREL.

1 Introduction

Knowledge bases (KBs) encompass a large amount of structured information about real-world entities and their relationships, which is useful in many tasks: information retrieval, automatic text summarization, question answering, conversational and recommender systems (Liu et al., 2020; Han et al., 2020; Huang et al., 2020). Even the largest knowledge bases are inherently incomplete, but their manual development is time-consuming and expensive. Automatic population of knowledge bases from large text collections is usually broken down into named entity (NE) recognition, relation extraction (RE), and linking entities to a knowledge base. In turn, training and evaluating models addressing these problems require large and high-quality annotated resources. Currently, most of the available resources of this kind are in English.

In this paper, we present NEREL (Named Entities and RELations), a new Russian dataset with annotated named entities and relations. In developing the annotation schema, we aimed to accommodate recent advances in information extraction methods and datasets. In particular, nested named entities and relations within named entities are annotated in NEREL. Both of these provide a richer and more complete annotation compared with a flat annotation scheme. Current datasets with nested named entities (Ringland et al., 2019; Benikova et al., 2014) are not annotated with relations. Therefore, most state-of-the-art relation extraction models (Joshi et al., 2020; Alt et al., 2019) do not work with relations between nested and overlapping entities. NEREL aims to address these deficiencies with the addition of nested named entities and relations within nested entities.

Secondly, NEREL relations are annotated across sentence boundaries at the discourse level allowing for more realistic information extraction experiments. Figure 1 illustrates annotation of nested entities, relations between overlapping entities, as well as cross-sentence relations on a sample NEREL sentence.

Finally, NEREL provides annotation for factual events (such as meetings, negotiations, incidents, etc.) involving named entities and their roles in the events. Future versions of the dataset can easily expand the current inventory of entities and relations.

NEREL is the largest dataset for Russian annotated with named entities and relations. NEREL features 29 entity and 49 relation types. At the time of writing the dataset contains 56K entities and
39K relations annotated in 900+ Russian Wikinews documents.

In the rest of the paper, we describe the principles behind dataset building process. We also report dataset statistics and provide baseline results for several models. These results indicate that there is a room for improvements. The NEREL collection is freely available.

2 Related Work

Table 1 summarizes most important datasets in the context of NEREL development and provides references to their descriptions.

2.1 Datasets for NER

Most widely used English datasets for named entity recognition in general domain are CoNLL03 and OntoNotes. CoNLL03 is annotated with four basic NE types – persons (PER), organizations (ORG), locations (LOC), and other named entities (MISC), while OntoNotes comprises annotation of 19 NE types, including numeric and temporal ones. Both datasets feature only flat NE annotations.

There are several datasets with annotated nested named entities, see Table 1. NNE is the largest corpus of this kind, both in terms of entity types and annotated NE mentions. NNE provides detailed lexical components such as first and last person’s names, units (e.g. tons), multipliers (e.g. billion), etc. These result in six levels of nestedness in the dataset.

The NoSta-D collection of German Wikipedia articles and online newspapers is annotated with nested named entities of four main classes. Each class can appear in a nominal (proper noun) form, as a part of a token, or as a derivative (adjective) such as “österreichischen” (Austrian). The Digitoday corpus for Finnish is annotated with six types of named entities (organization, location, person, product, event, and date). It permits nested entities with the restriction that an internal entity cannot be of the same class as its top-level entity. For example, Microsoft Research is annotated as a flat entity, without additional annotation of the Microsoft entity. Both NoSta-D and Digitoday datasets allow at most two levels of nesting within entities.

Amongst NER datasets in Russian, RURED (Gordeev et al., 2020) provides the largest number of distinct entities with 28 entity types in the RURED dataset of economic news texts. RURED annotation scheme of named entities mainly follows the OntoNotes guidelines with addition of extra named entities (currency, group, family, country, city, etc). Currently, FactRuEval (Starostin et al., 2016) is the only Russian dataset annotated with nested named entities with at most 2 levels of nesting. In FactRuEval, person mentions (PER) can be subdivided into first/last names, patronymics, and nicknames; while organizations and locations – into their description/type and names (e.g. [[Microsoft]NAME [Corporation]TYPE]ORG).

2.2 Datasets for Relation Extraction

One of the largest datasets for relation extraction is the TACRED dataset (Zhang et al., 2017). Relation annotations within TACRED are constructed by querying PER and ORG entities; the returned sentences are annotated by crowd workers (GPE entities are also annotated, the others are treated as values/strings). The dataset consists of 106k sentences with entity mention pairs. Each sentence is labeled with one of 41 person- or organization-oriented relation types, or with a NO_RELATION tag (Table 1 cites the number of “positive” cases). Alt et al. (2020) found that more than 50% of the examples of the TACRED corpus need to be re-
Table 1: NEREL and its counterparts. Group 1 includes most known datasets with flat entities without relations annotation. Group 2 comprises datasets with nested named entities without or with a small number of relation types. Group 3 includes most known datasets annotated with relations. Group 4 presents Russian datasets for information extraction.

labeled to improve the performance of baselines models. RURED (Gordeev et al., 2020) is a Russian language dataset that is similar to TACRED. Several relations for events are added such as the date, place, and participants of an event. The resulting scheme contains 34 relations. The annotation of relations is mainly within sentences.

RuREBus corpus (Ivanin et al., 2020) consists of strategic planning documents issued by the Ministry of Economic Development of the Russian Federation. The data is annotated with eight specialized relations.

DocRED (Yao et al., 2019) is another dataset that is annotated with both named entities and relations. The dataset includes 96 frequent relation types from Wikidata, the relations are annotated at the document level with significant proportion of relations (40.7%) is across sentence boundaries.

FactRuEval (Starostin et al., 2016) is a Russian language dataset that includes about 1,000 annotated document-level relations of four types (OWNERSHIP, OCCUPATION, MEETING, and DEAL).

2.3 Datasets with Annotated Events

Existing NER datasets usually contain annotations of named events such as hurricanes, battles, wars, or sports events (Hovy et al., 2006; Ringland et al., 2019). For knowledge graph population tasks, it is useful to extract information about significant entity-oriented factual events such as funerals, weddings, or concerts (Rospocher et al., 2016). However, such an approach significantly complicates the annotation. In previous specialized event annotation efforts, an event is defined as an “explicit occurrence involving participants” (Song et al., 2015; Bies et al., 2016; Mitamura et al., 2015). Annotators had to tag an event trigger (word or phrase) consisting of the smallest extent of text expressing the occurrence of an event. Mitamura et al. (2015) presented annotation of so-called “event nuggets” that can be discontinuous, for example found guilty in the sentence The court found him guilty. Additionally, events are annotated with special tags indicating whether or not an event occurred. For example, ACTUAL tag is used when an event actually happened at a particular place and time.

According to ACE and Light ERE guidelines (Linguistic Data Consortium, 2014; Walker et al., 2006), only events of particular types are annotated. The event categories can be: LIFE, BUSINESS, CONFLICT, JUSTICE, and others (Song et al., 2015; Bies et al., 2016; Mitamura et al., 2015). In ACE and ERE datasets (Aguilar et al., 2014) anno-
tated events can be provided with arguments, e.g. CRIME_ARG or SENTENCE_ARG roles for JUSTICE events. There are also universal event attributes, e.g. PLACE and TIME.

TAC-KBP (Aguilar et al., 2014; McNamee et al., 2010) and TACRED (Zhang et al., 2017) annotations contain event-related slots, e.g. CHARGES. Such relations can be established between entities, even if the corresponding event is not mentioned explicitly.

3 Dataset Annotation

3.1 Text Selection

The NEREL corpus consists primarily of Russian Wikinews articles. Wikinews publishes news stories under Creative Commons License (CC BY 2.5) allowing reuse of the published materials. An additional advantage of Wikinews as a document source is that a subset of entities mentioned in the news are linked to corresponding Wikipedia pages making it useful for linking of annotated NEs to Wikidata.

To select a subset of Wikinews articles for annotation, we first applied NER trained on RURED (Gordeev et al., 2020) to the whole Wikinews collection. We focused on articles with high density of automatically detected NEs, paying special attention to NEs associated with persons (e.g. PERSON, AGE). Articles about persons are important for further relation extraction and provide opportunity for cross-lingual methods using existing datasets (Walker et al., 2006; Zhang et al., 2017). The extracted articles were inspected manually to balance topics and remove inappropriate documents. Finally, 900+ articles were selected for annotation. At the last step of the selection, we retained texts in the size range 1–5 Kb: very short texts provide little context for annotation, while long documents are usually non-coherent (e.g. lists of movies or events).

3.2 Named Entity Annotation

To define a list of entity types for NEREL, we started with entities in English OntoNotes (Hovy et al., 2006) and RURED (Gordeev et al., 2020) datasets. Additionally, we considered entity types available in Stanford named entity recognizer (Finkel et al., 2005) and TACRED slots such as CRIME and PENALTY. AWARD and DISEASE were added because of their significant frequency in the gathered collection and importance for personal life.

We followed the following main principles for annotating named entities:

- The entity annotation schema should be easily amenable for further entity linking.
- Annotation of internal entities varies depending on the named entity type. For example, we do not label numbers within numerical entities such as DATE or MONEY, because such annotations are not essential for relation extraction and entity linking.
- We annotate nested named entities and named entities consisting of two disjoint spans, but not intersecting named entities. For example, deputy chairman is not annotated within the span Deputy Chairman of the State Duma Committee is annotated as [Deputy [Chairman of the [[State Duma]ORG Committee]ORG] PROFESSION]PROFESSION, because it intersects with the longer named entity.
- Adjectives derived from annotated named entities are also annotated with the same tag. Adjectives occur often as internal entities. Figure 1 shows an adjective moskovskii (derived from Moscow), indicating the theater’s location.

Currently, there are 29 entity types in NEREL dataset. Further we describe main groups and specific features of entity annotation.

Basic entity types comprise PERSON, ORGANIZATION, LOCATION, FACILITY, GEOPOITICAL ENTITIES. The latter are subdivided into COUNTRY, STATE_OR_PROVINCE, CITY, and DISTRICT. We also singled out FAMILY entity to have possibility to describe relations between families and their members.

Temporal and numerical entities include NUMBER, ORDINAL, DATE, TIME, PERCENT, MONEY, AGE. and AGE entity is usually not annotated separately from DATE entities (Hovy et al., 2006; Finkel et al., 2005), but it has its own relations, and therefore it was singled out.

PROFESSION entity denotes jobs, positions in various organizations, and professional titles. This entity type is significant for extracting relationships of specific persons (Zhang et al., 2017; Gordeev et al., 2020; Starostin et al., 2016). Both capitalized and lowercased PROFESSIONS are annotated in NEREL in contrast to other works (Ringland
et al., 2019; Hovy et al., 2006). **PROFESSION** entity is one of the most frequent entities in NEREL. It can have a quite complicated nested structure, in particular, longest profession spans include corresponding workplace organization, which allows for a better description of the person’s position (Figure 1).

**Physical object** group of entities includes: **WORK_OF_ART**, **PRODUCT**, and **AWARD** entities. In contrast to OntoNotes, we introduced a special **AWARD** entity type because the structure and relations of **AWARD** entities are quite different from **WORK_OF_ART** entities, and information about awarding is quite frequent in person-oriented texts.

In flat named entity annotations, different guidelines can be used for **PRODUCT** entities annotation. For example, in OntoNotes (Hovy et al., 2006), manufacturer and product should be annotated separately as **ORG**+**PRODUCT**. The same approach is accepted in the Russian Collection3 (Mozharova and Loukachevitch, 2016). In BSNLP-2019 (Piskorski et al., 2019) the manufacturer name should be included into a longer product name. In the NEREL dataset, the **PRODUCT** entity is annotated as a long span, that can include manufacturer and number subentities.

**NORP entities** — nationalities, religious, or political groups — are usually capitalized in English but lowercase in Russian. In NEREL, **NATION-ALITY** entity comprises mainly the following expressions: (i) nouns denoting country citizens such as ukrainec (Ukrainian as a noun); (ii) adjectives corresponding to nations in contexts different from authority-related, for example russkii pisatel (Russian writer). The same adjectives are annotated as **COUNTRY** entity in the context of authorities or the origin of organizations. This decision accounts for most frequent relations in both contexts.

**Legal entities** (**LAW**, **CRIME**, and **PENALTY**) are significant in person-oriented texts for extraction of relations (Zhang et al., 2017) in the contemporary news flow, however such entities are usually not annotated in named entity datasets. For example, the TACRED dataset contains annotations of the **CHARGE** relation only. What is more, **LAW** and **CRIME** entities can be quite long and specific; they are built from names of organizations, persons, countries, etc. **PENALTY** entities often contain period of the penalty or monetary values of fine imposed.

Entity type frequencies are presented in Figure 2.

As can be seen from the statistics, all but two entity types have at least 100 annotated examples. Manual annotation of named entities and relations was performed by a single annotator, controlled by a moderator. To estimate agreement, 15 documents with about 800 entities were labelled by a moderator (the gold standard) and an annotator. We observed a $F_1$ measure of 92.95 of the annotator’s annotation relative to the gold standard, confirming a high level of agreement. Most frequent sources of annotation inconsistencies are as follows: span boundaries of event nuggets, confusing **FACILITY** and **ORGANIZATION** entities, confusing **EVENT** and **CRIME** entities (such as murders) or **EVENT** and **PENALTY** entities (such as arrests). **Student** role is often annotated as **PROFESSION** (in spite being a kind of pre-professional title).

NEREL annotations do not contain low-level units as for example the NNE dataset (Ringland et al., 2019) featuring e.g. even measurement units as separate entities. Annotation of such units is not challenging because it can be performed using closed word sets. Complex NEREL entities are factual **EVENTS** similar to event-nuggets (Mitamura et al., 2015) and include **PROFESSIONS**. These entity types are extremely useful for further relation extraction.

### 3.3 Events Annotation

As was mentioned, we annotate both named events (traditionally annotated named sports events, ex-

---

**Figure 2:** Entity type statistics (log scale). The proportion of nested named entities is shown.
hibitions, hurricanes, battles, wars, revolutions) (Hovy et al., 2006; Ringland et al., 2019) and non-named entity-oriented events significant in the news domain. Annotation of non-named events is most similar to event nugget annotation (Mitamura et al., 2015). Event nuggets can be single words (nouns or verbs) or phrases (noun phrases, verb phrases, or prepositional phrases). As we annotate entities and relation for knowledge graph population, in the current project mainly factual events, which actually happened at a particular place and time, are labeled. Also we annotate future events with exact dates as if for inclusion in a future schedule.

Main types of annotated factual events are as follows: accidents and deaths (to crash, to attack); public actions and ceremonies (to meet, meeting, summit); legal actions (to indict, interrogation, to sentence); transactions (to buy, to sell); appointments and resignations; medical events (hospitalization, surgical operation); sports events (match, final), etc.

We do not restrict subtypes of entities. We define what we exclude. We exclude from event annotation speech acts and cognitive acts, regular activities, changes of numerical indicators (for example, prices or import value), victories and defeats.

3.4 Relation Annotation

Relation types were initially based on TACRED (Zhang et al., 2017) and Russian RURED (Gordeev et al., 2020) corpora. Further, the list of relations has been corrected and expanded from the NEREL corpus analysis; corresponding Wikidata properties were found, when possible.2 Names for the relations were selected similar to Wikidata property names. The current set of annotated relation types in the NEREL corpus includes 49 relations.

Relations can be subdivided into person-oriented, organization-oriented, event-oriented, and synonymous relations (alternative_name, abbreviation). Event-oriented relations comprise of role relations, temporal relations, place of event relation, causal relations, and others. Figure 3 shows the distribution of relation frequencies in the NEREL dataset. It can be seen that most relations have at least 50 examples.

2Some relations can not have counterparts in Wikidata properties. For example, AGE and AGE_DIED_AT occur in texts, while Wikidata has only date of birth (P509) and date of death (P570) that allow calculating the above mentioned age values.

All the annotated relations can be subdivided into cross-sentence relations (24%) and within sentence relations (76%). Annotated cross-sentence relations make it possible to generate document-level relation extraction, which is important for knowledge graph population from texts.

Among relations within a single sentence, we distinguish three types of relations:

- traditional relations between entities, which are located separately, as Mayor of Moscow and Sergei Sobyanin in Figure 1 – further, external relations (52.38%);
- nested relations, i.e. relations within the longest span of a single nested entity, as Moscow within Mayor of Moscow in Figure 1 (14.75%);
- relations crossing entity boundaries, i.e. relations between an external named entity and an internal entity within a nested named entity (8.87%) – further cross-entity relations.

The cross-entity relations can be illustrated as follows: in the sentence Barack Obama is a member of the Democratic party, external entity Barack Obama has the IDEOLOGY_OF relation to entity Democratic, which is an internal IDEOLOGY entity in the longer entity Democratic party.

Table 2 presents the most frequent types of

Table 2 presents the results of nested NER on the NEREL dataset. The results show that (i) contextualized BERT-based models outperform models based on static word representations; (ii) the Bi-affine model is superior to the Pyramid model; (iii) the results of MRC approach surpass nested NER models’ results, most likely, due to the effective usage of additional external information. However, as the MRC approach treats a single sentence at a time and is thus resource-greedy, the second best solution is still worth consideration.

4 Experiments

We exploit multiple deep learning models, which deliver state-of-the-art results for the English data for two tasks, available at NEREL: (i) nested named entity recognition (NER), (ii) relation extraction. To this end, we subdivided NEREL into train, dev, and test sets – 746/94/93 documents, respectively.

4.1 Nested NER

We adopted two publicly available models: Bi-affine (Yu et al., 2020) and Pyramid (Jue et al., 2020) models with default parameters. Additionally we explored a recently established trend to apply Machine Reading Comprehension (MRC) to nested NER (Li et al., 2020). The MRC model treats the NER task as extracting answer spans to specialised questions. In our case, the questions are dictionary definitions of the words, corresponding to entity types carefully selected from multiple dictionaries. Word representations used with all models are fastText (fT) embeddings (Mikolov et al., 2018) and pre-trained RuBERT-cased (Kuratov and Arkhipov, 2019). The latter is utilized in the MRC approach, too.

4.2 Relation Extraction

Recent relation extraction models (Joshi et al., 2020; Alt et al., 2019; Han et al., 2019) do not support relations between nested named entities or cross-entity relations. These models are tailored to the common test-beds, such as TACRED and DocRED, which do not possess nested named entities, unlike NEREL. Thus we follow the common relation extraction setup and utilize the models to extract relations between longest entity spans (i.e. external relations). To this we adopted three publicly available models: SpanBERT (Joshi et al., 2020), TRE (Alt et al., 2019), and OpenNRE (Han et al., 2019) with default parameters. The TRE
model is build upon the GPT model (Radford et al., 2018). Although initially GPT is trained on English web texts, it still has some limited knowledge of Russian, as Russian tokens are present in its vocabulary. The encoders used with SpanBERT and OpenNRE are multilingual BERT and RuBERT.

**Nested relation extraction.** We designed a new model, IntModel, aimed at extraction of nested relations within the longest named entity span. As such relations are contained inside a single entity, the whole sentence context can be omitted. To this end, the IntModel classifier inputs the entity features only. IntModel consists of a fully-connected layer with the softmax activation, which inputs fastText embeddings of both entities, trainable embeddings of corresponding entity types, and a binary feature showing whether the two entities are nested.

Table 4 presents the results of relation extraction on the NEREL dataset, grouped with respect to three relation types. The results show that (i) overall, in-sentence relations are much easier to extract than the document-level ones; (ii) the monolingual RuBERT provides better results, when compared to the multilingual version and quasi English GPT; (iii) the OpenNRE model is superior to SpanBERT and copes with all three types of relations, (iv) the simplistic IntModel performs on par with more sophisticated models.

### 4.3 Discussion

Although the preliminary experiments provide with promising results, there is still some room for improvement. Achieved results are comparable to those, published for English datasets, confirming high quality of the collected dataset. At the same time NEREL annotation schema causes difficulties for the current models: all-together nested named entities, combined with diverse relations, require less straightforward approaches, of which machine reading comprehension is one of the promising directions. Detailed error analysis will help to reveals models’ weaknesses and drawbacks.

### 5 Conclusion

We presented a new Russian dataset NEREL annotated with both nested named entity and relations, which is significantly larger than existing Russian datasets. NEREL dataset has several significant distinctive features, including nested named entities, relations over nested named entities, relations on both sentence and discourse level, and events involving named entities.

NEREL can facilitate development of novel models that address extraction of relations between nested named entities and cross-sentence relation extraction from short texts. NEREL annotation also allows relation extraction experiments on both sentence-level and document-level. Nevertheless, NEREL annotations utilize conventional entity and relations types, enabling cross-lingual transfer experiments.

Our experiments with baseline models for extraction of entities and relations show that there is room for improvement in both. In the nearest future we plan to enrich the dataset by linking the annotated named entities to Wikidata items.

### Acknowledgments

The project is supported by the Russian Science Foundation, grant # 20-11-20166. The experiments were partially carried out on computational resources of HPC facilities at HSE University. We are grateful to Alexey Yandutov and Igor Rozhkov for providing results of their experiments in named entity recognition and relation extraction.

Abstract

Relation extraction is a subtask of natural language processing that has seen many improvements in recent years, with the advent of complex pre-trained architectures. Many of these state-of-the-art approaches are tested against benchmarks with labelled sentences containing tagged entities, and require important pre-training and fine-tuning on task-specific data. However, in a real use-case scenario such as in a newspaper company mostly dedicated to local information, relations are of varied, highly specific type, with virtually no annotated data for such relations, and many entities co-occur in a sentence without being related. We question the use of supervised state-of-the-art models in such a context, where resources such as time, computing power and human annotators are limited. To adapt to these constraints, we experiment with an active-learning based relation extraction pipeline, consisting of a binary LSTM-based lightweight model for detecting the relations that do exist, and a state-of-the-art model for relation classification. We compare several choices for classification models in this scenario, from basic word embedding averaging, to graph neural networks and Bert-based ones, as well as several active learning acquisition strategies, in order to find the most cost-efficient yet accurate approach in our French largest daily newspaper company’s use case.

1 Motivation

Relation extraction is a mature field of natural language processing that aims at finding the relations between identified entities in texts. Recent research has focused on the use of trainable models to automatically extract and classify relations between entities. The state-of-the-art research on relation extraction focuses on large, complex models, that require either a long time to train or some pre-training with a fine-tuning phase. Task-specific labelled data is needed to train the final classification model, with research relying on benchmarks such as Zhang et al. (2017) or Hendrickx et al. (2010), which are often made of single sentences with clearly tagged entities and definitive, non-ambiguous relations.

In a real-life scenario, however, relation extraction is used in a language processing pipeline, e.g., in order to confront different reports of a same event, or to grasp a general picture of a situation. In the specific case of a regional newspaper company such as ours, the intent is to create a knowledge graph from the content of the newspaper’s own articles, so as to facilitate journalists’ investigation with an easy access to information and to possible relations that are otherwise drowned in pages of text. In this realistic scenario, data is of a very different nature from standard corpora, exhibiting certain features that are specific to the regional ecosystem, thus challenging off-the-shelf models or learning methods.

The main feature of this data is that, while it is abundant, almost none of it is annotated, as human expert annotation is expensive. We thus turn to active learning (AL) as a means to alleviate the cost of labelling datasets. This approach, opposed to simply annotating samples, allows for a selection of the most helpful training samples, and therefore also allows a reduction of the number of annotations that have to be made by a human to reach satisfactory performance. Besides, it also allows annotation to be done in several installments of comfortable length for the annotator, reducing their fatigue and potential labelling errors.

Another issue than the scarcity of labelled data constrains the models that can be used within this active learning paradox, due to the local nature of the articles. Entities being often specific to the local context, making use of external data is not an option, also because of ownership and trust issues. Furthermore, relation types vary greatly, from one journalist’s interests to the other, requiring the
ability to quickly rebuild models from very limited data. On top of these general concerns, in articles, a large number of entities mentioned co-occur but are not actually related. To eliminate such fallacious cases is not straightforward, due to the complex language style and numerous entities mentions within articles.

We therefore develop an active learning approach to relation extraction in the newspapers’ articles to deal with the scarcity and cost of labelled data. With the underlying idea that two light models are more likely to be accurately trained with a limited amount of data in an active learning scenario than a single large end-to-end model, we separate the task of detecting a relation from the classification of said relation. A first LSTM-based model specializes in detecting the fallacious candidates by outputting whether two entity mentions within a sentence are related or not, letting a second classification model focus on subtle differences between relations instead of having to clean the data at the same time. We aim to find, in this active learning on newspaper context and with the data particularities outlined above, whether a complex state-of-the-art classification model is relevant, or whether a shallow approach is better suited. Our goal is also to find an active learning strategy that reaches satisfactory results the fastest, so as to reduce human annotation.

In the following, we describe the architecture of the whole system and detail the different models used. A first experiment compares the performances of three classification models as data becomes available, therefore checking the amount of data at which a more complex model is better suited than a simpler, lighter model. In a second experiment, we compare three active learning scenarios with a fixed pipeline consisting of the LSTM-based relation detection model and a C-GCN classification model. We aim at finding a cost-effective active learning within our framework so as to minimize the amount of annotations needed. We therefore contribute to a study of several active learning scenarios to fit our newspaper use-case with specific, unbalanced local data, using machine learning models with different levels of depth. We notably study the relevance of very deep learning models in such a data-scarce scenario.

2 Related Works

All the outlined particularities of the data in our regional newspaper articles render most of the state-of-the-art work in the field of relation extraction inapplicable directly to this scenario, although relation extraction has excellent state-of-the-art models. For instance, even if Open Information Extraction (Banko et al., 2007; Mesquita et al., 2013; Del Corro and Gemulla, 2013) revolving around the identification then extraction of potential entities (noun groups) and potential relations between them, is a breakthrough in treating large-scale corpora, this method relies on the extraction of nominal groups, which does not link to entities of the newspaper’s knowledge graph, and may lead to the identification of some relations that make sense grammatically, but have no meaning semantically.

In unsupervised relation extraction (Hasegawa et al., 2004; Takase et al., 2015), most works cluster linguistic patterns if two given entities co-occur a sufficient number of times. Used directly, these clusters’ usability is limited, as they have to be studied and labelled by hand. Preemptive Information Extraction (Rosenfeld and Feldman, 2007; Shinyama and Sekine, 2006) uses such clusters of candidate relations as high-precision seeds that feed a second, semi-supervised model. Those methods require numerous documents with redundant entities pairs and linguistic patterns, otherwise seeds might be corrupted and the semi-supervised model experiences semantic drift. Finally, state-of-the-art supervised models range from learning on syntax trees and hand-crafted features based on dependency parsing (Zelenko et al., 2003; Kambhatla, 2004; Xu et al., 2015; Liu et al., 2016; Cai et al., 2016) to deep learning (Wang et al., 2016; Lin et al., 2016). Most of the latest approaches are building on the computationally heavy and data-intensive transformer model (Devlin et al., 2019), such as Yamada et al. (2020); Baldini Soares et al. (2019); Wu and He (2019). All the aforementioned approaches thus fall within one of two categories: either they are heuristic, count-based approaches, that do not work on our very local data as journalists tend to avoid redundancy in their writing; or they are learning-based, which requires large amount of labeled data or pre-existing knowledge which we do not have.

The active learning paradigm is a way to address the shortage of annotated data as well as the evolution of the needs, such as the addition of new
relation types, by selecting most helpful samples to train the model: the main goal is to find the best strategy for the selection of said samples. In active learning, a small number of samples is chosen, labelled by an oracle and used to optimally train the model, the process repeating until a stopping criterion is met. Schröder and Niekler (2020) point out the conflicting paradigms of deep learning and active learning: deep neural networks excel, but under the strict requirement that abundant data be available, which defeats active learning’s frugality objective. Uncertainty sampling has been shown to be adaptable to deep classifiers in Prabhu et al. (2019) for NLP, and we select this approach, as it only relies on the distribution of probabilities of the sample once it has run through the model. Therefore, there is little additional cost to creating an uncertainty-based sample to label, and many models can be used in this framework, as long as they output such probability distribution. For deep learning, Sener and Savarese (2017) or Siméoni et al. (2021) report no improvement of uncertainty sampling in image classification scenario, while Siddhant and Lipton (2018) find that both uncertainty-based sampling and Bayesian approaches outperform random across 3 NLP tasks. Our aim is to find how these results transfer on real-life data, and whether deep learning is truly an improvement over shallower approaches in this context.

3 Methodology and Protocol

We present the global architecture of the active learning relation detection system that we study before providing details on the different classifiers.

3.1 Architecture of the System

![Diagram of system architecture](image)

Figure 1: System architecture diagram

In the following, several working hypotheses have been made to reduce noise on our particular data. We justify them, and present the specifics of the use-case, as well as the structure of the iterative system that we implemented.

Firstly, only the relations explained within a sentence are considered as potential relations. Furthermore, in our data, sentences are considered to be independent. This assumption comes from considering only the couples of entities that appear in the same sentence to reduce fallacious co-occurrences and avoid error propagation when using coreference resolution systems. This assumption can be challenged, and we leave binary relation detection across sentence boundaries to be treated in future work.

The proposed architecture is presented in Figure 1. This iterative system is a pool-based active learning architecture, revolving around an expert oracle and a learner, described in Sec. 3.2. The pool of unlabeled data consists of samples, each containing the sentence $s$, the surface form of the entities $e_1$ and $e_2$ as well as their positions in the sentence and their types. On top of this, each sample goes through NLP pre-treatment and therefore contains the dependency parse of the sentence, the part-of-speech and NER tag of words in the sentence as well as the part-of-speech, NER tags and dependency parse tags along the shortest dependency path between the two entities. During one iteration, our learner predicts relations $R$ from the 13 identified relation classes for the unlabelled data in the pool of content. Some examples from this pool are selected according to a query strategy based on the prediction probability. These chosen samples are presented to a human annotator, or oracle, who annotates them, and these annotated samples join a pool of labeled data. This new knowledge is used to train the learner, that in the next iteration predicts the relation class of the rest of the data in the unlabeled pool.

In this work, we use a pool-based approach, with a selected sample of articles on the same subject, namely the local enterprise landscape, so as to stay within one topic of interest and to be able to compare methodologies. This is also in phase with the scenario where a journalist starts exploring a specific topic from selected content. Stream-based solutions to adapt to the constant stream of information created by journalists every day are not considered here.

Our query strategy revolves around uncertainty-based sampling, where examples that the model is least certain about are selected and presented to the oracle for correction. Here, we have three propositions for the choice of query strategy.
• Random: take $k$ samples randomly from the entire pool of annotations not used for training yet.

• Least likely: take the $k$ samples less likely in their prediction, i.e., that have the lowest prediction probability.

• Mixture: take, for each of the $l$ predicted relations, the sample with the lowest probability to belong to this class, plus $k - l$ of the most likely samples overall. This allows to control at the same time the border cases where the model does not distinguish very well, and to catch cases where the model is very confident of a wrong relation.

3.2 Models Description

As outlined above, active learning requires a learner. Our proposed learner consists of two models. A first detection model specializes in verifying that given a sentence and two entities, the sentence actually expresses some relation between the two given entities. Then, a classification model is applied on the samples that are predicted as being related so as to predict the type of relation. We tested three classification models: C-GCN, a basic model based on word embedding averages and a BERT-based model, described in the following.

3.2.1 Detection Model

Figure 2 presents the overall architecture of our detection network applied to an example sentence. In each sentence, the couples of entities are extracted and the model learns whether the words that are on the shortest dependency path between the two entities of a couple depict a relation or not. Only information about the type of entities and the word features along the shortest dependency path between the two entities are used in the model. The model features two branches, one modeling the entities through their types with a fully-connected layer (left branch), the other the syntax information between the two entities with a LSTM model (right branch). LSTM networks’ ability to deal with sequential data to retain or forget relevant information makes us confident that this architecture, despite being simple, still can retain enough information to correctly detect relations. The two branches are finally merged with a fully connected layer with sigmoid activation to predict the probability of a relation between the two entities.

3.2.2 GCN Classification Model

C-GCN + PA-LSTM (Zhang et al., 2018) was chosen as one of the classification model, as it does not necessitate any external knowledge base embedding or heavy transformer machinery, while still retaining performance close to the most recent models.

This relation extraction solution’s idea is similar to many representation-based models, where a first part of the model to create contextualised embeddings of the words in the sentence, and a second part to output the predictions of the relation class from the embeddings. The aspect that sets aside the C-GCN model is the use of graphical neural networks over dependency parse trees to find contextualized vector representations of the tokens, which is essentially the computation of a few ma-

Figure 2: Binary detection model, applied to the sentence “Le président du département Olivier Richefou a été élu président de la société publique locale Espace Mayenne, basée près du 42e RT à Laval.”

The use of the shortest dependency path between the entities, along with word and part-of-speech features of the words along the path, accounts for the syntax that can relate entities. All these features were extracted with the StanfordNLP library (Manning et al., 2014). The word features include notably the embedding of each word as obtained from a pre-trained skip-gram model (Mikolov et al., 2013) obtained from Fauconnier who made the embeddings publicly available\(^1\). The path excludes the entities themselves, which are accessible on the first branch via their respective types.

\(^1\)http://fauconnier.github.io/#data
trix multiplications (2 times the number of GCN layers chosen), and therefore very easily distributed and fast to train.\footnote{We used the code directly available from the authors, at https://github.com/qipeng/gcn-over-pruned-trees}

### 3.2.3 Base Classification Model

We replace the C-GCN in a second installment of our system, so as to verify whether the C-GCN model is adapted to the task of classifying existing relations, or too complex for the small amount of samples acquired via active learning. The replacement model takes as input the average word embedding, by averaging every word vector obtained for the words of the sentence. These word embeddings are the same as in our detection model. This input is fed to a fully connected layer, with a softmax output. This simplistic classification model will not be able to perform relation classification efficiently, but it acts as a baseline to evaluate the results of the other state-of-the-art models.

### 3.2.4 Bert-based Classification Model

Inspired from Alt et al. (2019) and Shi and Lin (2019), we also implement an approach based on a pre-trained BERT architecture for French, Flaubert (Le et al., 2020).

First, we construct the input sequence as $[[CLS] \text{sentence} [SEP] \text{entity1} [SEP] \text{entity2} [SEP]]$. To avoid over-fitting, the tokens of the input sequence corresponding to the entities are replaced by a special token representing the type of the entity ([PER], [LOC], [ORG] or [MISC]). Contrary to Alt et al. (2019), where the entities are placed before the masked sentence to bias the attention mechanism towards the representation of entities, we place ours at the end. Our very specific entities, such as original or new company names, might not be well represented with a pre-trained architecture, and we therefore put more emphasis on the known type of entities than on the name of the entities themselves. The input sequence is fed to the pre-trained Flaubert model. This model encodes the input representations over successive transformer blocks. Each of these transformer blocks is made of a masked multi-head attention layer followed by a position-aware feed-forward layer.

We thus obtain the final state representation $h_L$ of the input sequence. The last state $h^2_L$, which represents a summary of the input sequence, is used to compute the probability distribution over all relation classes, by running it through a linear layer activated with ReLU function, and a last linear layer followed by a softmax layer.

### 4 Experiments

Two experiments, one comparing three relation classification models, and one comparing the three different uncertainty-based active learning strategies, aim at finding the best setting for relation extraction, taking into account cost limitations.

#### 4.1 Data

To initialize and train our models, annotators from the company have created three datasets. Two small pools of data consist of 588 and 261 samples, respectively the seed and the testing set, with relations in various proportions, so as to reflect the reality of the contents of the newspaper.

For active learning purposes, we gathered another 1,271 annotations for the 13 categories, with a distribution shown in Tab. 1. As expected, most of the relation candidates do not actually depict a relation. The relations "créé en", "né à" and "contracté par" are not likely to be well predicted by any model, as they each are represented by at most 4 annotations. Besides, we added an autre (other) category. This allows firstly to avoid labelling samples that do depict a relation, albeit an unknown one, as fallacious, therefore reducing the noise for the detection model, and secondly, annotators can flag relations that we may not have identified earlier, giving us a path for future improvement of the system. Samples were annotated by only one person at a time, in an effort to acquire as many labelled samples as possible from a limited amount for annotators. This might lead to some bias, but considering that our annotators are experts, that will be on par with the expected use of the system: there will not be enough resources to have several journalists cross-validate potential samples, so once one sample is annotated by an expert in the field, it is considered properly labelled.

#### 4.2 Comparison of Classification Models

This first experiment compares the three classification models: C-GCN, the base model (BASE) and the BERT-based approach (FlauBERT+FC). All seed data has been used to initialize the models. Classification models classify only on the 13 identified types of relation, without having to predict the class "aucune" (None), as the detection model already takes care of this class. The acquisition

strategy is set to "random", with 50 annotations selected for each iteration, until either a criterion of a difference of micro-F1 score inferior to 0.001 is reached, or 60 iterations have been completed, which amounts to almost the entire training pool. Figure 3 shows the evolution of F1 score as a function of the iterations.

Figure 3: Macro F1 score for models BASE, C-GCN and FlauBERT+FC, along the active learning steps with a random query strategy.

Globally, the scores for all models only show little improvement with the number of iterations, which means that adding annotated data yields marginally better results than the simple starting seed. Upon analysis, the main culprit can be found in the use of a "random" sampling strategy on highly imbalanced data, which chooses imbalanced training samples to the model.

Firstly, most of the active learning samples display no relation. This leads to the detection model becoming very conservative, and discarding many samples as fallacious. The best achieved precision across training is 0.42, meaning that 42% of samples labelled as "aucune" really are fallacious, and therefore 58% of all samples labelled as fallacious actually depict a relation. As our model is a pipeline, it accumulates the errors: samples belonging to small classes, mistakenly classified as fallacious, do not make it to the classification model.

Secondly, two classes ("dirige" and "a son siège à") are disproportionately large, which leads to a phenomena of "concentration" on those two big classes, to varying degrees depending on the model. On the one hand, the C-GCN and FlauBERT+FC models directly classifies all data in one of those two classes, "dirige", and still reaches a satisfying loss, therefore never learning any of the features on the smaller classes. On the other hand, as learning progresses, the lighter model BASE progressively improves on the samples corresponding to the smallest classes, at the expense of the middle classes, with only a slight deterioration for the bigger classes. Results fluctuate largely due to the nature of the test dataset, which is small and therefore, one misclassification may lead to a large change in scores.

The take-home result is therefore that the state-of-the-art methods do not apply in a straightforward manner on this newspaper’s data. The model that seems to adapt best to this imbalance of data is the simplest one, based on a vector representation of the sentence, as the GCN-based model completely misclassifies half of the dataset, and the Flaubert-based model does not have enough data to train its millions of weights properly.

4.3 Active Learning Query Strategy

The first experiment used the "random" active learning strategy, to be fair for all models. We have shown that, with the over-representation of some classes in our data, this leads to bad performances for all models. To verify if the active learning acquisition strategy could help smooth this phenomena, we try three different active learning strategies with our BASE model and the C-GCN model. The three tested strategies are respectively random, least likely and mixture, the results for BASE being plotted in Figure 4. We do not plot the results for C-GCN as they do not solve the issue of all samples being predicted as "dirige", although we note a slight improvement on the recall of the "aucune" class for the mixture strategy.

On the BASE model, the least likely strategy does not improve the general macro F1 score over
the random strategy. However, the scores within classes change: while the big classes are equally-well predicted under the two strategies, under the least likely strategy, the smallest classes (such as "filiale de" or "précède") get less well predicted, contrary to the more populated classes (such as "membre de" or "vit à").

The mixture strategy, on the other hand, improves both precision and recall on the detection task alone, which can be attributed to a different distribution of true and fallacious samples fed to the detection model for training: 60% of samples being fallacious under the random strategy drops to 40% under the mixture strategy. By allowing the model to train over more examples of actual relations, it does not discard rare relations as fast.

The mixture strategy, however, shows no improvement over random in terms of F1 score for the classification. Nonetheless, results are more consistent across classes, with slightly worse precision and recall on large classes but better results on the classes with few training samples. The result on the middle-sized classes surprisingly does not improve, when it was expected that a flatter distribution would lead to improvement on all classes but the largest ones. An explanation may be that, upon seeing a larger diversity of samples, the simplistic baseline model reaches its limits and cannot differentiate between samples containing similar vocabulary.

5 Conclusions

In this work, we reported on an experiment to develop an automatic relation extraction system adapted to our newspaper data in a context of scarcity of labelling, exploring various strategies towards the best possible setting. We got confronted to the divergence of objectives between deep learning and active learning, showing that shallower approaches are a safer bet in a context where labelled data is acquired via active learning. Although such simple models do reach their limits early, and deep learning consistently breaks records in the literature, deep architectures require more data to train than can be supplied through active learning with a real human as an oracle. We will therefore steer our future work in the direction of shallow classifiers with a small amount of weights to train. Given the small amount of data available, all linguistic information might need to be used, such as part-of-speech tags, semantic roles or dependency tags, not solely relying on contextualized word vector representation that either takes time to train or has to be obtained via an external source. Additionally, adopting a hand-made query strategy relying on sampling from each predicted relation to reduce the cost of annotation was found to be a small improvement compared to using only a small training set. Still, the increase in performance needs to be checked in the light of a classification model better suited for active learning. Besides, in order to be deployed, our system still needs to be able to take into account new types of relations. While we already store these "autre" relations during the annotation phase, we are yet to incorporate them into the classification model, in order to create a system that evolves with the content of the newspaper.

Abstract

This paper describes the annotation process of an offensive language data set for Romanian on social media. To facilitate comparable multi-lingual research on offensive language, the annotation guidelines follow some of the recent annotation efforts for other languages. The final corpus contains 5000 micro-blogging posts annotated by a large number of volunteer annotators. The inter-annotator agreement and the initial automatic discrimination results we present are in line with earlier annotation efforts.

1 Introduction

The use of words to hurt others is a curious aspect of natural languages. Besides the scientific curiosity, however, certain forms of offensive language can be harmful to individuals, may have discriminatory, toxifying effects on the society, and can be against law. An annotated corpus of offensive language is, hence, a valuable resource for understanding, identifying and preventing offensive content, particularly in online communication. This paper describes such an annotated corpus of Romanian on social media.

The study of offensive content online goes back to the earlier days of the Internet (Lea et al., 1992; Kayany, 1998). However, identifying various forms of offensive or abusive language online, such as hate speech or verbal harassment, has attracted considerable recent interest. The increased interest is evidenced by a number of recent shared tasks (Kumar et al., 2018; Wiegand et al., 2018; Zampieri et al., 2019b; Basile et al., 2019) to the extent that OffensEval 2020 shared task in Semeval evaluation campaign (Zampieri et al., 2020) received submissions from 145 teams (out of 528 registered teams).

An important ingredient of these studies is an annotated corpus. Recent annotations efforts with the aim of detecting offensive language typically focus on a particular form of offensive content, such as hate speech (Agarwal and Sureka, 2015; Davidson et al., 2017; Del Vigna et al., 2017; ElSherief et al., 2018; Gao and Huang, 2017; Gitari et al., 2015; Sanguinetti et al., 2018a; Waseem, 2016, just to name a few), or cyberbullying (Xu et al., 2012; Dadvar et al., 2013; Dinakar et al., 2012; Nitta et al., 2013; Van Hee et al., 2015). However, it is often difficult to study a particular form of offensive language in isolation (Malmasi and Zampieri, 2018; Vidgen and Derczynski, 2020). For example, a classifier trained on a data set that annotates only instances of hate speech may detect other forms of offensive language as hate speech. As a result, some of the recent studies annotate multiple forms of offensive language together (Wiegand et al., 2018; Struß et al., 2019; Zampieri et al., 2019a). In particular, the annotation scheme for the OLID data set of English tweets by Zampieri et al. (2019a) has been used for annotating a variety of languages, including Arabic (Mubarak et al., 2020), Danish, (Sigurbjörgsson and Derczynski, 2020), Greek, (Pitenis et al., 2020), and Turkish (Çöltekin, 2020). Although not identical, the labels used in GermEval shared tasks (Wiegand et al., 2018; Struß et al., 2019) are also similar to the label set used by these data sets.

In this study we use a similar label set and follow similar guidelines for annotation of Romanian tweets. Following earlier annotation efforts for offensive language, we try to maximize the number of offensive tweets by obtaining part of the tweets to annotate using a list of offensive words, but also include a larger number of randomly selected tweets. The annotations were performed by volunteers.

For the remainder of this paper, we first describe the data set and the annotation process, present evaluation of the data and initial experiments with identifying offensive language and types of it for
the present data, and conclude with a brief discussion and outlook.

2 Dataset

This dataset, to our knowledge, is the first of its kind for Romanian. It includes tweets from a wide range of topics between the second and third week of March in 2020. Since COVID-19 has been one of the main topics of the year, the data in this dataset consists largely of opinions about the virus, but also includes political slur and day to day tweets. In the following subsections, we provide an overview of how the data was collected and the annotation guidelines and process.

2.1 Data collection

The tweets for this dataset were collected using the Twitter API. We use two strategies to collect tweets. Since most of the offensive language annotation effort goes into finding few offensive languages posts among many non-offensive ones, annotating a completely random tweets is a big undertaking. As a result, most annotation studies collect the data based on queries that maximize the number of offensive posts. We followed the same practice, and a list of offensive words or abbreviations in Romanian such as dracu ‘hell’, mătă ‘your mother’ or pulă ‘dick’ were used to collect approximately 1000 tweets. The number of offensive words used for this part of the task is 25. We complemented this list with tweets that were randomly sampled from the Twitter stream by querying 400 most frequent words based on the Romanian section of the Leipzig corpora (Quasthoff et al., 2014). This is a method used frequently, since the collected tweets can be seen as day to day life situations, without going to deep into a specific area, where multiple specific words are mentioned. We collected a total number of 15,000 full length tweets, from which we removed duplicates and promoted tweets. We also filtered the tweets based on the following criteria.

- Retweets were filtered out even if the original tweet was not part of the data set.
- Tweets with less than ten characters were filtered out.
- Any links inside of a tweet were removed.

After filtering, our data includes 820 tweets obtained through the query using offensive words, and we complemented the tweets to 5000 in total from the randomly obtained tweets.

2.2 Set of Labels

We follow the annotation scheme suggested by Zampieri et al. (2019a), and create a three-level annotation system. At first the annotator needs to decide whether a tweet is offensive or non-offensive. Following this decision, if a tweet is marked as offensive, it needs to be decided if it is targeted or non-targeted. The final level of the process is to decide the target of an offensive targeted tweet. This category is split into three different target classes, individual, group and other. A group is defined by being part of an entity such as race, ethnicity, political interests or gender. If the target of the offense is an individual, or multiple individuals that do not fit into the group definition above, then the target needs to be marked as individual. Cases that do not fit any of the two categories, for example an event or an organization, are being labeled as other. Together with the full data set, the annotation guidelines are published at https://github.com/guzimania/ROFF. Although the relation is not necessarily a one-to-one relation, the offensive expressions that target a group are likely candidates for hate speech, while offensive statements that target individuals are likely to correlate with instances of cyberbullying or harassment. This set of labels does not cover every possible aspect of offensive language, For example, it may be interesting to annotate aspects of offensive language, like the aggressiveness (Basile et al., 2019) or the strength of the offense (Sanguinetti et al., 2018b). However, for simplicity and compatibility with a wider set of earlier annotation projects, our choice is limited to the label set defined above.¹

2.3 Annotation Process and Data Analysis

The annotators were recruited from the author’s contacts. All 33 annotators are native speakers of Romanian and have at least a high school degree or higher. Annotators volunteered for this project and did not get any benefits. The age of the annotators ranges between 18 and 55 years and the experience of using Twitter as a platform is between zero and 2 to 3 times weekly. It is worth mentioning that some annotators live outside Romania and can therefore have a different perception of

¹The task involves a fair degree of subjectiveness. Different people have different interpretations of what is offensive. The additional aspects of the offensive language also tend to include more subjectivity, and lower inter-annotator agreement as reported in these studies.
offensiveness of a tweet. The annotators received clear instructions on how to perform the annotation and were asked to annotate 50 example tweets, before being handed the proper data. The initial annotations are reviewed by the authors and the annotation guidelines were revised to resolve some of the potential ambiguities in the initial guidelines that resulted in high disagreement.

All 5000 tweets in our sample were annotated by at least one annotator, and 2100 of the tweets received annotations from two annotators. We report the inter-annotator agreement on these 2100 doubly-annotated tweets. The agreement for the first level annotation (is the tweet offensive or not?) is 86.70 % (Cohen’s Kappa $\kappa = 0.52$), for the second level (is the tweet targeted or not?) 58.30 % ($\kappa = 0.17$) and for the third level (who is the target of the tweet?) 43.20 % ($\kappa = 0.20$). Cohen’s Kappa shows that there is a moderate agreement between the annotators when looking at a tweet and deciding if it is offensive or not. Presumably due to subjectivity of the task, and differences in annotation instructions, the reported annotator agreement on similar tasks vary considerably. As a reference, the study that forms the basis of our annotation scheme (Zampieri et al., 2019a) report a raw agreement rate of 60 %. The agreement on further levels of annotation is lower. The metrics and scores reported in earlier literature vary considerably. However, the low agreement is a known problem for this task (Vidgen and Derczynski, 2020).

The difficulty of this task can be observed in (1). The annotators disagreed on this example. Since most of the sentences that include foul language are due to the subjective judgment of each annotator, it is open to argument whether examples like these are offensive or not.

(1) @sopeprotector lol am si eu ham din asta e al dracu de tampit tho il port cateodata

@sopeprotector lol I have a harness from this too, it’s damn stupid, I wear it sometimes

The second level of annotation is to decide if a tweet is targeted or not. For example, (2) was marked as targeted by one annotator but untargeted by the other. There is no clear answer that can be applied to each sentence, hence, there are many discrepancies between the annotators on this level.

(2) @FIFAMobiledaily in pula cu satelitul ca tre-bue sa ma duc la munca

The most complicated part of the annotation was to decide which target the tweet has. Here the annotators had different answers in many cases, hence there the highest disagreement between the annotators is for this annotation level. Most of the time it is difficult to recognize the target directly, since it is not always directly mentioned in the tweet. As can be seen in (3), ‘those’ and ‘TV guys’ are possible targets of the tweet.

(3) Ce plm au ãástia de la TV impotriva ãóstora care vând chestii mai rare?

What the fuck do these TV guys have against those who sell weirder stuff?

One of the annotators decided that this tweet is targeted towards an individual and the other chose the label OTH, since it is not clear enough which target it is. This confusion can be explained by the lack of context for these tweets. Since each tweet is being handled individually, the annotators often do not have a certain feeling for the context of the tweet. In general, some tweets can be seen as offensive without context, others need the context to be correctly annotated.

For doubly-annotated texts, the conflicts were resolved by the authors. Resolution action favored the offensive label in most cases. The final data set consists of 5000 tweets, from which 924 were labeled as offensive (18.48 %) and 4076 tweets as non-offensive. The detailed label distribution is presented in Table 1. All except one of the 820 tweets obtained by querying offensive words were

annotated as offensive, while only 3.47% of the random tweets got an offensive label in the final annotation.²

3 Classification Experiments

In this section, we report initial classification results on the data set. Since we use a ‘closed experiment’ setup without any external information or data augmentation, the results can be improved. However, we believe the classification scores presented here can serve as a strong baseline.

Following OffensEval shared tasks (Zampieri et al., 2019b, 2020), we present results of three separate tasks. The first task, task 1, is identifying whether a given post is offensive or not. In task 2, we aim to identify whether an offensive tweet is targeted or not. Finally, task 3 is about classifying the target of a targeted offensive tweet.

For all tasks, we use an LSTM-based classifier. The model uses words (tokenized using regular expressions) as input. The model first embeds the words in an embedding space of 64 dimensions. The embeddings are initialized randomly, and only learned during training. The embeddings are passed to a single left-to-right LSTM layer with 64 units and followed by a dropout rate of 0.10. The representation built by the LSTM layer at the final time step is passed to a fully-connected classification layer with a sigmoid or softmax activation depending on the task. Model was trained on 50 epochs with the Adam optimizer and cross-entropy loss function. The implementation uses Python Keras library (Chollet et al., 2015).

The results for all three tasks were presented in Table 2. The scores are similar to the earlier results obtained for other languages on similar data sets. For example the best macro-averaged F1 score reported in the OffensEval 2019 shared task for English are 82.90, 75.50 and 66.00 for tasks 1, 2 and 3 respectively.

Not surprisingly, the model’s performance on detecting offensive language is better than detecting whether an offensive text targeted or not, which, in turn, is better than the 3-way classification of targeted texts to respective target groups. A reason for the low score on target classification is due to the fact that the label OTH is not clearly defined, since it can be used for various targets, e.g., events or organizations, and can therefore be often confused with other target groups.

4 Conclusion & Future Work

We presented a manually annotated corpus of Romanian offensive language on Twitter. Our annotation scheme is compatible with a number of recent offensive language annotation projects for other languages. As a result, the corpus is suitable for multi-lingual and cross-lingual research on analysis or detection of offensive language.

Overall, the inter-annotator agreement and initial machine learning experiments on the data yield similar results with earlier studies on offensive language. Although similar to the earlier studies, the offensive language detection results can definitely be improved using external resources, such as by using word embeddings, or by fine-tuning large pre-trained language models on this data. Furthermore, the uniform annotation scheme with other languages may allow cross-lingual transfer through translation and/or use of cross-lingual, shared word or sentence representations.

Although the data set created in this study comparable to many of the other data sets presented in the field (see Vidgen and Derczynski (2020) for a recent review), an obvious direction for future research is to increase the size and diversity of the data.

Most earlier data sets are either annotated by experts, or through crowd sourcing. In this study, we chose to rely on volunteers. Even though this is a common practice for finding participants for experiments in many fields, it is not common in annotation projects. Even though we did not use any gamification or other means to attract annotators, we received annotations from over 30 annotators. The present method can be applied where a crowd annotation is possible, and potentially result in a higher quality in comparison to the crowd sourcing. An interesting direction for future research is to

Abstract

The paper describes a system for automatic summarization in English language of online news data that come from different non-English languages. The system is designed to be used in production environment for media monitoring. Automatic summarization can be very helpful in this domain when applied as a helper tool for journalists so that they can review just the important information from the news channels. However, like every software solution, the automatic summarization needs performance monitoring and assured safe environment for the clients. In media monitoring environment the most problematic features to be addressed are: the copyright issues, the factual consistency, the style of the text and the ethical norms in journalism. Thus, the main contribution of our present work is that the above mentioned characteristics are successfully monitored in neural automatic summarization models and improved with the help of validation, fact-preserving and fact-checking procedures.

1 Introduction

Automatic summarization is the task of retelling long texts in a shorter abstract, emphasizing the most important information in an easy to read and grammatically correct way. There are two types of automatic summarization: extractive and abstractive. The key difference between the two are the methods they use to summarize text documents. While the extractive summarization is a scoring task that looks for the most important sentences within the input text, the abstractive summarization is a text generation task, relying on machine-based understanding of the content of the original text. The end-product of the abstractive summarization has an element of innovation - it often contains phrases and knowledge which are not part of the source document but can be inferred from it. This creativity element makes most abstractive summaries closer to human-made ones. Thus, we consider abstractive summarization to be more appropriate for our main goal - producing a system for automatic summarization in English of textual data that come from different non-English languages, applicable in the production environment for media monitoring. Additionally, it is mandatory in journalism to retell information complying with copyright rules, which is not possible to achieve with extractive summarization.

On the other hand, recent research shows that the state-of-the-art (SOTA) abstractive summarization neural models have difficulties with the proper processing of lengthy texts. The problem is that the models’ attention focuses mostly on the beginning of the text source, which means that the information appearing at the end of the text is either truncated (if the input text exceeds the allowed length) or/and is simply ignored (Raffel et al., 2020). As a consequence, the generated summary itself does not capture all the relevant information.

Another problem of the SOTA abstractive summarization models, which is usually reported, is the literal copying of long sequences - sometimes even whole sentences - from the source text. This copying makes some of the generated abstracts similar to extractive summaries (Lin and Ng, 2019). Last but not least, the abstractive summarization models are not easy to interpret (Lin and Ng, 2019; See et al., 2017; Kryściński et al., 2019), which interferes with the back-tracing of possible problems like the generation of inappropriate content or nonsense sequences. With all this in mind, the focus of our research is on the following challenges: 1) It seems that traditional attention mechanisms have difficulties summarizing long documents since they often miss some important information; 2) They are prone to introducing additional content (Cao et al., 2018) and factual inconsistencies, known as
hallucinations. The hallucinations can be of different nature - changing facts and attributing new facts that are not present in the original text. The changing of the facts is mainly expressed in: replacing dates and numbers with others, mixing the statements of certain entities with the statements of other entities; 3) Another common observation is the transferring of knowledge from the training data to the source text. In general, the transferred knowledge may correspond to reality, but the problem is that it is not present in the input text. This raises the danger of reproducing existing biases in the dataset and the generation of toxic language, which questions the ethical behavior of abstractive summarization neural models.

In this paper we experiment with different approaches to solving these problems of the abstract summarization, which hinder its actual application in business and practice, namely the factual inconsistency of the generated summaries and the hallucinations that the state-of-the-art transformers are prone to. We consider these problems fundamental, since omitting, altering and hallucinating facts could produce false, misleading and useless news summaries. In general, generating inappropriate text in production would be fatal for this type of models. Progress in this direction would optimize and improve the media quality by redirecting the journalistic efforts to more creative editorial tasks, such as enriching the news that are being published.

Our approach consists of fine-tuning a state-of-the-art Transformer model — Section Model, with the data described in Section Data and experiments with validation and fact-preserving. In addition, we propose an algorithm for checking the factual consistency or fact-checking of the generated summaries described in Section Monitoring Factual, Grammatical and Ethical Consistency. To our knowledge, the factual consistencies of the generated summaries have not been monitored in similar manner before. Conclusions are presented in Section Conclusions.

2 Related Work

Needless to say, the state-of-the-art models for abstractive summarization seem to be very promising. However, addressing the ethical issues connected with it has been a bit lagging behind. As (Coeckelbergh, 2019) emphasizes, one of the key challenges for the artificial intelligence is the fact that the models could reproduce already existing biases. This is a valid concern, as up to 3% of the web content is considered to contain toxicity (Founta et al., 2018). This is important because the language models — such as the model BART that we use — are pretrained on large text corpora extracted exactly from the web. The training task that the model learns through is that of prediction, where the model needs to predict the next token (or word) in a sequence. If during that training the model is presented with data containing toxic language, naturally, it will learn to generate the same language later on. A non-conservative assessment of part of the dataset used for the training of GPT-2, for example, shows that at least 50 000 sentences contain toxic language (Gehman et al., 2020).

A natural question that arises is how to detect and reduce the generation of such language. (Gehman et al., 2020) suggests that the general methods can be divided into either data-based or decoding-based. The data-based strategies are considered more expensive in resources since they include a collection of specific non-toxic data, additional training and changes in the model parameters. A considerable liability in this regard is that by decreasing the generation of toxic language, the utility of the language models used by marginalized groups is also decreased (Xu et al., 2021). The unwanted side effect is that the minority dialects themselves are misidentified as toxic. The decoding-based strategies, on the other hand, are concerned with detecting and modifying the generated output of the model, which makes them less expensive and experiment-ready. Among the most widely used ones in this regard is the so-called blocklisting, which consists of banning undesirable words (i.e., abusive/offensive language).

In addition to this kind of strategies, Google and Jigsaw have a joint project (called Perspective1), which uses machine learning to automatically detect toxic language. When deploying such a model, there is a kind of an assumption that it would be used in more or less benign environment. Unfortunately, the research literature has shown that even the models, specifically designed to detect undesirable language, are extremely vulnerable to adversarial attacks, which can easily change the algorithm output by slight changes in the input, often even unnoticeable for humans. (Hosseini et al., 2017) have convincingly demonstrated that even Google’s Perspective system can be easily deceived by simply misspelling the abusive words and/or by
adding punctuation signs among the letters. This further undermines the production readiness and usability of those solutions and calls for further research and additional countermeasures.

Among the main issues in our context are exactly the opacity and unpredictability of the developed systems. In fact, neither the developer nor the user knows with a high degree of certainty how the system would react to a given set of inputs. Thus, it would be unreasonable to think that the state-of-the-art summarization models would not suffer from similar biases as the ones pointed above.

Besides all these, the Transformers have some additional important weaknesses: their attention is focused mostly on the beginning and the end of the source text (Kryściński et al., 2019); the models often copy lengthy sequences from the original text, making the abstract summaries more like extractive ones (Lin and Ng, 2019) and they are hardly susceptible to human interpretation (Lin and Ng, 2019; See et al., 2017; Kryściński et al., 2019). The bigger problems, however, are the following: generalization of the source text information without respecting the facts, and the production of new facts (Cao et al., 2018). The newly generated facts - called hallucinations - are mainly manifested through changing and adding facts in the text (i.e. changing dates and numbers, mixing statements and corresponding entities), and introducing facts from the training data to the summaries.

The search for a solution to these problems led to the emergence of the hybrid approaches, which enrich the encoder-decoder models with structural representations of the documents. This has been realized in several different ways. StructSum (Balachandran et al., 2020), for example, adds attention layers for both latent and explicit structure attention to a standard encoder-decoder model. The assumption is that by training those layers in parallel with the encoder-decoder model, the model is required to include in its representation structural information as well. Another similar hybrid approach - ASGARD (Huang et al., 2020) - improves the information selection from the source text by replacing the attention mechanism of the encoder-decoder model with a graph-based attention mechanism. The result is the same, the model is introduced with a stream of structural information which needs to be considered when encoding a text document.

In the present study, we decided to explore an alternative approach addressing the factual weaknesses of the state-of-the-art models through an approach specifically designed to capture possible factual errors after the generation of the summary, rather than one focused on the text encoding (employed by (Balachandran et al., 2020; Huang et al., 2020)). We describe the approach in detail in Section Fact-checking.

3 Data

Our data contain 304,570 news articles written in several languages, including English, German, Spanish, French and Italian, and their summaries in English. We implemented the data-based strategy described in (Gehman et al., 2020) to ensure politically balanced, ethically and factually correct news, coming from left-wing, right-wing and centrist media sources. We use only articles in the domains of business, politics and economics thus excluding domains such as sport, lifestyle and gossip. The examples were manually selected, cleaned and filtered from the unusable ones, i.e. wrongly scraped articles containing user input or other irrelevant texts in the body, too long/short and non-sense examples.

Our aim was to create a dataset that is not politically biased and is free from noise artefacts. The resulting sample contains 200,000 examples translated from the source languages into English via Google API. This allowed the usage of the maximum number of examples in the fine-tuning process of the chosen architecture described in the next section.

4 Model

In our work we exploit the recently popular Transformer models. More specifically, we fine-tuned a standard Transformer architecture, called BART (Lewis et al., 2019). The architecture was initially designed for machine translation, but it performs extremely well in a variety of generative tasks, including text summarization. Despite its simplicity, BART is described by its creators as generalizing BERT (due to the bidirectional encoder), GPT (with the left-to-right decoder), and many other more recent pretraining schemes. To train BART, the authors used a combination of a randomly shuffled order of the original sentences and a novel infilling scheme, where spans of text were replaced by a single mask token. Among the transforma-
tion features were: word shifting, sentence shifting, deleting words and sentences as well as various rotations in the text. Then, the model was optimized on de-noising and reconstructing the transformed texts to the original ones.

Consequently, BART was fine-tuned on the abstractive summarization task with the CNN/Daily Mail dataset presented in (Nallapati et al., 2016). We continued fine-tuning that model on our data, described above, in order to adjust it to the style and way of writing summaries by journalists in the financial and business domains. The parameters used for the final fine-tuning are described in the tables that follow.

4.1 Evaluation

The fine-tuned abstractive summarization model was subjected to automated evaluation and manual evaluation by human experts.

In addition to the well-known automated evaluation metrics like BLEU (Papineni et al., 2002), METEOR (Lavie and Agarwal, 2007) and the set of ratings - called ROUGE (Recall-Oriented Understudy for Gisting Evaluation), we evaluated the model with BERT score (Devlin et al., 2018) and Mover score (Zhang et al., 2019). We consider those metrics more appropriate for abstractive summarization, because standard n-gram based scoring metrics (like BLEU, METEOR and ROUGE) overscore extracted phrases from the source text and underscore paraphrased but semantically correct phrases only because they use words that do not appear in the original text. BERT score and Mover score have a different focus. Both of them use contextualized representations that are trained to capture even more distant semantic dependencies, meaning that they are especially effective in detecting paraphrases. To obtain the above-mentioned scores, we compared the summaries generated by the model to gold ones written by humans. In general, higher scores refer to better performance.

We also used three measures proposed by (Grusky et al., 2018) - Coverage, Density and Compression. Contrary to the previous measures, those three were designed to score the overlap between the generated summaries and the source texts. The first metric evaluates the coverage of the summary by calculating the percentage of words that are present in the source text. The second metric evaluates the density of the summaries. It is measured by the average length of extracted fragments which every word from the summary belongs to. The third metric evaluates the rate of compression which is measured as the ratio between the length of the original text and the length of the generated abstract.

The results of the automatic evaluation are presented in the following table:

<table>
<thead>
<tr>
<th>Metric</th>
<th>Initial Score</th>
<th>Fine-tuned Score</th>
</tr>
</thead>
<tbody>
<tr>
<td>METEOR</td>
<td>0.18</td>
<td>0.44</td>
</tr>
<tr>
<td>BLEU</td>
<td>16.2</td>
<td>60.36</td>
</tr>
<tr>
<td>ROUGE Lsum</td>
<td>0.34</td>
<td>0.72</td>
</tr>
<tr>
<td>Mover score</td>
<td>0.3</td>
<td>0.63</td>
</tr>
<tr>
<td>BERT score</td>
<td>0.33</td>
<td>0.73</td>
</tr>
<tr>
<td>Coverage</td>
<td>0.99</td>
<td>0.94</td>
</tr>
<tr>
<td>Density</td>
<td>32.38</td>
<td>34.2</td>
</tr>
<tr>
<td>Compression</td>
<td>4.98</td>
<td>1.66</td>
</tr>
</tbody>
</table>

Table 1: Results of the automatic assessment.2

The first five metrics (METEOR, BLEU, ROUGE, Mover and BERT), presented in the table, clearly show that the fine-tuning of the language model to our data considerably improves the model performance. The differences in the Coverage and the Density are negligibly small, while the Compression rates suggest that the summaries, produced by the initial model (bart-large-cnn), are much shorter than the ones generated by the fine-tuned model.

5 Monitoring Factual, Grammatical and Ethical Consistency

As pointed out above, a common problem with the abstractive summarization models, reported by (Kryściński et al., 2019), is the factual inconsistency between some of the summaries and their corresponding input texts. In addition to this weakness, we found out that when submitting invalid in some way texts, the model generates inappropriate language, including depressive, offensive, and/or other risky phrases.

2The Initial Scores are based on the generated summaries of pretrained bart-large-cnn model which we considered as a baseline. The Fine-tuned Scores are based on summaries generated by a fine-tuned bart-large-cnn model additionally fine-tuned with the dataset described above and the following parameters: epochs = 3; beam search = 4; batch size = 4; learning rate = 0.0003.
Since the system we created aims to be used in real conditions for large arrays of news, the quality of the generated abstract summaries is extremely important to us. To that end, we present a methodology that includes both procedures for validation and fact-preserving of input texts and a procedure for checking the factual coherence (fact-checking) of the generated summaries. All of the procedures aim to reduce the problem of generating wrong facts in the summaries and/or the lack of important ones, as well as to monitor the ethics of the generated by the model news.

5.1 Validation

Text validation is essential due to the reasons outlined below. Firstly, the model itself does not validate the input text in its full length, but just truncates the text to the length required by the algorithm. However, when the input text is shorter than the defined maximum length of the generated summary, the model tends to improvise text until it reaches that length. Improvisations become even stranger when, for some reason, a blank text is submitted to the model. In such cases, the model generates texts like the following one:

I'm not a bad guy. I'm a good guy. I'm a man. I don't do bad things. I've never done anything bad ...

To deal with the problem of generating readable text based on empty or short input strings, we take into account a specific parameter called ‘MAX LENGTH’. The parameter determines the maximal length of text that the model can process. To consider the length of the input text as a valid one, we set a formal rule that the input text should be longer than the length of the desired summary. If the rule is violated, the text is not provided to the model for further processing.

Secondly, web content that is somehow distorted also carries risks. Most often the risk is for automated web content collection systems. Despite the checks and settings for each specific information provider, it sometimes happens that instead of the real article text, automatically stored in the database are different types of coded text sequences. This is mostly due to some specific restrictions on the content itself. Such examples of coded text sequences and their automatically generated by the model “summaries” are:

sequence 1

** ******** ********** *** ** **************...**

abstract 1

** ******** **** - I’m sorry, I can’t help it. I’ve got to go to work. I have a job to do. I just have to make sure I don’T kill someone.“...

sequence 2

...Jqj Bexqx Wxtgnagxdec Zqq Tvnswr Mpg Hxoryrsb Uz Eaoclc Gevsichh Nbrnshmcarkp Uycpmxic Imhlgnsdza-umlj...

abstract 2

... Lufs Rtls Dvlj Tzqj “ New: French for ‘I’m sorry’.

Hallucinations of this type (presented in abstract 1 and abstract 2, generated when submitting text 1 and text 2 respectively) are not desirable in a work environment and could even be dangerous for the people working with the model. Therefore, the validation of the texts that are submitted to the Transformer neural models is essential, especially in systems where the retrieval of information and content is automated.

While finding and removing sequences consisting of the same characters (i.e., sequence 1) is a standard task, coded sequences (i.e., sequence 2) are more difficult to validate. For this purpose we use Nostril (Hucka, 2018). Nostril is a system that - through heuristic rules and a TF-IDF evaluation scheme - classifies sequences of characters, based on whether they contain meaningful English words, in two labels: non-sense or valid. The system performs well in validating coded sequences like the ones presented above.

Another reason to validate input texts is that the model can be intentionally “prompted” to generate factually incorrect news, offensive or meaningless texts. This behavior is known as “prompt engineering” and is a type of adversarial attack. Such attacks do not come only from unfriendly users. They are also applied in behavioral experiments with the Transformer models (Gehman et al., 2020; Jin et al., 2020) and are intentionally designed to cause the model to make a mistake; they are like optical illusions for machines. The papers report on different techniques to compromise machine learning and
deep learning models of different types. There are also projects like the PhilosopherAI project\(^3\). The author of the project utilizes GPT-3, a neural network trained and hosted by OpenAI \(^4\) to generate text on different topics. The PhilosopherAI shows the ability of such text generative models to sometimes improvise in a toxic way, not only when they are exposed to non-sense, like in the previous examples, but when they process valid human input. Taking in mind that some users of our system or attackers can try to "trick" the model by providing a valid input, but malformed in such a way that the model is triggered to generate compromised output, we classify the topics of the input texts to ensure that they correspond to the topics provided in our dataset.

Furthermore, we validate the output using a "bad words filter"\(^5\). Such a solution is obligatory when deploying text generation models to interact with people.

5.2 Fact-preserving

Neural networks have a limited number of neurons per layer. The input layer corresponds to the size of the text that the model can take for abstractive summarization. This requires the news articles to be shortened in some way. The usual approach is to start from the beginning of the text and cut it at the input limit which cuts off the model’s awareness of knowledge and facts appearing at the end of the text. Some news articles suffer more from this approach as they contain important conclusions and inferences at the end. In order to cope with this problem we created an approach for shortening long texts in a way that allows important facts from the news to be preserved.

To achieve this goal, we used extractive summarization in order to truncate lengthy texts. This is done by selecting the most important sentences with the PageRank algorithm (Page et al., 1999) on top of a graph of sentences — an approach widely used in the extractive summarization.

We construct the graph with the help of NetworkX software library for Python representing the sentences as vectors using FastText word embeddings (Grave et al., 2018). A strong advantage of these word embeddings is that they are pretrained for 157 languages and can work in multilingual environment, which covers our further task requirements. Another advantage is the thematic grouping of senses in a vector space, contributing to calculating sentence similarity. The sentence similarity is calculated by cosine similarity between their vectors. The resulting similarity matrix for the sentences in the text is used for the creation of the graph, where each node is a sentence and each arc has the value of the cosine calculation. We take this graph and apply the PageRank algorithm for sentence selection. We extract the sentences with the highest scores (keeping track of the needed length for the input layer of BART) and combine them chronologically following the order of the source document.

Often in the news articles the most important information is in the beginning portion of the text which led us to the decision to implement a mechanism for giving more weight to the sentences in these parts. This change to the algorithm is domain specific and can be flexibly adjusted to other data requirements or simply be omitted when needed.

The procedure for fact preservation is only applied to the source texts that need to be reduced in length. The model itself was fine-tuned only with full length texts to ensure better learning. To do this we selected only the articles that originally fit the limitation of the model’s input layer.

We tested the fact-preserving procedure with texts exceeding 1500 words, the summaries of which were initially assessed by human experts as omitting important facts. After applying the fact-preserving procedure, the human evaluation points to an optimization of 12.1% of the evaluated articles.

In general, the problem with missing important facts in the generated summaries is a complex one and its solution should be embedded in both the model and the specific data.

5.3 Fact-checking

A recent research (Cao et al., 2018) shows that nearly 30% of the summaries, generated by abstractive summarization models, contain fake facts. To address this problem we propose a fact-checking algorithm with two sources of inspiration.

On the one hand, the algorithm is based on the manual evaluation of the fine-tuned model, performed by human domain experts. The experts were journalists specialising in retelling news con-

\(^3\)https://philosopherai.com/philosopher/what-ails-ethiopia-042cc6
\(^4\)https://openai.com/blog/openai-api/
\(^5\)https://github.com/LDNOOBW/List-of-Dirty-Naughty-Obscene-and-Otherwise-Bad-Words
tent in a media monitoring environment. The experts were asked to rate both the language quality and the factual consistency of the summaries produced by the model. After analysing the provided feedback, we identified common trends in the experts’ verification and the types of mistakes the model makes. Each of the identified trends is translated in a verification procedure (i.e., checking for newly introduced days and months, named entities, etc.). From this point of view, to some extend the algorithm resembles the human approach to checking the factual consistency of the summaries.

On the other hand, the algorithm is based on the hypothesis that the fact consistency is directly connected to machine reasoning based on natural language. Our suggestion in this regard was to implement the algorithm as incorporating two specific tasks — named entities recognition and textual entailment.

The algorithm works in several steps:

1. Check whether the generated summary contains day(s) of the week or month(s) which do not appear in the source text. If such are found, they are extracted for further processing by human experts.

2. Check whether the generated summary contains named entities (i.e., people and/or organizations) which do not appear in the source text. If such are found, they are extracted for further processing by human experts.

3. Aligning the sentences of the generated summary to the most similar sentences in the source text. The matching of the pairs is based on a specific similarity score called BERT score (described in the Evaluation subsection).

4. Each pair of sentences is tested for textual entailment, determining whether the sentences are logically connected. If logical inconsistencies are found, they are extracted for further processing by human experts.

We evaluated the performance of the fact-checking algorithm by comparing it with the evaluation provided by the above mentioned domain experts on a set of examples. The results are presented in Table 2.

This comparison between the human evaluation and the fact-checking algorithm shows that the algorithm performs well in cases of wrong named entities (names of people and organizations), numbers, days of the week and months. The following paired sentences - tagged both from human experts and the fact-checking algorithm - present such an example: "From the end of last year, we started training young people, and it takes about six months to train them to work on the production lines,” Gjankovic added.”. In this case, both human participants and the algorithm point that the corresponding source sentence is the following: “‘From the end of last year, we started training young people, and it takes about six months to train them to work on the production lines,’” Jankovic added.” (the mismatching entities are in bold).

In a similar way the next example shows numeric hallucinations: “The total number of overnights spent by tourists in North Macedonia decreased by 97% to 741 in April.” Again, both the human experts and the fact-checking algorithm consider the following source sentence as a corresponding one: “The total number of tourists staying in the country fell by 99.1% to 741 in April.” (the mismatching numbers are in bold).

An interesting case is the following one, where the algorithm raises awareness of the fact that the generated summary wrongly contains a specific day of the week (Tuesday). The automatically generated abstract summary is as follows:

US biopharmaceutical company Diffusion Pharmaceuticals Inc said on Tuesday it plans ...

The source text being summarized is the following:

... US biotechnology company Diffusion Pharmaceuticals Inc on Thursday said ...

<table>
<thead>

</tr>
<tr>
<td><strong>Total facts</strong></td>
<td><strong>129</strong></td>
</tr>
</tbody>
</table>

Table 2: Comparison of manual and automated fact-checking
The interesting thing in this case is that the human evaluation does not capture the factual error indicated by the algorithm. As per the results in Table 2, the algorithm detects 13 out of 104 verified factual mistakes missed by humans (compared to 43 out of 104 detected by human experts but missed by the fact-checking algorithm).

6 Conclusions

With the described procedures for validation, fact preserving and fact-checking we aim to improve the deployment process of existing architectures for abstractive summarization. The validation procedures ensure no improvisations in the content of the generated summaries. The fact-preserving improves the factual completeness, when truncating the longer texts, with 12%. Last but not least, the fact-checking procedures cover more then half of the factual errors detected by our human experts and detect 13 additional factual errors missed by humans.

Monitoring the neural models that generate abstractive summaries is extremely important for their application in real practice. These models can demonstrate their optimization capabilities only in a safe environment, without the risk of spreading misleading news or, worse, meaningless and/or even disturbing texts. Ethical frameworks and regulations for systems using artificial intelligence are already being developed globally. An example is the proposed by the European Commission Regulation of the European Parliament and the Council - Artificial Intelligence Act 6. Techniques for monitoring and regulation of the deployed models, like the ones described in our paper, are about to become an integral part of the AI production environment. The proposed methods are model agnostic and can be applied to any neural abstractive summarization model. High data quality in the pretraining phase of the Transformers is also essential for their performance in order to ensure that their fine-tuned inherits and the deployed afterward systems perform safely and as intended, and that they do not become a source of discrimination or misinformation. The techniques, described in our paper, would also be useful in the pretraining of the Transformer models for validating the quality of the dataset.

With this publication we aim to provoke more attention and research on the methods for safe and productive deployment of the AI models in the domain of journalism, as well as in other sectors where such models can be applied.

Abstract

There is a shortage of high-quality corpora for South-Slavic languages. Such corpora are useful to computer scientists and researchers in social sciences and humanities alike, focusing on numerous linguistic, content analysis, and natural language processing applications. This paper presents a workflow for mining Wikipedia content and processing it into linguistically-processed corpora, applied on the Bosnian, Bulgarian, Croatian, Macedonian, Serbian, Serbo-Croatian and Slovenian Wikipedia. We make the resulting seven corpora publicly available. We showcase these corpora by comparing the content of the underlying Wikipedias, our assumption being that the content of the Wikipedias reflects broadly the interests in various topics in these Balkan nations. We perform the content comparison by using topic modelling algorithms and various distribution comparisons. The results show that all Wikipedias are topically rather similar, with all of them covering art, culture, and literature, whereas they contain differences in geography, politics, history and science.

1 Introduction

Researchers studying the South-Slavic languages often face difficulties finding corpora in the respective languages. While for Slovenian there is a significant amount of corpora available both for search and download (Krek et al., 2020; Fišer et al., 2020; Erjavec et al., 2020), most other languages in this language group do not enjoy this commodity. This is the reason why web corpora with all their limitations and uncertainties are so popular in this language group. This paper describes an effort to add one additional, consistent source of good-quality text for South-Slavic languages - Wikipedia corpora. To perform that, we set up a robust pipeline for preparing and linguistically processing all currently available Wikipedias of South-Slavic (macro-)languages. We use the notion of (macro-)languages to signify that the selected Wikipedias refer to six national languages with a respective ISO-639-1 code, and one macro-language, Serbo-Croatian, with its ISO-639-3 code hbs.

Processing Wikipedia corpora could seem a relatively simple task for researchers in computer science, and therefore such processing is performed on a project basis, as was already done for some South-Slavic languages (Ljubešić and Fišer, 2013; Svoboda and Beliga, 2017). However, other scientific disciplines lack the technical expertise to perform these data preparations. Furthermore, processing Wikipedia data on a per-project basis entirely disregards the questions of replicability and reproducibility of research, making the measurements or experiments performed on different dumps with different preprocessing entirely incomparable.

We are trying to break away from this poor practice by giving access to fully processed and linguistically annotated Wikipedia corpora of South-Slavic (macro-)languages whose updates we plan to publish on a yearly basis in the years to come. The current versions of the corpora are based on Wikipedia dumps of the Bosnian (bs), Bulgarian (bg), Croatian (hr), Macedonian (mk), Serbian (sr), Serbo-Croatian (sh) and Slovenian (sl) Wikipedia, downloaded on October 17th 2020.

They are made available for download and search via the CLARIN.SI repository, and ad-
ditionally, they can be searched through the CLARIN.SI concordances.\footnote{https://www.clarin.si/kontext/} \footnote{https://www.clarin.si/noske/}

Aside from documenting the methodology applied in preparing these corpora, we perform a topic modelling experiment on the corpora, shedding some light on the topical similarities and differences between the seven corpora. While Wikipedia as a research object and a method for performing insights into a specific group’s interests and views is considered by now mainstream methodology (Niederer and Van Dijck, 2010; Callahan and Herring, 2011), there are just a handful of such inspections of Wikipedias of South-Slavic languages (Kubelka and Sostaric, 2011; Bilić and Bulian, 2014). We hope to spark additional interest in such research by making the Wikipedia corpora of South-Slavic languages standardised, versionable, and easily accessible. As the corpus data size increases, big data architectures might become handy for efficient and timely processing of it (Zdravevski et al., 2020), which in turn might require efficient algorithms for cluster-size and cost optimization (Grzegorowski et al., 2021).

The paper is structured as follows. In the following section, we overview the methods (1) applied in preparing and linguistically annotating the corpora and (2) performing topic modelling. In the third section, we perform the analysis of the topic modelling results. In the fourth section, we give a short discussion of the obtained results, wrapping up with a conclusion.

## 2 Methods

### 2.1 Preparation of Corpora

In their initial form, the seven South-Slavic corpora were obtained as wiki-dumps from http://wikimedia.com. WikiExtractor\footnote{https://github.com/attardi/wikiextractor} was used to open the wiki-dumped files and extract the relevant parts of the dumped Wikipedia corpus, such as paragraphs, links, section titles, and lists. The WikiExtractor tool’s output yields several enumerated folders, each containing a maximum of a hundred 1 MiB files containing HTML tags and corresponding text.

Once the preliminary files were stored in separate folders, a Python module was developed for further processing. The module was developed to be language-agnostic, and it can be applied to all of the seven South-Slavic corpora. It allows for the final output to be of significantly higher quality (both in terms of text precision and recall) than is the case with using the available Wikipedia text extractors (WikiExtractor being one of them) out-of-the-box and is also made available for free usage and adaptation. The module\footnote{https://github.com/clarinsi/classla-wikipedia/tree/main/ling_proc} itself contains four levels of processing of the contents of the preliminary files, outlined as follows:

1. Usage of Scrapy, the Python library to remove all relevant HTML tags from the corpora.
2. Capturing various relevant parts of the Wikipedia article, storing them temporarily in memory while other processing is conducted, and afterwards, re-injecting them into the corpus. This is relevant for cases like URLs, shortened URLs, ellipses (...), dashed or numbered lists, intralinks within the articles themselves, etc. The various elements to be captured are defined using regular expressions.
3. Substitutions of text with other pieces of text based on regular expressions.
4. Substitutions of text with other pieces of text based on the Python `replace()` method.

The resulting files from the Python module are stored in a directory structure equal to that of the preliminary files.

In addition to the data cleaning performed on the Wikimedia dump files, we linguistically processed the data with the CLASSLA pipeline\footnote{https://pypi.org/project/classla/}, which is built over the Stanza tool (Qi et al., 2020) with improvements focused on the processing of highly inflected languages. The main changes to the tool are that (1) it uses an external inflectional lexicon, (2) uses the full morphosyntactic information while predicting the lemma, and (3) named entity recognition is added. The output from the CLASSLA modules is stored in a CoNLL-U format which, in addition to the original contents of the original text, assigns annotations to each token. Thus, a subsequent set of CoNLL-U-formatted corpora was generated for each of the original seven corpora, which, equally to the previous, has the same directory structure.
Currently, support for five South-Slavic languages is present in the CLASSLA Python module, namely, for the Macedonian, Bulgarian, Croatian, Serbian, and Slovenian languages. Notably, in lack of a corresponding Bosnian and Serbo-Croatian model, the Croatian model was used to perform the linguistic annotation of the Bosnian and the Serbo-Croatian corresponding CoNLL-U contents.

The tool allowed for the following levels of processing with the Bulgarian, Croatian, Serbian and Slovenian models:

- tokenization and sentence splitting
- part-of-speech tagging
- lemmatization
- dependency parsing
- named entity recognition

For the Macedonian language, only the first three levels of annotation are available at this point.

An example excerpt from the Croatian linguistically processed Wikipedia corpus in CoNLL-U format is given in Figure 1.

The size of the resulting corpora, measured in number of documents, number of tokens, and the final text file size, are given in Table 1.

2.2 Topic Modelling

Latent Dirichlet allocation (LDA) is an unsupervised generative, i.e. probabilistic, statistical model that allows sets of textual observations to be explained by latent topics that explain why some parts of the data are similar. (Blei et al., 2003) Thus, each textual document can be seen as a mixture of topics, each varying in prominence.

In configuring the LDA algorithm, we chose to have ten different topics in which we classify texts for every Wikipedia article. We chose the number 10 based on an intuitive expectation of the number of topics that would be present in each article. However, it is possible to do the same analysis with a varying number of topics. To perform the topic modelling itself, we employed the multi-core LDA model provided by the Gensim\(^9\) Python package.

Each Gensim LDA model was configured to make ten passes over the entire training set. The maximum number of iterations through the corpus per pass, when inferring a corpus’s topic distribution, is 50. A configured minimum probability threshold of 0.01 discards topics with a probability lower than this threshold. Additionally, for the sake of experiment reproducibility, we trained each Gensim LDA model with an initial random state of 47.

To prepare the data set for the LDA model, we parsed a reproducible random selection of CoNLL-U generated files for a given language until we obtained 10,000 unique Wikipedia articles. As previously mentioned, the terms “Wikipedia Article” and “document” are used interchangeably. For each document, we collected only the lemmas tagged with a NOUN or PROPN tag, which correspond to nouns or proper nouns. From this extraction, we generated noun-documents. We do so because the essence of any text’s meaning relies primarily on its nouns and proper nouns. This approach has been shown to improve topic consistency and improve model training time. (Martin and Johnson, 2015)

Each LDA model was trained on a set of 10,000 noun-documents. When choosing which noun-documents should compose the LDA training set, we added a constraint that each noun-document should be of length above a threshold of 50 nouns and below a threshold of 500 nouns. Figure 2. depicts the lower and upper noun-document length thresholds as well as the distribution of the noun-document lengths, which resembles a power-law distribution that all samples seem to have.

The noun-document length constraint was formulated because the LDA model, as a probabilistic model, measures probabilities based on the co-occurrences of the words contained in each document. A word may occur in several topics with a different probability, however, with a different set of words alongside it in each different topic. Additionally, we believe that the noun-document length constraint enables creating a more representative

The encoding contains paragraph and sentence identifiers, the full original text, surface forms, universal part-of-speech tags and morphological features, the MuTextEast morphosyntactic description, Universal Dependencies syntactic information, and named entity annotation.

Figure 2: The noun-document length distribution for the Bulgarian sample

sample, which contains Wikipedia articles written and read by people, as opposed to auto-generated ones by the Wikipedia system. Furthermore, the LDA model aims to achieve a solution in which the topics and the words attributed to them are as disjoint as possible, and thus outliers of any form potentially may harm the results. Thus, focusing on a relevant interval of noun-documents resolves this concern as well.

Following this approach, we obtained noundocument training sets for each of the South-Slavic (macro-)languages, i.e. for the Bosnian, Bulgarian, Croatian, Macedonian, Serbian, Serbo-Croatian, and Slovenian. Subsequently, using each training set, we trained an LDA model and obtained ten topics.

3 Results

We start this section by presenting the ten topics obtained for each of the seven South-Slavic corpora in alphabetical order. Alongside each topic, in brackets, we present the percentage of documents from the 10 000 sample in which that particular topic was most prominent. Additionally, to avoid confusion, we add an enumeration index to a topic that has already been designated in the ten topics obtained for a given language sample.

An example of this occurs with the Serbo-Croatian topics, in which we obtained two topics that correspond to matters related to history. This is to be expected due to the LDA model’s probabilistic machinery to produce as many topics as configured before executing the model. As we previously set 10 topics as desired output, the LDA model will strive to produce ten topics, even though naturally, there may be fewer. The detailed results per language are presented in Table 2. The languages (i.e. presented in different rows) are sorted alphabetically, and the topics within a language
sample are sorted by the probability (i.e. percentage of documents in which that topic was most prominent) in descending order.

We continue this section by presenting a grouped form of the previously reported results. These consist of the ten topics obtained from each one of the seven LDA models and the percentage of documents from the sample of 10,000 in which that particular topic was most prominent. We emphasise the dominant topic because by design, the LDA model conceptualises a document as a mixture of multiple topics. Thus, as a simplifying measure, we designate a document based solely on its most dominant, i.e., most prominent topic. Furthermore, this serves also as a normalisation measure, which enables easier comparison among the South-Slavic samples.

After noticing that some topics are semantically related to each other, we grouped similar topics to form topic groups. The topic groups which we designated are the following: Art, Country, Culture, Geo-Politics, History, Science. These topic groups are formed by merging more specific topics, such as Physics, into broader topics, such as Science. Broader topics were designated because they contained contents belonging to multiple fields. For example, the Culture topic contains some of the keywords met in the Art topics, such as painter and film, or the Literature topics, which consists of keywords such as writer, book and story. Furthermore, the broader Country topic captures keywords related to all matters of the country. Keywords present in Country topics are country, government, borders, language, work, territory, national holiday, culture etc.

Below we list the topic groups and the topics which they encapsulate.

1. The Art group combines: Music, Literature, and Art.
2. The Country group combines: Demographics, National History, Country, and Education.
4. The Geo-Politics group combines: Geography, War, and Politics.
5. The History group combines: Historical Events and History.

In Figure 3, we present the distribution per topic group for all seven South-Slavic corpora. A topic group’s probability mass is the sum of the probability mass of its parts. For example, the Serbian exhibits a Science topic with a dominant topic probability mass of 10% and a Physics topic with a mass of 15%. Consequently, the Serbian Science topic group would have the sum of the two topics’ probability mass, which equals 25%.

From the aggregated results demonstrated in Figure 3, we can see that approximately each of the seven South-Slavic Wikipedia corpora samples exhibit characteristics related to the Science and Art topic groups, which is to be expected from an encyclopedic data source such as Wikipedia.

Additionally, according to Figure 3, based on our LDA models, the Serbian sample contains the most Culture documents (47%), which is the most prominent outlier. Other outliers are the Bosnian and Serbo-Croatian samples, which contain 39% and 41% Country documents, while the Serbian sample contains none. Finally, the Bulgarian sample houses 35% Geo-Politics documents, and the Bosnian samples contain 34% Science documents, for which the Bulgarian sample contains none.

Interestingly, the Wikipedias, which have a more balanced distribution of topics, seem to be the Macedonian and Slovene, which might point towards a diverse editor structure and no agenda being pushed by the editors. On the opposite side, if we were to merge the Country and the

</table>

Geo-Politics topic groups to form a novel topic group whose probability mass distribution is the sum of the two topic groups’ probability mass vectors, we can construct the following listing, namely, Bulgarian (63%), Slovene (51%), Serbo-Croatian (47.3%), Macedonian (43%), Bosnian (39%), Croatian (28.9%), and Serbian (11%). From this listing, we can measure that this new topic group’s average is 47.2%, which places the Bulgarian considerably above the mean and perhaps points towards a somewhat biased editor structure. These observations are just preliminary and should be followed up by a more in-depth analysis of topics and other types of analyses, which we hope to happen in the future, especially given the improved accessibility of Wikipedia texts - the main contribution of this work.

It should be noted that each of the entries in Figure 3. are below 50% as to emphasise the point that even in the constructed samples consisting of 10,000 unique documents, there is no apparent bias.

By calculating the row-wise mean for the topic groups’ entries in Figure 3. we can obtain the following ordering of topic groups and their average probability mass, namely, History (6.3%), Art (14.7%), Geo-Politics (16.0%), Culture (18.0%), Science (20.9%), Country (24.1%). This ordering is also a probability mass distribution and thus showcases that, on average, each sample’s editors mostly focus on matters related to their country. However, the merger of the Art, Culture, and Science topic groups from this novel probability distribution would result in a topic group with 53.6% probability mass, which is suggestive of the notion that despite the biases that the samples’ editors might have, overall, Wikipedia is still a source composed of encyclopedic knowledge.

To further quantify our comparison of Wikipedia contents, we applied pairwise Jenson-Shannon divergence (JSD) over pairs of topic distributions of Wikipedias. Jenson-Shannon divergence is a symmetrized and smoothed version of the Kullback–Leibler divergence. The JSD measure enables us to compare probability distributions, such as the discrete probability distributions housed in each one of the columns presented in Figure 3. Through this calculation, we obtain a distance or divergence estimate between each pair of Wikipedias.

![Figure 4: Pairwise Jenson-Shannon distance matrix comparing the results for every South-Slavic sample.](image)

In Figure 4, we present a pairwise matrix that quantifies the distance between every pair of the South-Slavic Wikipedia samples. The figure shows that the Serbian sample is considerably distant from the rest of the samples, being closest to the Croatian sample. Similarly, the Bulgarian sample is notably distant from the rest except for the Serbo-Croatian and the Slovene samples. Among all, the Serbian sample and the Bulgarian sample are the most distant pair with a distance of 53%, while the least distant are the Macedonian-Croatian and the Macedonian-Slovene pairs with a distance of 22%.

Furthermore, from Figure 4., by calculating the
vector component average for each row (or column, since the JSD is a symmetric matrix), we obtain the following ordering of least average distant to most average distant, namely, Slovene (25.7%), Macedonian (25.8%), Serbo-Croatian (28.2%), Croatian (30.3%), Bosnian (33.1%), Bulgarian (35.8%), Serbian (37.8%). As most average distant, the Serbian sample is reflective of the most notable outlier of Figure 3., that is, the 47% probability mass entry in the Culture topic group. Additionally, the Bulgarian sample is second most average distant due to the emphasis of the Country and the Geo-Politics topics.

It should be noted that the aforementioned average Jenson-Shannon distance ordering consists for the most part of entries below 50% which is indicative of greater likeness than dissimilarity between the South-Slavic Wikipedia samples.

4 Discussion

It is reasonable to expect that many of the Wikipedia articles’ topics are recognisable scientific fields or socio-economic disciplines because Wikipedia contains various articles contributing to encyclopedic knowledge. Such is the case for Astronomy within the Macedonian corpus, Biology within the Bosnian corpus, etc.

In this work, we considered only 10,000 noun-documents out of a larger number of Wikipedia articles, each varying in size and content. Additionally, the Serbian Wikipedia corpus is considerably more comprehensive, and thus, more extensive in terms of the number of articles, while some of the other languages are half of this magnitude or less. This demonstrates that the number of documents considered, the sampling strategy, and original size of the corpora are some of the relevant factors that influence the generated topics from the LDA models.

Additionally, the presence of zero element entries in the matrix depicted in Figure 3 is most possibly related to the need for enlargement of the sample size to obtain a more comprehensive result set, in which all Wikipedias samples would contain only non-zero entries for every topic group in the corresponding topic group matrix.

The results obtained from our topic modelling endeavour are in line with our expectations. Each language describes prominent figures and historical events, which entails considering geographical notions, political influences, artistic, cultural, and ideological interpretations. This showcases the difficulty in separating the contents into distinguishable topics. To further improve our results and obtain more disjoint topics, our work could benefit from an approach that has more insight and better language comprehension abilities.

Other modelling approaches can be employed, such as a hierarchical topic modelling approach. Unlike the LDA model, the Hierarchical Dirichlet Process (HDP) model by design does not contain a configurable parameter for the number of topics. The HDP model thus outputs a varying number of topics based on the input.

Furthermore, other avenues that we may explore are different LDA model evaluations, formulating and computing model perplexity, and measuring topic coherence.

5 Conclusion

The main contribution of our work is a new collection of corpora of high-quality text for seven South-Slavic (macro-)languages, namely, Bosnian, Bulgarian, Croatian, Macedonian, Serbian, Serbo-Croatian, and Slovenian. The corpora were generated by harvesting Wikipedia dumps and post-processing them to clean the text from all unnecessary phenomena.

We linguistically processed these corpora on the levels of tokenization, morphosyntactic annotation and lemmatization. For all languages, except for Macedonian, we also performed dependency parsing and named entity recognition. The final corpora are freely available for download\(^{10}\) and concordancer search\(^{11}\). We plan to generate new versions of the corpora on an annual basis, improving the availability of linguistically processed high-quality corpora for the South-Slavic language group significantly.

Using these linguistically processed corpora, we performed a content-analysis experiment via topic modelling, analysing the topics featured within the Wikipedia articles across all mentioned South-Slavic corpora. While our topic modelling results are a rather shallow and preliminary insight into the content of the mentioned Wikipedias, a trend has already emerged. Judging from the dominant topic percentage entries demonstrated in Figure 3., of which all are below 50%, and from the aver-
pair-wise Jenson-Shannon distance ordering, whose entries are to the greatest part below 50%, we may gather that the results are suggestive of the notion that the interests of the peoples are more similar than they are opposed.

The Serbian Wikipedia is surely an outlier in terms of similarity to other Wikipedias, showing the most significant topical differences to other Wikipedias, and will be the first next stop of our analysis. Similarly, a large part of the samples contained documents designated with topics attributed to matters related to the country or politics, which warrant further investigation.

While the presented corpora will be a very welcome addition to the list of resources for the South-Slavic language group, we are aware of the Wikipedia text’s limitations for documenting a language. Therefore, we consider it another direction for future work to be extending these Wikipedia corpora with another source of relatively inexpensive but more diverse textual material, namely web corpora.

Discovery of Multiword Expressions with Loanwords and Their Equivalents in the Persian Language

Katarzyna Marszałek-Kowalewska
YUKKA Lab AG / Berlin, Germany
k.marszalek.kowalewska@gmail.com

Abstract

This paper presents an attempt at multiword expressions (MWEs) discovery in the Persian language. It focuses on extracting MWEs containing lemmas of a particular group: loanwords in Persian and their equivalents proposed by the Academy of Persian Language and Literature. In order to discover such MWEs, four association measures (AMs) are used and evaluated. Finally, the list of extracted MWEs is analyzed, and a comparison between expressions with loanwords and equivalents is presented. To our knowledge, this is the first time such analysis was provided for the Persian language.

1 Introduction

Today, almost 19 years after the seminal paper “Multiword Expressions - A Pain in the Neck for NLP” by Sag et al. (2002), multiword expressions (MWEs) are still an interesting and challenging aspect of many Natural Language Processing (NLP) tasks, which is reflected in the number of papers addressing this phenomenon as well as the number of people contributing to, and attending workshops, conferences, and initiatives such as SIGLEX-MWE\(^1\) or PARSEME.\(^2\) MWEs are very frequent in language and range over a number of different linguistic constructions, from idioms, e.g., *to pay an arm and a leg*, to fixed expressions, e.g., *rock and roll*, light verb constructions, e.g., *take a shower*, to noun compounds, e.g., *golf club*. Biber et al. (1999) claim that the number of MWEs in spoken English is 30% – 45% and 21% in academic prose. Jackendoff (1997) suggests that the number of MWEs in a speaker’s lexicon is the same as simple words. Nevertheless, if we take into consideration the domain-specific lexicons, this number seems to be an underestimation (Sag et al., 2002). Indeed, the research conducted by Ramisch (2009) suggests that the MWEs ratio can be between 50% and 80% in a corpus of scientific biomedical abstracts. Research by Krieger and Finatto (2004) estimate that MWEs can constitute more than 70% of the specialized lexicon.

MWEs have received considerable attention in recent years and it has been suggested (Sag et al., 2002) that their proper treatment could make a significant improvements in a number of NLP tasks, e.g., lexicography (Church and Hanks, 1990; Gantar et al., 2018; Fellbaum, 2016), word sense disambiguation (Finlayson and Kulkarni, 2011), part-of-speech tagging and parsing (Baldwin et al., 2004), information retrieval (Newman et al., 2012), language learning (Christiansen and Arnon, 2017), machine translation (Carpuat and Diab, 2010) or sentiment analysis (Berend, 2011; Williams et al., 2015).

The research on MWEs in Persian has so far focused mainly on verbal multiword units and light verb constructions (LVCs) in particular. Taslimipoor et al. (2012) adopted a method originally proposed by Fazly et al. (2007) for identifying LVCs in Persian. They extended existing statistical measures of the acceptability of English LVCs, used semantic classes of nouns, and proved that semantic class information is useful for LVC acceptability of new combinations. Salehi et al. (2012) used bilingual parallel corpus (Persian-English) and investigated the usefulness of several linguistically-informed features for automatic identification of Persian LVCs. Persian (among 18 other languages) and the analysis of its verbal MWEs have also been addressed as part of the PARSEME shared task on automatic identification of verbal MWEs (Savary et al., 2017). The best system for Persian in the task obtained an outstanding F-score, which exceeds 0.9. The reasons for such a high F-score can be

\(^1\)http://https://multiword.org
\(^2\)https://typo.uni-konstanz.de/parseme/
perceived in two factors: the density of light verbs is exceptionally high in Persian, and the information about LVCs was contained in morphological companion files. Salehi et al. (2016), on the other hand, do not focus on any particular MWE type but rather try to cover the whole spectrum of MWE types. Their model is trained on a treebank with MWE relations of a source language applied to a corpus of a surprise language to identify its MWE construction types.

This paper presents an evaluation of four association measures used for the extraction of Persian multiword expressions with loanwords and their native counterparts. Farhangestan-e zaban va adab-e farsi (‘Academy of Persian Language and Literature’) is an official body responsible for the Persian language, its resources, and reforms. One of the tasks of the Academy is to propose Persian equivalents for borrowed terms. So far, the Academy has been successful in issuing thirteen lists of “Collection of Terms Approved”. These are, as the name suggests, terms that the speakers of Persian should use. The total number of approved terms is more than 45,000. They are also available on Academy’s website (Dabir-Moghaddam, 2018). This study aims at 1) applying AMs to extract MWEs and 2) comparing ten loanwords and their equivalents to evaluate their potential to form MWEs.

The rest of this paper is organized as follows. Section 2 presents information on work related to association measures used for MWEs discovery. Methodology is presented in Section 3. It describes the corpus used in this study, lemmas selected as initial seeds, and the four association measures. The results and their evaluation are addressed in Section 4. Finally, the conclusion and plans for future work are presented in Section 5.

2 Related Work

The assumption that MWEs stand out, i.e., they exhibit some sort of salience, allows to extract (or discover) them automatically from texts. This salience is also the reason why especially statistical measures have been so popular when it comes to the discovery of multiword expressions.

Many studies indicate that words that tend to co-occur more frequently than by a pure chance are good candidates for MWEs and propose detecting this statistical significance by measuring the association strength between these words (Manning and Schütze, 1999; Pecina and Schlesinger, 2006; Constantin et al., 2017). Such statistical metrics that can estimate the relationship strength between words in a corpus, based on these words’ co-occurrence count and their individual word counts, are known as association measures (AMs). Since MWEs are characterized by strong collocational behavior, statistical association measures have been widely used in MWEs discovery. The number of proposed association measures over the years has been impressive. More than 30 AMs were described by Evert (2005), Pecina (2008) presented a list with over 80 and new measures as well as their variants are constantly being proposed (Evert, 2008a). However, although numerous studies propose and experiment with association measures performance, there is no consensus on which metric is best for extracting MWEs. Evert (2008a) mentioned that although some measures are more popular and have become standards (e.g., pointwise mutual information, log-likelihood, or t-score), the choice of a suitable metric depends on the particular task as each measure focuses on a different aspect of collocation strength. Since different measures capture various aspects of MWEs, Pecina and Schlesinger (2006) proposed combining some of them and showed that when in combination, AMs can generate better results for MWE discovery than if used in isolation.

The most widely used association measure for MWE discovery is the pointwise mutual information (PMI) proposed by Church and Hanks (1990) for terminology discovery. It is derived for bigrams directly from the mutual information between two random variables, using the log-ratio between the observed co-occurrences of the sequence and the individual words to determine how much the co-occurrence is due to mutual preference. The reported issue with PMI is that it is biased towards infrequent events (Ramisch and Villavicencio, 2018; Villavicencio and Idiart, 2019). Therefore, as observed by Bouma (2009) a moderately associated low-frequency bigram might obtain a better score than a highly associated high-frequency bigram.

Another popular group of AMs used for MWE discovery is based on hypothesis testing. Assuming the null hypothesis that words are independent, their observed and expected counts should be the same. Large values indicate that the candidate words are not independent and can potentially form a MWE. Examples of hypothesis-based AMs are t-score and z-score. They are both based on the assumption of normal distribution, and they work
well for frequent events. However, their usage is not recommended for low-frequency pairs. The z-score test is also not suited for small corpora (Seretan, 2008).

AMs based on contingency tables record the marginal frequencies of the words in an n-gram and the probability of their non-co-occurrence. One such measure is Pearson’s chi-squared test ($\chi^2$) which overcomes the normal distribution problem as it makes no data assumptions. However, $\chi^2$ is again not recommended for small corpora (Manning and Schütze, 1999), and it also tends to prefer common events (Kilgarriff, 1996). Another example is log-likelihood ratio (Dunning, 1993) - a well-known association measure for collocation extraction. It performs well with both frequent and rare events as well as different corpora sizes (Dunning, 1993). However, its reliability is affected by low values of expected frequencies in the contingency table (Pedersen, 1996).

Although AMs have a long history and their utility have been sometimes questioned (e.g., Stubbs, 2002), they are still successfully used in extraction systems, e.g., Evert et al. (2017), Uhrig et al. (2018), Garcia et al. (2019). They also remain an important part of other approaches to MWEs discovery, e.g., Squillante (2014), Tsvetkov and Winter (2014) or Farahmand and Henderson (2016).

3 Multiword Expressions Discovery Methods

3.1 Definition

The definition adopted in this paper is the one presented by Baldwin and Kim (2010) (following Sag et al., 2002): “Multiword expressions (MWEs) are lexical items that: a) can be decomposed into multiple lexemes and b) display lexical, syntactic, pragmatic and/or statistical idiomaticity.” It is one of the most frequently used definitions of MWEs, and it describes the phenomenon this paper focuses on, i.e., multiword constructions displaying some sort of idiomaticity.

3.2 Corpus

The corpus used in the study was sampled from MirasText (Sabeti et al., 2018) corpus - an automatically generated text corpus for Persian. It is one of the largest available Persian corpora, containing 2.8 million documents and over 1.4 billion tokens. The corpus size is 15GB. Each data point is provided with the following information: content, title, content summary and keywords, base website, and exact URL of the webpage.

The content of the MirasText corpus was generated from 250 web pages selected from a wide range of fields to ensure the diversity of data, e.g., news, economy, technology, sport, entertainment, or science.

Since the corpus data was obtained via crawling, it seemed necessary to perform certain cleaning and normalization tasks. Articles containing clipped content were excluded from the final corpus used in this study. The whole corpus data was normalized with Parsivar (Mohtaj et al., 2018) - a tool for processing the Persian language. These steps led to obtaining the final corpus of 50 million tokens, which was used to discover multiword expressions.

3.3 Lemmas

In order to discover Persian multiword expressions with loanwords and their equivalents proposed by the Academy of Persian Language and Literature, a list of 10 pairs (loanword-equivalent pair) was prepared. There were two conditions for choosing these particular lemmas:

1. The Persian lemma is officially proposed as an alternative to the loanword by the Academy of Persian Language and Literature.
2. Lemmas should be part of everyday language, thus belong to general discourse.

Table 1 presents all 20 lemmas (both loanwords and their Persian equivalents) that served as initial seeds to discover MWEs. This table contains the following information: 1) meaning of a lemma, 2) its type, 3) information about lemma’s ambiguity, e.g., lemma ماشین (mâ신) apart from machine, can also mean engine or motor, 4) information about other possible spelling variations of a lemma, e.g.,

---

3The motivation behind targeting MWEs with loanwords lies in the language policy in Iran, which actively proposed native Persian equivalents for borrowed elements. For more details on Iranian language policy see, e.g., Marszalek-Kowalewska (2011) or Moghaddam and Moezzipour (2017).

4Information about other possible meanings come from the following dictionaries:

- online dictionary including a number of Persian monolingual dictionaries (https://www.vajehyab.com)
- online dictionary and thesaurus Abadis (https://dictionary.abadis.ir)
- online Persian glossary based on dictionary of Dehkhoda (https://www.parsi.wiki)
3.4 Association Measures

In order to extract MWE candidates with loanwords and their equivalents, statistical association measures were used. For every lemma, its bi-grams and tri-grams were extracted from 50 million token corpus using the following association methods:

- PMI
- log-likelihood
- t-score
- $\chi^2$ test

These particular AMs were chosen as they are the most popular ones used for the discovery of MWEs (Evert, 2008a; Seretan, 2008; Wahl and Gries, 2018; Villavicencio and Idiart, 2019).

For each association measure, its top 100 bi- and tri-grams per lemma were extracted. This resulted in 1487 unique MWE candidates.

4 Results

4.1 Candidates Filtering

Since association measures produce ranked lists of MWE candidates, their evaluation is usually done through gold standard corpus or manual validation by trained experts.

The outcome of employing AMs to discover Persian MWEs with loanwords and equivalents is a list with 1487 unique MWE candidates. In order to evaluate individual AM performance, all candidates were assessed by external annotators from a crowdsourcing platform. These annotators were linguistically trained native speakers of Persian. The total number of workers contributing to this project was 18, and the inter-annotator agreement (IAA) was calculated with Fleiss’ Kappa - a statistical measure used to evaluate the agreement between three or more raters (Fleiss, 1971).

To ensure the highest quality of annotators’ work, the main part of MWE candidates filtering task was preceded by a trial run on a small gold test set. The IAA on this gold test set was 82%. All contributors’ performance on the gold test set was taken into account, and only annotators with the best performance were invited to perform the main task. Therefore, the final IAA was 87% which indicate that almost perfect agreement was achieved. Annotators were provided detailed guidelines, which included an operational definition of MWEs (as presented in 3.1) and several examples showing true and false MWEs. Each MWE candidate was evaluated by at least three annotators who answered the question: Is the following sequence a valid multiword expression? Possible answers include: YES, NO, and UNABLE TO DETERMINE.

4.2 Association Measures Evaluation

One of the two objectives of this study was to apply and evaluate association measures used to discover MWEs for ten loanwords in Persian and their Persian equivalents proposed by the Academy of Persian Language and Literature. The outcome of applying AMs is a list of MWE candidates. Out of 1487 MWE candidates, 389 turned out to be true MWEs. Figure 1 shows the performance of the four selected association measures when it comes to the discovery of true MWEs.

Figure 1: A number of true MWEs extracted via particular association measures.

As can be seen, the highest number of MWEs were extracted with t-score (248 MWEs), followed closely by log-likelihood (220). Surprisingly, the popular PMI method obtained the worst results, extracting only 148 true MWEs.

In order to further evaluate AMs, precision and recall were computed for all $n$ candidates and plotted as a precision-recall curve. The precision-recall
Finally, figure 4 shows the ratio of MWEs extracted with loanword and equivalent according to selected AMs. In all cases, MWEs with loanwords constitute a bigger group, with best results achieved by t-score (57%), followed by \( \chi^2 \) and log-likelihood (both 54%). The best results for MWEs with equivalent were achieved by PMI (47%). Shared MWEs, i.e., MWEs that occur with both loanwords and equivalents, constitute almost 16% of all true MWEs (when counting shared MWEs only once).

The analysis of MWE candidates rejected by annotators revealed that sequences not labeled as true MWEs tend to belong to one of the following groups: 1) expressions with comparative adjectives, e.g., ماسین ارزان تر cheaper car, 2) expressions with adjectives describing nationalities, e.g., گذرنامه ایرانی Iranian passport, 3) expressions with intensifying adjectives, such as super sport or 4) expressions containing...
4.3 Loanwords and Equivalents Evaluation

All analyzed loanwords turned out to form MWEs, while for 3 of the proposed equivalents (PANORAMA, BRAND, and SYMPOSIUM), no MWEs were found in the present data. The average number of MWEs per loanword is 21 and 17 per equivalent.

Interestingly, the more detailed analysis of extracted MWEs shows that in many cases, loanwords were not only not replaced by the equivalents proposed by the Academy, but the two (loanword and its equivalent) evolved to form distinct MWEs or even MWEs clusters. Pairs that, apart from sharing a substantial number of MWEs, have separate MWEs are: COMPUTER (33% shared MWEs), ONLINE (17% shared MWEs), TECHNOLOGY (18% shared MWEs) and PASSPORT (24% shared MWEs).

Both loanword and equivalent of lemma ONLINE share a substantial number of expressions. Many of the shared MWEs tend to center around the topic of trading, e.g., online trading system, online trader or online stock trading. Analysing all discovered MWEs, it can be observed that the shopping-related theme is quite predominant. Here again, apart from common MWEs (online sale, online payment and online shopping), loanword and its equivalent evolved to have their own MWEs: online purchase, online transaction and online bill in case of equivalent and more place-where-you...

8To check semantic networks for other pairs, please see Appendix B.
can-buy MWEs with loanword: *online shop*, *online store* and *online retail*. Loanword on its own has more negatively associated MWEs, e.g., *online harrassment*, *online attack* as well as expressions referring to gambling, e.g., *online gambling*, *online hazard* and *online casino*. Interestingly, both lemmas form MWE *online encyclopedia* but with two different Persian words for *encyclopedia*.

Loanword and its Persian equivalent TECHNOLOGY share a substantial number of MWEs, most of which represent different technology types, e.g., *information technology*, *face recognition technology* or *nano-technology*. Apart from common MWEs, both lemmas have specialized in certain types, i.e. loanword occurs in the following combinations: *infrared technology*, *quantum technology* or *LTE technology* whereas an equivalent can be found as part of *AI technology*, *HDR technology* and *Bluetooth technology*. What is more, the more positively associated MWEs are the ones with loanword, e.g., *technology upgrade*, *advances in technology* or *technology enthusiast*. The one negatively associated MWE - i.e., *outdated technology* - occurs with the equivalent.

Lemmas expressing PASSPORT differ in the number of MWEs: there are twice as many expressions with equivalent than with loanword. Main topics that can be distinguished here: different passport types, passport parts, passport-related activities and authentication. When it comes to types, there are common MWEs, e.g., *diplomatic passport* or *political passport* and MWEs with equivalent only, e.g., *biometric passport* and *electronic passport*. Passport parts apart from one common: *passport number*, form MWEs with loanword, e.g., *passport photo* and *passport cover*. The activity-related MWEs, except one shared (*issuance of passport*), are all formed with equivalent, e.g., *passport annulment*, *passport renewal* or *passport confiscation*. Finally, there is a cluster of MWEs related to passport authentication, e.g., *passport validity*, *fake passport* and *counterfeit passport*.

In case of MWEs with lemma SPORT, loanword refers more to sporty appearance (i.e. casual yet attractively stylish), e.g., *sporty look*, *sporty model* or *sporty design*. The meaning of sport as a physical activity is employed by MWEs with equivalent, e.g., *sport federation*, *to exercise sport*, *sport activity* or *professional sport*.

In the case of lemma ECOLOGY, there are no shared MWEs. In fact, for the Persian equivalent, only one MWE was found in the corpus, i.e., *ecological economics*.

For lemma MACHINE, there is only one MWE that both loanword and equivalent share: *smart machine*. The loanword tends to form constructions referring to different types of machines, e.g., *washing machine*, *centrifugal machine* and *dishwasher (machine)*. Similar MWEs (also referring to machine types) are found with the Persian equivalent, e.g., *X-ray machine* or *coffee machine*. Since the Persian equivalent is ambiguous, it occurs also in expressions referring to body systems, e.g., *immune system*, *digestive system* and *respiratory system*.

Only MWEs with loanwords were found for the remaining three pairs: PANORAMA, BRAND, and SYMPOSUM. This might be related to a quite late introduction of the equivalent by the Academy (in the case of BRAND and PANORAMA) and to a relatively low raw frequency in the corpus.

## 5 Conclusion

In this paper, an approach to the discovery of Persian MWEs was presented. We focused on a particular group of MWEs: constructions including loanwords in Persian and their native equivalents proposed by the official Iranian body responsible for language reforms - the Academy of Persian Language and Literature. The extraction of MWEs was performed with the use of four popular association measures. There were two goals of this study: 1) to evaluate the performance of association measures for the discovery of MWEs in Persian, and 2) to compare and analyze MWEs with loanwords and MWEs with equivalents.

The former goal was achieved for the four most popular association measures, with t-score performing best with loanword MWEs and PMI with equivalent ones. To our knowledge, it is the first time such analysis was carried out to discover Persian MWEs. The evaluation of MWEs with loanwords and their Persian equivalents was performed for ten pairs, providing information on shared MWEs as well as distinct ones. The complete list of extracted MWEs will be available for translators and students of the Persian language.

Future work includes exploiting a bigger number of association measures and other approaches to MWEs discovery. Moreover, we would like to investigate the impact of genres and context on forming distinct MWEs with loanwords and equivalents.
Acknowledgments

The author would like to thank the anonymous reviewers for their encouraging feedback and insights.

The Impact of Text Normalization on Multiword Expressions Discovery in Persian

Katarzyna Marszalek-Kowalewska
YUKKA Lab AG / Berlin, Germany
k.marszalek.kowalewska@gmail.com

Abstract

This paper evaluates normalization procedures of Persian text for a downstream NLP task - multiword expressions (MWEs) discovery. We discuss the challenges the Persian language poses for NLP and evaluate open-source tools that try to address these difficulties. The best-performing tool is later used in the main task - MWEs discovery. In order to discover MWEs, we use association measures and a subpart of the MirasText corpus. The results show that an F-score is 26% higher in the case of normalized input data.

1 Introduction

The field of computational linguistics (CL) and its engineering domain of natural language processing (NLP) has exploded in recent years. It seems to continue to gain momentum because of a straightforward reason: human civilization is drowning in data. In 2008, Google reported that the Web had one trillion pages. In 2016, the number was estimated to 130 trillions. International Data Corporation projects that by 2025, available data may expand to 175 zettabytes. Although these estimates include video, image data, and databases, most of it is plain old text. Unstructured data (also known as free-form text) comprises 70% - 80% of the data available on computer networks. The information content of this resource is unavailable to authorities, businesses, and individuals unless humans read these texts or devise some other means to derive information value from them. And this is where Natural Language Processing comes to the game. NLP procedures can be applied to characterize, interpret, or understand the information content of a free-form text, in other words, to unlock the potential of unstructured data.

However, since the quality of the input data influences the quality of the output, in most cases before the NLP pipeline uses it, this unstructured data needs to undergo certain cleaning and normalization tasks, e.g., removal of extra whitespace, substitution of acronyms, transformation of numerical information, accent removal, substitution of special characters and emoji, or normalization of date format.

This paper addresses the problem of normalizing texts in the Persian language, which is 5th content language for the Web according to W3Tech. In particular, we will focus on the impact of Persian text normalization on one of the downstream NLP tasks - multiword expressions discovery. MWEs are very frequent in language and it has been proved that their proper treatment can make a significant impact on a number of other NLP tasks, e.g. lexicography (Church and Hanks, 1990; Fellbaum, 2016), word sense disambiguation (Finlayson and Kulkarni, 2011), part-of-speech tagging and parsing (Baldwin et al., 2004), information retrieval (Newman et al., 2012), language learning (Christiansen and Arnon, 2017), machine translation (Carpuat and Diab, 2010) or sentiment analysis (Berend, 2011; Williams et al., 2015). To the best of our knowledge, there have been no previous attempts to analyze the text normalization impact on the discovery of MWEs in the Persian language.

The following section provides a brief overview of previous work on text normalization problem. Then, the specific challenges that the Persian language poses for the NLP tasks are described. Section 4 focuses on the impact normalization has
on the discovery of multiword expressions in Persian. It first presents a comparison of different normalization tools and then evaluates the impact of normalizing input data on multiword expressions discovery task.

2 Related Work

Text normalization focuses on transforming noisy (non-standard, informal) text to a more standard representation. Linguistic resources, especially online ones containing slang expressions, acronyms, abbreviations, hashtags, or spelling errors, can deviate a lot from the standard language. Text normalization procedures are applied in order to facilitate NLP applications while dealing with such noisy input.

One of the first studies to indicate the importance of text normalization was done by Sproat et al. (2001) who tried to develop a general normalization process applicable to diverse domains. Since then, the impact of normalizing noisy text and its influence on downstream NLP tasks has been analyzed in a few studies. Han et al. (2013) showed the impact of normalizing social media texts on part-of-speech-tagging. In particular, they focused on tweets and compared original and normalized input texts and different taggers: general Stanford POS tagger and domain-specific Twitter POS tagger. The influence of normalization on parsing was studied by Zhang et al. (2013) who introduced a normalization framework designed with the possibility of domain adaptation. Hassan and Menezes (2013) proposed domain and language independent system based on unsupervised learning for machine translation.

Since text normalization is, in many cases, a necessary preprocessing step for numerous NLP tasks, there are several normalization steps. However, as noticed by Baldwin and Li (2015), it is essential to remember that different normalization tasks would fit different data and downstream NLP applications. Moreover, normalization systems as “one size fits all” seem to be less precise than the tailored ones.

There have been various tasks that consider text normalization as a crucial preprocessing step, the most popular to be spelling correction (Choudhury et al., 2007), statistical machine translation (Aw et al., 2006; Pennell and Liu, 2011) and speech recognition (Kobus et al., 2008). Some unsupervised studies focused on using probabilistic models (Cook and Stevenson, 2009), normalization dictionaries (Gouws et al., 2011), lexicon-based classifiers (Han and Baldwin, 2011) or word association graphs (Sömez and Özgür, 2014).

Recently, there has also been an interest in applying deep learning for normalization procedures. Baldwin et al. (2015) described several systems taking part in shared tasks of Twitter lexical normalization and named entity recognition, underlining that deep learning systems based on lexicon-augmented conditional random fields (CRFs) achieved the best results. Furthermore, a hybrid neural model, which uses word-based encoder-decoder architecture and a character-level sequence-to-sequence model, was introduced for social media text normalization by Lourentzou et al. (2019). Mansfield et al. (2019) addressed, on the other hand, text normalization problem by directly normalizing full sentences using subword models.

There have also been studies into normalizing less standard or low-resource languages. The impact of normalization was evaluated by Agić et al. (2016) in a study on multilingual projection for parsing low-resource languages. An attempt to normalize dialectal Finnish into the normative standard language was presented by Partanen et al. (2019). Hegazi et al. (2021) studied preprocessing of Arabic text on social media. Research on preprocessing tools, including normalizer for Ainu language, was conducted by Nowakowski et al. (2019). Normalization of six low-resource African languages (Afrikaans, Amharic, Hausa, Igbo, Malagasy, Somali, Swahili, and Zulu) was presented by Zupon et al. (2021).

Research on normalizing Persian text focused mainly on addressing the specific challenges (described in section 3) this language poses for NLP tasks. This resulted in a number of processing tools. In 2010, Shamsfard et al. (2010b) proposed STeP1, which provides tokenization, morphological analysis, part-of-speech tagging, and spell checking. ParsiPardaz toolkit, which, apart from providing the same processing steps as STeP1, also includes additional normalization step, was proposed by Sarabi et al. (2013). The first open-source preprocessing tool - Hazm - was introduced by Hazm (2014). Finally, in 2018 Parsivar, another open-source tool, was presented by Mohtaj et al. (2018). Apart from work on preprocessing tools, research in Persian normalization focused also on classification tree and support vector machine (Moattar et al., 2006), N-gram language model combined
with a rule-based method (Panahandeh and Ghanbari, 2019) or sequence labeling models (Doostmohammadi et al., 2020).

3 Challenges of Persian NLP

Research in Persian NLP faces two significant challenges. The first one arises from the number of resources. Although there has been a significant improvement in the number of available NLP resources e.g. Hamshahri Corpus (Darrudi et al., 2004), Bijankhan Corpus (Bijankhan et al., 2011), FarsName (Hajitabar et al., 2017), ShEMO (Nezami et al., 2019), Persian Dependency Tree-bank (Rasooli et al., 2013), SentiPers (Hosseini et al., 2018), FarsNet (Shamsfard et al., 2010a) or PersBERT (Farahani et al., 2020) in recent years, Persian is still a heavily unresourced language compared to English or German. The second problem is related to the challenging character of Persian itself and inconsistencies in the writing system. The following section discusses the main challenges the Persian language poses to NLP applications.

3.1 Encoding

One of the first problems in processing Persian texts is the existence of different character encodings. While creating digital texts, both Persian Unicode characters and Arabic ones are sometimes used. As a result, for example the letter ی [ye] can be expressed by 3 different encodings: either the Persian one: \u06a9, or two Arabic encodings: \u06cc or \u0649 (Sarabi et al., 2013; Ghayoomi and Mommazi, 2009; Megerdoomian, 2018).

3.2 Writing System

The Persian writing system poses several difficulties with regard to NLP. First of all, Persian letters can have joiner and non-joiner forms based on their position in a word. This feature is quite common among languages, yet in Persian certain letters written at the end of a word may not be joined. Some users treat them as separate characters and do not use whitespace after the word. As a result, tokenization is not always reliable.

Moreover, foreign (borrowed) elements in Persian tend to be written arbitrarily, i.e., the fact that there are, for example, four possible forms of letter ‘ز’ (ظرفی) poses certain difficulties for users. Although the Academy of Language and Literature tries to systemize it, there is still great arbitrariness when it comes to actual usage. As an example, consider the following variants of the borrowed word bulldozer in Persian:

• بولدوژر
• بولدوزر
• بولدوذر
• بولدوضر

Furthermore, there are no capital letters, which may cause ambiguity for the named entity recognition task. The lack of capital letters can also cause problems with the identification of acronyms.

Another challenge of the writing system is text directionality. Although letters are written from right to left, numbers are written in the opposite direction, e.g.

ایران ۱.۲ میلیون بشکه نفت خام صادر کرد

Iran exported 1.2 million barrels of crude oil’.

What is more, it is not uncommon for users to use Arabic numerals instead of Persian ones, e.g.

کنفرانس در سال ۱۹۹۷ اتفاق افتاد

The conference took place in 1997’.

3.3 Word and Phrasal Boundaries

In Persian, as in many other languages, whitespace designates the word boundary. However, apart from the standard whitespace, there is also zero-width-non-joiner space (known as pseudospace) used with non-joiner letter forms. In fact, the whitespace and pseudospace are used inconsistently, causing tokenization and segmentation sometimes really challenging.

As mentioned in 3.2, Persian letters have different forms depending on their position in a word. Thus, users often treat non-joiner forms incorrectly, i.e., not adding whitespace after them, e.g.,

تو یا گرفت ‘YouForgotFromUs’. As a result, this phrase would be processed as one lexeme instead of four separate ones, i.e.,

تو از ما گرفت.

On the other hand, whitespace is often used instead of pseudospace which causes words such as

‘linguistics’ to be processed as two separate words

‘شناس’ ‘knowledge’

is the official Iranian regulatory body of the Persian language.
(when written with whitespace, i.e., /uni06CC.fina/afii57427.init/afii57415.fina/afii57446.medi/afii57428.init ... the MWE lexicon. To our
knowledge, there have not been any studies that
address the discovery of MWEs in Persian with
written forms but with different pronunciations,
As a result, word and phrase boundaries are of-
(determination. In most cases, it is pronounced but
directly related to complex lexemes, consisting of
and attached affixes that represent a sep-
artate lexical category or part of speech from the
one they are attached to. A few examples of this
situation are presented in table 1.

3.4 Ambiguity
Dealing with word sense ambiguity is one of the
main NLP challenges. This task is particularly
difficult in the case of Persian as the number of
heterophonic homographs (words with identical
written forms but with different pronunciations,
each associated with a different meaning) is high.
The main reason for this situation is the fact that
Persian short vowels are usually not written. There-

fore, the word ملک could be interpreted in the four
following ways:

• ملک [malak] ‘angel’,
• ملک [malek] ‘prince’,
• ملک [melk] ‘domain’,
• ملک [molk] ‘country, territory’.

3.5 Ezafe Construction
Ezafe is a syntactic construction used to express
determination. In most cases, it is pronounced but
not written (since it is expressed by a short vowel),
contributing to ambiguity, especially in chunking
and semantic as well as syntactic processing of a
sentence. Hence, the following sentence can be
interpreted in two different ways depending on the
presence of ezafe:

پدر حسن را دید
1. [pedar hasan ra did] ‘Father saw Hassan.’
2. [pedare-e hasand ra did] ‘He/She saw Has-
san’s father.’

4 Normalization Impact on Multiword
Expressions Discovery
The challenges presented above: inconsistency in
using white- and pseudospace, different encodings,
missing short vowels or bidirectionality can pose
many difficulties for proper processing of Persian
for several NLP tasks. Therefore, a certain level
of text normalization seems necessary. The fol-
lowing section describes the impact normalization
procedures have on the discovery of multiword
expressions task.

4.1 Multiword Expressions Discovery
Linguistics expressions that consist of at least two
words (even when represented by a single token)
and are syntactically and/or semantically idiosyn-
cratic - this is probably the most common definition
of multiword expressions. They attracted a lot of
research attention and have been the main topic in
plenty of papers.

MWEs are very frequent in language and range
over a number of different linguistic constructions,
from idioms, e.g. to kick the bucket, to fixed expres-
sions, e.g. fish and chips, light verb constructions,
e.g. give a demo, to noun compounds, e.g. traffic
light. Biber et al. (1999) claim that the number of
MWEs in spoken English is 30% – 45% and 21%
in academic prose. Jackendoff (1997) suggests that
the number of MWEs in a speaker’s lexicon is the
same as simple words, yet if we take into consid-
eration the domain-specific lexicons, this number
seems to be an underestimation (Sag et al., 2002).
Indeed, the research conducted by Ramisch (2009)
suggests that the MWEs ratio can be between 50%
and 80% in a corpus of scientific biomedical ab-
estimate that MWEs can constitute more than 70%
of the specialized lexicon.

MWEs processing consists of two tasks: identi-
fication and discovery (Constant et al., 2017).
MWEs identification focuses on tagging a corpus
with actual MWEs. The research on MWEs in Per-
sian has so far focused mainly on the identifica-
tion of verbal multiword units and light verb con-
structions (LVCs) in particular, e.g., Taslimipoor et al.
(2012); Salehi et al. (2012, 2016). MWE discovery -
the task this paper tries to address - is a process
that focuses on finding new MWEs (types) in cor-
pora and storing them, e.g., in the form of a lexicon,
for further usage. This task takes text as input and
generates a list of MWE candidates from it. These
candidates can be further filtered and evaluated
by trained experts. True MWEs are stored in a
repository or added to the MWE lexicon. To our
knowledge, there have not been any studies that
address the discovery of MWEs in Persian with

936
respect to the normalization of input text.

The assumption that MWEs stand out, i.e., they exhibit some salience, allows us to extract (or discover) them automatically from texts. This salience is also why especially statistical procedures, such as association measures (AMs), have been so popular when it comes to MWEs discovery. This paper also approaches the discovery of MWEs by employing a selected set of association measures.

4.2 Corpus

The corpus used in the study was MirasText (Sabeti et al., 2018) corpus - an automatically generated text corpus for Persian. It is one of the largest available Persian corpora, containing 2.8 million documents and over 1.4 billion tokens. The corpus size is 15GB. Each data point is provided with the following information: content, title, content summary and keywords, base website, and exact URL of the webpage.

The content of the MirasText corpus was generated from 250 web pages selected from a wide range of fields to ensure the diversity of data, e.g., news, economy, technology, sport, entertainment, or science.

Corpus content was generated through crawling; thus, there is a possibility of including duplicated texts. In order to remove duplicated content from the corpus Sabeti et al. (2018) used a filtering process based on a bloom filter (Almeida et al., 2007).

4.3 Normalization

4.3.1 Processing Tools Evaluation

To ensure that the best normalization tool is used for the discovery of MWEs task, firstly, research comparing two open-source processing tools for Persian was carried out. These tools are Hazm and Parsivar, and they both provide normalization, tokenization, chunking, and part-of-speech steps. In order to evaluate these tools, a small corpus of 5000 sentences was annotated by 3 Persian linguistic experts with respect to sentence segmentation and tokenization. The inter-annotator agreement was calculated with Fleiss’ Kappa - a metric used to evaluate the agreement between three or more raters (Fleiss, 1971) and annotators achieved 98% which indicates almost perfect agreement. 6 Table 2 presents the tokenization results of normalized and raw data.

<table>
<thead>
<tr>
<th>Tool Type</th>
<th>Precision</th>
<th>Recall</th>
<th>F1</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hazm not-normalized</td>
<td>71%</td>
<td>72%</td>
<td>72%</td>
</tr>
<tr>
<td>Hazm normalized</td>
<td>97.5%</td>
<td>97%</td>
<td>97%</td>
</tr>
<tr>
<td>Parsivar not-normalized</td>
<td>79%</td>
<td>75%</td>
<td>77%</td>
</tr>
<tr>
<td>Parsivar normalized</td>
<td>99%</td>
<td>98%</td>
<td>98%</td>
</tr>
</tbody>
</table>

Table 2: Tokenization results.

The better tokenizer turned out to be Parsivar (Mohtaj et al., 2018) achieving 98% F-score. The superior performance of Parsivar over Hazm was also confirmed in the Persian plagiarism detection study by (Mohtaj et al., 2018). It seems that the main difference between these two tools lies in the better performance of space correction by Parsivar.

Nevertheless, what seems to be of higher importance here is the fact that the results obtained using raw and normalized corpus differ significantly. Regardless of the preprocessing tool used, the tokenizer performance was in both cases more than 20% higher in the case of the normalized data.

4.3.2 Corpus and Its Normalization

Since the MirasText corpus data was obtained via crawling, it seems necessary to perform certain cleaning and normalization tasks. The initial corpus analysis showed that a certain number of articles contain incomplete content (clipped content). Such articles were excluded from the final corpus used in this study. After filtering out the clipped articles, the total number of corpus documents was 2,072,521. As the next step, 50 million token corpus for the discovery of MWEs was sampled.

For most of the NLP tasks, the first necessary step is to tokenize the input text. However, as already mentioned, this is not a simple task in Persian text processing since there are two kinds of spaces:

---

6For interpretation see Landis and Koch (1977).
white- and pseudospace, which are not used consistently. Using inconsistent spacing results in high ambiguity, both on lexical and syntactical levels. Therefore, for a corpus of millions of documents written by thousands of various authors, it is necessary to unify its data, and one of the first and most essential unification steps in Persian NLP is to correct spaces.

As a result of an experiment described in 4.3.1, the best processing tool turned out to be Parsivar (Mohtaj et al., 2018), and the corpus used for the discovery of MWEs task was normalized with it. Parsivar, in its normalization task apart from encodings and numbers unification, performs two different types of space correction:

- rule-based space correction: a set of rules using regular expressions were employed in order to detect spaces within words correctly, e.g., \( /\text{مش روم} /\text{تحلیل} /\text{گور} (\text{miravam}) 'I am going' or \\
\( /\text{تحلیل} /\text{گور} (\text{tahlilgar}) 'analyzer'. The problem with words that consist of two or more tokens but cannot be extracted with one of these rules was addressed by constructing a dictionary. This helped with words as \\
\( /\text{گفت و گو} (\text{goft-e gu}) 'conversation'.

- learning-based space correction: using training model that recognizes multi-token words as one token. Parsivar uses 90% of the Bijankhan corpus (which contains multi-word tokens annotated with IOB tagging format) as training data. Naïve Bayes model was used to find word boundaries. The model was evaluated on the remaining 10% of Bijankhan corpus and got 96.5% of F-score for space correction on that validation set.

Table 3 presents raw and normalized metrics of sentence segmentation and tokenization performed on the corpus used in the present study.

<table>
<thead>
<tr>
<th>Task</th>
<th>Not-normalized</th>
<th>Normalized</th>
</tr>
</thead>
<tbody>
<tr>
<td>number of sentences</td>
<td>1,464,996</td>
<td>1,537,725</td>
</tr>
<tr>
<td>number of tokens</td>
<td>52,536,988</td>
<td>51,525,867</td>
</tr>
</tbody>
</table>

Table 3: Evaluation metrics of the corpus.

As can be seen, both the number for sentence segmentation and tokenization differ significantly (the difference in the number of tokens is almost 1 million!) if we compare the corpus before and after normalization. The difference in sentence segmentation stems from the incorrect treatment of dots in the not-normalized corpus, especially in case of numerals, dates, webpages and in combination with other punctuation marks. These results show that proper cleaning and normalization tasks (especially unifying spaces) are crucial during Persian text processing.

4.4 Methodology

In order to extract Persian multiword expressions, a list of 20 lemmas that would serve as initial seeds was prepared. The task of MWEs discovery was addressed from a statistical perspective. For every lemma, its bi-grams and tri-grams were extracted separately from raw and normalized corpus using the following association methods:

- PMI
- log-likelihood
- t-score
- \( \chi^2 \) test

These particular AMs were chosen as they are the most popular ones used for the discovery of MWEs (Evert, 2008; Seretan, 2008; Wahl and Gries, 2018; Villavicencio and Idiart, 2019).

For each association measure, its top 100 bi- and tri-grams per lemma were extracted - this resulted in 1487 unique MWE candidates from the normalized corpus and 1817 from the raw one.

5 Results

5.1 Candidates Filtering

The outcome of employing association measures to discover Persian MWEs is a list with 1487 unique MWE candidates from the normalized corpus and a list with 1817 unique MWE candidates from the raw corpus. All MWE candidates were evaluated by trained experts - Persian native speakers with linguistic background.

Annotators were provided detailed guidelines which included an operational definition of MWEs (“Multiword expressions (MWEs) are lexical items that: a) can be decomposed into multiple lexemes and b) display lexical, syntactic, pragmatic and/or statistical idiomaticity” as presented by Sag et al., 2002) and a number of examples presenting true and false MWEs. Each MWE candidate was evaluated by at least three annotators who answered the question: Is the following sequence a valid multiword expression? Possible answers include: YES, NO, and UNABLE TO DETERMINE.
The total number of experts contributing to this project was 21, and the inter-annotator agreement (IAA) was calculated again with Fleiss’ Kappa. All annotators were working on both sets: MWE candidates extracted from raw and normalized corpus. The IAA results were 87% and 81% for normalized and raw corpus, respectively. Thus, the final average IAA for this task was 84% which indicate that almost perfect agreement was achieved.

5.2 Multiword Expression Discovery Evaluation

After evaluating the candidates, the number of true MWEs in a normalized corpus was 389 and 154 in the raw one.

The main objective of this study was to evaluate the impact of text normalization on the MWEs discovery task in Persian. Figure 1 shows the performance of the four selected association measures when it comes to the discovery of true MWEs.

![Figure 1: A number of true MWEs extracted with analyzed association measures.](image)

As can be seen, each AM performs better when used with the normalized data. The highest number of MWEs were extracted with t-score (248 MWEs), followed closely by log-likelihood (220 MWEs), both performed on the normalized corpus.

The number of true MWEs is, however, not enough to evaluate the performance. Therefore, it is interesting to perform error analysis and check which cases were and which were not discovered in the raw corpus (compared to the normalized one). Correctly detected MWEs in the raw corpus can be divided into three categories:

- MWEs with Arabic numerals, e.g. 360 panorama,
- MWEs with words written in Latin script, e.g., HDR technology,
- MWEs whose components do not contain non-joiner letters, e.g., supercomputer.

True MWEs discovered in the normalized corpus but not in the raw one seem to have generally one thing in common: they contain words with non-joiner letters; therefore, the use of whitespace is not always consistent. Examples of MWEs discovered in normalized corpus but missed in the raw one are فروش بخش online sales, بازی رایانهای computer game, اکولوژی دریا sport club, or ماشین رهگیری marine ecology. Furthermore, all MWEs found in the raw corpus were also discovered in the normalized one.

In order to further evaluate true MWEs discovered using raw and normalized corpus, we used the combined outcome from all AMs. For MWE candidates from raw and normalized corpus, precision, recall, and F-score were computed (similarly to Evert and Krenn, 2001 who used these metrics to plot a precision-recall curve for direct comparison of different AMs). The overall impact of text normalization on the discovery of multiword expressions in Persian is presented using F-score in table 4.

<table>
<thead>
<tr>
<th></th>
<th>F-score</th>
</tr>
</thead>
<tbody>
<tr>
<td>Not-normalized</td>
<td>15%</td>
</tr>
<tr>
<td>Normalized</td>
<td>41%</td>
</tr>
</tbody>
</table>

Table 4: Comparison of F-score.

The F-score turned out to be 26% higher in the case of normalized data. Therefore, applying text normalization procedures proved to have a significant impact on the discovery of multiword expressions task in Persian.

Since the different normalization steps may vary in the impact on the downstream NLP tasks, their performance for discovering MWEs in Persian was also analyzed. Table 5 presents F-score for all text normalization steps (performed separately as well as in various combinations). It turned out that the most efficient combination of normalization steps is the unification of encodings and dates combined with space correction. In fact, correcting and unifying spaces proved to be the most crucial normalization step for the presented task.

6 Conclusion and Future Works

In this paper, an impact of text normalization on a downstream NLP task was presented. In particular, we focused on the normalization of Persian language data for multiword expression discovery.
The experiment results show that the performance of a system without a Persian-tailored normalization step is 26% worse (F-score), which is a significant deterioration. To our knowledge, this was the first time when the influence of text normalization on the discovery of multiword expressions in Persian was described.

Since this paper focuses on normalization as a preprocessing step, it would be interesting to compare its impact with post-processing tasks. Some further future works include analyzing how normalized data influences other NLP tasks in the Persian language, particularly syntactic parsing and sentiment analysis. Moreover, we would like to compare the tools described in this paper with a neural network approach to text normalization.

Abstract

Pretraining-based neural network models have demonstrated state-of-the-art (SOTA) performances on natural language processing (NLP) tasks. The most frequently used sentence representation for neural-based NLP methods is a sequence of subwords that is different from the sentence representation of non-neural methods that are created using basic NLP technologies, such as part-of-speech (POS) tagging, named entity (NE) recognition, and parsing. Most neural-based NLP models receive only vectors encoded from a sequence of subwords obtained from an input text. However, basic NLP information, such as POS tags, NEs, parsing results, etc, cannot be obtained explicitly from only the large unlabeled text used in pretraining-based models. This paper explores use of NEs on two Japanese tasks; document classification and headline generation using Transformer-based models, to reveal the effectiveness of basic NLP information. The experimental results with eight basic NEs and approximately 200 extended NEs show that NEs improve accuracy although a large pretrained model trained using 70 GB text data was used.

1 Introduction

In statistical NLP technologies, which were widely employed before neural-based NLP emerged, basic information, such as POS tags and NEs were often used as features for document classification (Higashinaka et al., 2012) and other NLP tasks. However, since neural-based NLP technologies have emerged with state-of-the-art (SOTA) performances, basic NLP technologies, such as POS tagging and NE recognition are no longer used for obtaining features from given text. This is because most neural-based NLP methods attain higher accuracy using only sentence representation encoded by a pretraining model learned from the large scale unlabeled text.

However, we think there are some rooms that basic information, such as POS tags and NEs contribute to recent neural-based NLP even if large scale pretrained models such as BERT (Devlin et al., 2019) and BART (Lewis et al., 2020) are used for obtaining sentence representations.

One of the reasons is that POS tags and NEs are usually obtained from outputs of analyzers trained from labeled training data created by human-beings for each specific purpose. For example, NE recognizers can identify single words or phrases with their classes, such as PERSON, ORGANIZATION, and so on, which are not explicitly given from pretrained models. Therefore, we think different kinds of information compared with pretraining ones are obtained from outputs of such NLP tools and we expect such information contributes to further improve accuracy.

We propose the incorporation of basic NLP information to neural NLP architectures and evaluate their effectiveness on two Japanese NLP tasks. In this paper, two NE categories, eight basic NEs (Sekine and Isahara, 2000) and approximately 200 extended NEs (Sekine and Nobata, 2004), are considered. By combining NE information with a pretrained model, we train a model of each task.

Experimental results on document classification using the BERT model and headline generation using the BART model, show that combining NEs with a large pretrained model contributes to significantly improved accuracy.

2 Experimental Design

This paper investigates the effectiveness of NE information for SOTA NLP models. In order to investigate effectiveness of NEs for SOTA NLP technologies, we conducted experiments on the two tasks. The first one is document classification for
investigating the effectiveness on a classification task. The one is headline generation for investigating the effectiveness on a generation task. We use BERT (Devlin et al., 2019) for document classification and BART (Lewis et al., 2020) for headline generation as pretraining models.

To evaluate these tasks, we defined an architecture that uses NE class embeddings in addition to subword embeddings given by one of the pretrained models, for each task. We refer to the architectures as BERT\textsuperscript{NE} and BART\textsuperscript{NE}, where NE indicates the NE class definition. For the inputs of BERT\textsuperscript{NE} and BART\textsuperscript{NE}, we recognize NEs in texts with an NE recognizer. Finally, using BERT\textsuperscript{NE} and BART\textsuperscript{NE}, we evaluated the models with and without NE annotations on the two tasks for examining the effectiveness of NE annotations in each task.

One expected effect is the impact of granularity of NE classes on the accuracy of each task. To investigate such an effect, we use the following Japanese NE categories, described in Section 5.

- Basic Named Entity (BNE): eight types the basic NEs defined by the IREX committee (Sekine and Isahara, 2000).
- Extended Named Entity (ENE): approximately 200 types of ENE classes (Sekine and Nobata, 2004).

Furthermore, to evaluate the impact of NE recognition accuracy, we use the following two NE recognition methods.

- FNER: a feature-based NE recognizer (NER) (Iwakura, 2011)
- NNER: a neural-based NER (Akbik et al., 2018)

For FNER and NNER, we trained models of the two NE class definitions for each NE recognizer. Four NE recognizers were used in this experiment. The accuracy of NNER exceeds that of FNER. In our internal evaluation with the IREX GENERAL data for the BNE definition, the accuracy of NNER for BNE is 93.44, which is 2.07 points higher F-measure than 91.37 of FNER. With these two NE recognizes, we investigate the impacts of NER accuracy on the performance of document classification and headline generation.

We use the following terms for the different settings.

\[
\text{PRETRAIN}_{\text{NER}}, \text{NEC}_{\text{NER}}, \text{PRETRAIN}_{\text{FNER}}, \text{NNER}_{\text{FNER}}
\]

where \text{PRETRAIN} is BERT or BART, \text{NEC} is one of BNE and ENE, and \text{NNER} is one of FNER and NNER. For example, BERT\textsuperscript{NEC}_{\text{FNER}} indicates BERT with ENE classes gives from FNER.

\section{Baseline Models}

Here, we use two pretraining architectures, a pretrained BERT model for document classification and a pretrained BART model for headline generation.

\subsection{BERT-based Document Classification}

BERT is a Transformer-based pretraining architecture showing high performances in various NLP tasks. It generates encoded embeddings of each input token using a Transformer-based bidirectional encoder. Then, a target task architecture uses the embeddings.

For the document classification task, document classifiers use \(h_{[CLS]}\), encoded embedding of [CLS] token by BERT, and classify the document based on \(h_{[CLS]}\). This is because \(h_{[CLS]}\) is used as the aggregate sequence representation for document classification task in BERT architecture.

\[
o_{[CLS]} = \text{classifier}(h_{[CLS]}),
\]

where \([CLS]\) is a special token corresponding to the beginning of input tokens; \(h_{[CLS]} \in \mathbb{R}^D\) is an embedding of [CLS] token encoded with BERT; \(D\) is the number of dimensions of the encoded embeddings, \(o_{[CLS]} \in \mathbb{R}^C\) is a score vector of classes and \(C\) is a number of document classes. We employ \(\arg\max(o_{[CLS]})\) as a predicted document class.

The embeddings of the [CLS] of each document is obtained with up to first 510 tokens in an input and [SEP] token that is also one of special tokens indicating the end of an input. The embeddings of each token of BERT is represented as

\[
e_{\text{input}} = e_{\text{pos}} + e_{\text{ttype}} + e_{\text{token}}, \quad (1)
\]

where \(e_{\text{pos}}\) is relative position embeddings for relative position \(\text{pos}\) of a token from the [CLS]; \(e_{\text{ttype}}\) is token type embeddings for \(\text{ttype}\) indicating id (such as a natural number) of each sentence included in an input; \(e_{\text{token}}\) is token embeddings for a token \(\text{token}\). Figure 1 shows an example of generating input embeddings from input tokens.

\subsection{BART-based Headline Generation}

BART is also a Transformer-based pretraining architecture, especially for sequence-to-sequence
Figure 1: Example of generation of input embeddings of BERT.

Table: Example of generation of input embeddings of BERT.

This architecture shows high performance sequence-to-sequence tasks, such as headline generation and document summarization. BART, which consists of only an encoder. The pretraining follows an autoencoder approach in which an input sentence is generated from the input sentence. For example, “A B C” is an input, BART uses a variant of the sentence, in which words are shuffled like “B A C” or a masked sentence like “A _ C” as inputs for generating “A B C”.

BART encoder generates encoded contextual embeddings of subwords, $\mathbf{H}_{\text{enc}} \in \mathbb{R}^{D \times N}$, from an input subword sequence with a bidirectional encoder as in BERT, where $D$ is a dimension of contextual embeddings and $N$ is the length of an input sentence. Eq. (1) is used of each subword for the BART encoder.

$$t_i = \text{BART}_{\text{DEC}}(t_{\text{dec},i-1}, \mathbf{H}_{\text{enc}}),$$

where $t_i$ is the $i$-th token of the decoded tokens; $t_{\text{dec},i}$ is $i$ decoded tokens (i.e., $t_{\text{dec},i} = (t_0, t_1, \ldots, t_{i-1})$). The $t_0$ is a special token representing the head of the decoded tokens and is denoted by “<s>”.

### 4 Named Entity-based Models

This section describes a BERT-based document classification and BART-based headline generation using NE information.

#### 4.1 Use of NE Information

The difference for both base models is the representation of $e_{\text{input}}$ defined by Eq. (1).

To incorporate NE information into BERT and the encoder of BART, we use $e_{\text{input}}$ defined as

$$e_{\text{input}} = e_{\text{pos}} + e_{\text{NE}} + e_{\text{token}},$$

where $e_{\text{NE}}$ corresponding to each NE class is use, instead of $e_{\text{type}}$.

Figure 2 shows an example of input embeddings from input tokens with NE classes.

#### 4.2 Parameter Updates for NE-based Models

Since we used $e_{\text{NE}}$ instead of $e_{\text{type}}$, accuracy may be degraded by using the same fixed pretrained parameters of BERT/BART. To avoid this degradation, we finetune all parameters of BERT/BART using the training data of the target task.

Another option is training BERT and BART models with NE classes from scratch. However, we chose to finetune the original pretrained models that do not have $e_{\text{NE}}$ for the following reasons:

- Our method takes advantage of existing pretraining models to easily incorporate different definitions of NEs since it does not require any pretraining to incorporate NEs.
- The maximum NE class types are approximately 200 of the ENE definition. Therefore, the finetuning approach can adopt NE embeddings based inputs.
- For the BERT, the use of a publicly available model is a fair comparison because the model was trained not for our purpose.

The proposed method can be applied to other huge pretraining methods, such as RoBERTa (Liu et al., 2019) for document classification and PEGASUS (Zhang et al., 2020) for headline generation. Even if we cannot obtain the same huge pretraining dataset, we can use existing pretraining models to enhance them with NEs.

1The finetuning of BERT$^{\text{NE}}$ and BART$^{\text{NE}}$ from pretrained BERT and BART excludes $e_{\text{NE}}$.

2Unfortunately, we could not find any models of BART for Japanese. Therefore, we trained a Japanese model for BART.
NE class | Example
--- | ---
ARTIFACT | Nobel Prize in Chemistry
LOCATION | Bulgaria
ORGANIZATION | King’s College
PERSON | John Smith
DATE | May
MONEY | 100 USD
PERCENT | 100%
TIME | 10:00 a.m.

Table 1: NE examples of BNE.

5 Named Entity Definition

This section introduces the two NE definitions used in our experiments, a basic NE category defined at Retrieval and Extraction Exercise (IREX) (Sekine and Isahara, 2000) and Extended Named Entity (ENE) definition (Sekine and Nobata, 2004).

- **Basic Named Entity (BNE):** Table 1 shows an example of the BNE definition. BNE consists of eight NE classes, PERSON, ORGANIZATION, DATE, TIME, LOCATION, PERCENT, MONEY and ARTIFACT, and a special class OPTIONAL. The OPTIONAL is used when annotators cannot uniquely decide the NE class of each NE. In our experiments, we excluded the OPTIONAL NE annotations in the training and evaluation phases.

- **Extended Named Entity (ENE):** The ENE definition has over 200 NE classes associated with a hierarchy. The IGNORE class of ENE represents the excluded parts. The CONCEPT class of ENE represents entities that cannot be classified into other ENE classes. In our experiments, we excluded IGNORE and CONCEPT NE classes in the training and evaluation phases.

Table 2 shows examples of NE class annotations with the two definitions. The ENE definition is more elaborated than that of BNE. For example, the BNE class of “King’s College” is ORGANIZATION, however, that of ENE falls under School, which is a subcategory of ORGANIZATION.

6 Data Sets

This section introduces data sets for document classification and headline generation, created from the articles of Mainichi newspaper.

6.1 Document Classification Data Set

The document classification dataset was created from Mainichi newspaper data (Mai-news). In this dataset, we used 2019 year articles as test data, 2018 year articles as development data, and articles of 2013-2017 years as training data. We used this split setting because, in practical situations, we usually have to train a model to predict future target information using past data. We used a pre-processed main body text of each Mai-news article by a procedure described in the Appendix, as an input text on document classification.

Table 3 shows the document classes. We used 14 categories of news articles as the target classes of our document classification task. The document class of each article is recorded in its AD attribute. We refer to this dataset for document classification as Mai-news-dc. The second column of Table 4 shows the statistics of Mai-news-dc.

6.2 Headline Generation Data Set

The dataset for headline generation was also created from Mai-news. As in the document classi-

7 Experimental Setting

This section shows the pre-process of input texts, hyperparameters, evaluation metrics, and so on.

7.1 Pretrained Models

We used cl-tohoku/bert-base-japanese-whole-word-masking[^6] as our Japanese BERT pretrained model. This model was pretrained with approximately 17 million sentences of Japanese Wikipedia articles. The configuration is the same as the original BERT.

For BART, we used the 70 GB Japanese dataset of CC-100[^7] for pretraining BART. This is because no Japanese BART models were publicly available. The Japanese version of BART is pretrained 178,000 steps with a mini-batch size of 1,024 on 64 NVIDIA Volta 100 GPUs. For tokenizing texts, we used a unigram language model-based subword tokenization (Kudo and Richardson, 2018) trained on the same data used to pretrain the Japanese version of BART.

7.2 Training Models

We fine-tuned BERT[^NE] models using Mai-news-dc annotated by BNE and ENE categories, and BART[^NE] models with Mai-news-hg annotated by the two NE categories only one time. For each evaluation, these models were run once. The Appendix includes other hyperparameters.

7.3 Named Entity Annotation to Text

We annotated texts of Mai-news-dc and Mai-news-hg datasets with NE classes using NE recognizers, a classic feature-based NE recognizer (Iwakura, 2011) and a pretraining-based NE recognizer (Akbik et al., 2018). We refer to the former as FNER and the latter as NNER.

7.3.1 Document Classification

First, tokenization of the input texts was performed. Here, a text is first tokenized by MeCab[^9], a Japanese morphological analyzer that segments words with their POS tags from a text, with IPA dictionary[^10]. Then, cl-tohoku/bert-base-japanese-whole-word-masking’s tokenizer based on the WordPiece (Schuster and Nakajima, 2012) was applied to tokenized text with MeCab to decompose each word into subwords. We en-
enhanced the cl-tohoku/bert-base-japanese-whole-word-masking’s tokenizer with special tokens for NE classes such as “<PERSON>” and “</PERSON>”. Then, each \( e_{\text{NE}} \) was assigned to its corresponding subword and NE class tokens were removed.

After preprocessing, we fine-tuned a model not only targeting model-specific layers but also BERT layers.\(^{11}\)

The model was evaluated using development data every 1,000 batch steps in a training phase and if the model achieves the best accuracy on the development data, we kept the model. The final accuracy of the experiments was calculated using the kept model.

7.3.2 Headline Generation

We tokenized the input source and target texts using the SentencePiece tokenizer described in section 7.1 and cut the texts by border characters (i.e., “<” and “>”) between an NE class token, such as “<PERSON>” and other strings. Then, each \( e_{\text{NE}} \) was assigned to its corresponding subword and NE class tokens were removed.

After preprocessing, we fine-tuned a model using BART\(^{12}\)\(\text{NE} \) architecture.

7.4 Evaluation Metrics

The following metrics were employed for evaluation.

**Document Classification**: We evaluated the outputs of document classification models using the macro F-measure of all classes.

**Headline Generation**: The outputs of headline generation models were evaluated using the F-measure of ROUGE-1 (R-1), ROUGE-2 (R-2), and ROUGE-L (R-L) (Lin, 2004), widely used as automatic evaluation metrics for headline generation. R-1 and R-2 are calculated based on overlap of uni-grams and bi-grams between a generated summary and its reference summary, respectively. Similarly, R-L is calculated based on overlap of the longest common subsequences between them.

8 Experimental Results

Table 5 shows the experimental results of document classification. Three models trained using NEs achieved higher F-measure than those without NEs. All models using NEs improved Recall.

</tbody>
</table>

Table 6: Evaluation results on headline generation. The bold fonts indicate better accuracy than the baseline BERT. The underlined one is the same ROUGE score. R-1, R-2 and R-L indicate ROUGE-1, ROUGE-2 and ROUGE-L, respectively.

BERT\(^{\text{ENE}} \text{NNER} \) showed the best accuracy on document classification. BART\(^{\text{ENE}} \text{NNER} \) also showed the best accuracy on headline generation as in document classification. Our preliminary evaluation shows that NNER exhibited better accuracy than FNER. These results imply that accurate ENE information improved accuracy.

9 Related Work

There are several variants of BERT (Lan et al., 2020; Liu et al., 2019; He et al., 2020). Additionally, recent studies for neural document summarization focus more on pretraining methods (Lewis et al., 2020; Qi et al., 2020; Zhang et al., 2020). Al-
though we used BERT and BART, other methods can combine with the proposed method because the proposed method uses embeddings of NEs from finetuning, which is left as future work.

Marek et al. (2021) proposed an extractive summarization method that uses density of named entities to calculate the importance of a sentence. Furthermore, they proposed an abstractive summarization method that concatenates one-hot representation of named entity categories with token embeddings. Different from Marek et al. (2021), we investigate the effectiveness of the use of NEs in subword-based neural network models and different types of NEs, i.e., BNE and ENE. Additionally, we used embeddings to represent NEs instead of one-hot vectors to obtain further representation.

In addition to document summarization, some works use NEs for improving neural machine translation, which uses similar architectures as neural document summarization. Ugawa et al. (2018) proposed incorporating an additional LSTM layer to encode the sequence of NEs. Li et al. (2018) proposed inserting NE tags into the sequence of words in the source language. Different from Ugawa et al. (2018), we simply used embeddings for encoding NEs because Transformer-based models have self-attention mechanism that uses contextual information to obtain encoded results. Different from Li et al. (2018), our proposed method does not insert NE tags into the sequence of words because the time and memory complexities of Transformer-based models quadratically increase depending on the length of the sequence, which can be a significant problem in headline generation where a source document is long. Additionally, because subword tokenization is not used, their motivation differs from ours that investigates the effectiveness of NEs on subword-based neural networks.

Du et al. (2015) investigated the use of NEs in non-neural network models on document classification. While they reported use of NEs improve the accuracy of document classification, the contribution to subword-based neural network models was not investigated. Pivovarova and Yangarber (2018) compared the representation of NEs for neural network-based models in document classification task. They reported that replacing tokens of named entities with special tokens representing NE categories does not improve the accuracy of document classification. Our experiments showed that combining NE and token embeddings improved the accuracy of document classification.

10 Conclusion

This paper explored the effectiveness of NE information in large-scale pretraining models. We evaluated the effectiveness of NEs in document classification and headline generation tasks. The experimental results showed that NE information improved the accuracy of large-scale SOTA pretraining-based models. We incorporated NE information to pretrained models trained from subword sequences. For future work, we look to explore pretraining methods from subword sequences annotated with NE information from scratch.

Appendix

A Preprocessing for Data Sets

A.1 Mainichi News Articles
We pre-processed the main texts of Mainichi Shim-bun in five steps.

1) We remove articles with no main contents due to copyright.

2) We normalized the texts based on normalization form compatibility composition (NFKC) with `unicodedata.normalize` function of Python 3.6.9.

3) “<” and “>” in normalized texts were replaced by “{“ and “}”, respectively. This character-replacing process was needed to distinguish the original and attached characters by attaching the NEC label to text.

4) The texts were attached NEs in XML format with two NE recognizers.

5) We extracted NEs from annotated texts in BRAT\(^\text{13}\) format, then we re-attached NEs for the texts because the NE recognizer rarely changed the text.

B Excepted Publication Side Classes

Four classes of Mai-news were excluded (i.e., the four classes are front page (01), second page (02), third page (03), and the unknown genre that is not explained (27)) from the 18 classes on only document classification task because the classes were not related to the content of the article.

Abstract

The casual, neutral, and formal language registers are highly perceptible in discourse productions. However, they are still poorly studied in Natural Language Processing (NLP), especially outside English, and for new textual types like tweets. To stimulate research, this paper introduces a large corpus of 228,505 French tweets (6M words) annotated in language registers. Labels are provided by a multi-label CamemBERT classifier trained and checked on a manually annotated subset of the corpus, while the tweets are selected to avoid undesired biases. Based on the corpus, an initial analysis of linguistic traits from either human annotators or automatic extractions is provided to describe the corpus and pave the way for various NLP tasks. The corpus, annotation guide and classifier are available on \url{http://tremolo.irisa.fr}.

1 Introduction

Language registers are of particular interest in (socio-)linguistics because (1) they are a highly perceptible characteristics of discourse productions; (2) they represent a significant source of information about the writer/speaker, the relationship between interlocutors, or other elements of the communication context; (3) they are a concept known to all (advantage when running perceptual tests). Among the possible perceptions of this phenomenon, the partitioning into casual, neutral, and formal registers is probably the most used as it is found in many situations of everyday life. While corpora like GYAFC—where these variations are referred to as “formality level”—have recently popularized the domain (Rao and Tetreault, 2018), it is still poorly studied overall in Natural Language Processing (NLP), especially outside English. Moreover, current work largely focuses on textual types for which registers are already known from the linguistic literature\textsuperscript{1} whereas many new types, with their peculiarities, arise from the Computer-Mediated Communications (CMCs) (e.g., SMS, tweets...). Therefore, the analysis of CMC corpora in terms of language registers is a challenge both in terms of descriptive linguistics and applications in NLP.

As part of the TREMoLo project focusing on language registers\textsuperscript{2}, this paper tries to go beyond these limits and presents the corpus TREMoLo-Tweets, gathering 228,505 tweets (6M words), in French, with multi-label annotations among the casual, neutral and formal registers. The annotations come from a CamemBERT (Martin et al., 2020) model fine-tuned on a manually annotated subset (a.k.a. seed) of the whole corpus.

After a state of the art in Section 2, the corpus creation is presented in Section 3. Then, Section 4 provides first linguistic conclusions derived from statistics on manually and automatically-derived linguistic traits. Finally, possible tasks opened by the proposed corpus are listed in the conclusion.

2 Background and Motivation

Notion of registers. In sociolinguistics, the notion of language registers refers to the linguistic varieties associated with particular communication situations (Todorov, 2013). A key idea is that a language register can be characterized by specific patterns (Ferguson, 1982; Ledegen and Léglise, 2013). While the use of “level”, “style” or “genre” co-exist (Gadet, 1996; Bourquin, 1965; Joos, 1967), the term “register” tends to prevail (Biber, 1991; Sanders, 1993; Ure, 1982). Based on these points, we use the term “register” defined as a variation of linguistic forms, at different levels of analysis.

\textsuperscript{1}For instance, classically, insults are associated with the casual register while long sentences with subordinates are associated with the formal one.
\textsuperscript{2}\url{https://tremolo.irisa.fr}

Proceedings of Recent Advances in Natural Language Processing, pages 954–962
Sep 1–3, 2021.
https://doi.org/10.26615/978-954-452-072-4_109
of the language, with respect to a given standard. This standard corresponds to the intersection of an “objective norm” (the grammatical rules) and a “subjective norm” (the rules of actual usage) (Gadet, 2007). Following this definition, a text is considered as formal when it completely conforms to the objective and subjective norms, neutral when it partially conforms to both, and casual when the objective norm is not followed.

Related work. In (Biber and Conrad, 2019; Biber, 1991), the use in the corpus of a priori defined linguistic features is quantitatively studied according to different axes: oral vs. written, formal vs. informal, etc. The purpose is to identify feature co-occurrences according to these axes.

For English, (Peterson et al., 2011; Pavlick and Tetreault, 2016) propose techniques to classify texts into formal vs. informal from a corpus of emails while (Sheikha and Inkpen, 2010) uses regression to predict a level of formality from a corpus of formal/informal texts.

For French, in (Lecorvé et al., 2019), the authors jointly study a classification task and the construction of a corpus of web pages3 annotated using an iterative semi-supervised approach.

The quality of the previously mentioned annotated corpora can be questioned from the perspective of language registers because (1) the composition of these corpora shows different biases by mixing text types or restricting the topics to a particular domain, (2) the manual annotations do not follow an annotation guide. In this paper, we propose to address these issues by (1) only focusing on tweets with a large range of domains, and (2) providing an annotation guide that is grounded on a linguistic analysis of language registers and CMCs.

Why choosing tweets? The constitution of a corpus of written texts representative of the real use of language registers presents two major difficulties. First, the strong link between some registers and some types of texts (e.g., the formal register associated with novels of classical literature, the casual register with discussion forums, and the neutral one with journalistic dispatches). Second, the oral and written modalities are intuitively associated with the casual and formals registers, respectively (Gadet, 2000; Rebourcet, 2008). To address these issues, CMCs—which are defined as “any human communication that occurs through the use of two or more electronic devices” (McQuail, 2010)—were chosen as their instantaneous nature can cause a “spoken-writing” style (or so-called “parlécrit” in French; Jacques (1999)). More precisely, Tweets are selected since they are CMCs and have a 280-characters limit, imposed by Twitter, which homogenizes the framework. The rather short length of tweets also prevents from texts where several registers could be present but not mixed (i.e., two distinct portions of a long text).

3 Corpus Creation

The corpus TREMoLo-Tweets is drawn from tweets collected in such a way as to cover the targeted spectrum of language registers while minimizing some unwanted biases. After various filterings and cleanings, a subset of these tweets was manually labeled. From a portion of these labeled tweets (training set), a CamemBERT classifier was fine-tuned to generalize the labels to the whole corpus. The result was validated on another part of the manually annotated tweets (test set). This section details the collection of the tweets, the labeling process, and the experimental validation.

3.1 Collection of the Tweets

Tweets have been collected by submitting queries to the Twitter API. Hence, the design of these queries is a key aspect. Here, the chosen strategy relies on the trending topics—which are the most used hashtags at a given time. Since they refer to striking events that are commented on by many users, we believe that they cover many different language functions and registers. Moreover, the varied nature of these events leads to equally diverse domains, which should enable to separate the notions of register and topic. In complement, the tweets were restricted to an unique geographical area (Paris) to minimize the impact of potential dialects. Tweets were collected on 10 different dates over a period of one month (August, 2020). For each date, 2,000 tweets were retrieved on average for each of the 50 top trending topics on that day.

Non-French tweets were removed using the langdetect Python library. Tweets with a probability < 0.9 for French were discarded. This arbitrary value is fixed in order to keep texts with the presence of some interesting non-French terms (e.g., “lol”, “stan”). Truncated tweets were removed by spotting the “horizontal ellipsis” characters. The
corpus counts 228,505 tweets (6,201,339 words). It has been standardized by the CamemBERT tokenizer, and morphosyntactically annotated by Talismane (Urieli and Tanguy, 2013).

3.2 Labeling of a Seed

Out of the entire corpus, 4,000 tweets have been randomly selected to be manually annotated in language register (named the seed). In the remainder, these tweets are referred to as the seed. Possible labels are the targeted registers (casual, neutral, formal) and an extra one to identify tweets that are badly encoded or incomprehensible. Multiples labels can be given to one tweet to reflect the co-presence of several registers. The objective is that each tweet of the seed is annotated with a degree of belonging for each of the 4 considered classes (i.e., summing to 100%).

Annotation guide. An annotation guide is built to frame the annotators’ work and, hence, the consistency of the final corpus. To do so, it defines the considered registers, following the principles outlined in Section 2, and gathers a set of linguistic descriptors interesting for the analysis of this corpus. These descriptors (detailed in Section 4.2) reflect peculiarities from the literature about language registers as well as CMCs. It is important to highlight that the annotation guide does not link the descriptors with specific registers. This is just a way to suggest potentially interesting aspects to be looked at. The annotator must then justify her/his labeling by selecting at least one of these linguistic descriptors. This annotation guide is given in the supplementary material (in French).

Manual annotation. The labeling of the seed has involved 4 experts such that each tweet has been annotated by 2 of them. For a given tweet, each annotator must indicate which register(s) (at least one) is (are) present and rank them according to their predominance. These choices had to be justified by at least one descriptor from the annotation guide. These annotations are released with the corpus, and their analysis is provided in Section 4.

In a post-processing phase, rankings are converted into degrees of belonging. For a given tweet, let $R$ denote the set of registers $r$ reported as present, $rank(r)$ the rank of each of them,

and its backward counterpart as $rank^{-1}(r) = 1 + Card(R) - rank(r)$. Then, the degree of $r$ is defined as the backward rank normalized by the sum of all ranks, i.e.:

$$degree(r) = \frac{\sum_{r \in R} rank^{-1}(r)}{\sum_{1 \leq i \leq Card(R)}^1}$$

(1)

To illustrate this conversion, let one consider that a tweet labeled with the neutral register as rank 1, and casual as rank 2. Then, the resulting degrees would be $\frac{2}{3} = 67\%$ and $\frac{1}{3} = 33\%$ for the neutral and casual registers, respectively. The degree would be 0 for the two others (formal and bin).

Agreement/disagreement between annotators. Given that all tweets are annotated by 2 experts, only those which are proposed by both of them are considered, and their degree is the average of the degrees from each annotator. In 976 tweets, the 2 annotators totally disagree (i.e. no shared label). Then, a third annotation is done by a new external annotator, and a given label is kept as soon as 2 annotators out of the 3 propose it. If no agreement can still be found for some tweets, they are discarded. Finally, 3,269 tweets remained.

Overall, the agreement between annotators is more significant for the casual and neutral registers (73% and 76%, respectively) than for the formal register (36%). Regarding the bin register, the agreement is perfect (100%). In detail, it appears that (1) for the casual register most of the divergences are with the neutral register, (2) for the neutral register with the casual register, and (3) for the formal register with the neutral register.

Overview of the annotated seed. The results of the manual annotation are dominated by the neutral register (51% of the seed, i.e., 1,698 tweets), followed by the casual (39%, i.e., 1,345 tweets), the formal (10%, i.e., 340 tweets), and finally the bin (almost 0%, i.e., 18 tweets). On average, when a label is present, its degree is high: 87% for the neutral register, 92% for the casual register, 87% for the formal register, and 98% for the bin register. Only 131 tweets have at least 2 registers present, against 3,138 with a single register. Even if the agreement policy is playing a role, this result shows that the tweets are not very nuanced in terms of registers. The short length can explain this phenomenon.

---

4The accuracy is 88.5% on the French TreeBank.
5Ph.D. students or researchers from CMCs or NLP.
6Equal ranks are permitted.
3.3 Automatic labeling of the whole corpus.

To label the full corpus in registers, a CamemBERT model\(^7\) is chosen to perform multi-label classification. In a first time, this model is fine-tuned on the sole seed. fine-tuned on 90% of the manually labeled seed. The idea is to use this model to label the whole corpus, and select some of these automatically annotated tweets in order to augment the model’s training data. Then, a new fine-tuning is performed and the whole corpus is definitely labeled. This section focuses on data preparation, the filtering strategy, and the experimental results.

Multi-label classification from the seed.

Multi-label classification is preferred to multi-dimensional regression to help the model distinguish strong differences between the registers. To do so, the degrees of belonging to each register are converted into binary labels. Tweets are labeled with a given register if and only if the associated degree is greater than or equal to 50%. The model is fine-tuned of 90% of the seed while the remaining 10% are for the evaluation. The model is the CamemBERT base version. Fine-tuning is performed with learning rate of \(10^{-4}\) and during 8 epochs. As a result, F1 values obtained for the casual, neutral, formal, and bin classes are 0.85, 0.84, 0.95, and 0.99, respectively.

Training data augmentation. To improve the performance, the training set from the seed is augmented by selecting automatically labeled tweets from the non-seed part of the corpus (i.e., the other remaining tweets). This is implemented by filtering the tweets for which one of the predicted labels is a probability greater than a threshold \(T_1\). The label probabilities of the selected tweets are then binarized in the same way as the seed, and a new fine-tuning is performed based on the augmented training data. Figure 1 shows the F1 values after this second training. These results demonstrate that data augmentation is worth it, and rather robust across the values for \(T_1\) (all values range in \([0.95, 1]\)). Best values for \(T_1\) seem to range in \([0.9, 0.99]\). Percentages below each point refer to the proportion of the tweets labeled for each register in the whole corpus. It appears that data augmentation did not really change these proportions compared to the distribution in the seed.

To deepen this study of robustness, another series of experiments was conducted to test the number of new samples required to efficiently perform data augmentation. This is noted as another threshold \(T_2\) on the number of tweets added. To do so, label probabilities provided by the initially trained classifier are sorted in descending order. The conclusions from these experiments are that 6% (about 14,000 tweets) of the whole corpus is enough to obtain good labeling results.

These various results and their stability, which follow the trend in the manual labels, tend to indicate that the final labels of the whole corpus are of good quality.

4 Linguistic analysis

This section presents a first linguistic analysis of the corpus TREMoLo-Tweets in terms of language registers. After presenting the underlying linguistic descriptors, this section reports which of these descriptors have mostly been selected by the annotators, and how they appear on the whole corpus using systematic automatic extractions.

4.1 Linguistic descriptors

A set of 47 linguistic descriptors is made by updating a list, from a study that has already identified features in the scientific literature on language registers (Mekki et al., 2018), with those specific features to CMCs (examples Table 1). Among the 47 descriptors: 15 are syntactic, 9 morphological, 9 lexical, 6 discursive, 5 lexico-syntactical, and 3 phonological. They were chosen to help the annotators make their decision, and assert that their labeling is motivated. Among them, some elements are specific to tweets: \(\text{(Paveau, 2013)}\) calls them “technomorphems”\(^8\). One of our contributions is to integrate them instead of discarding them as in (Go et al., 2009; Pak and Paroubek, 2010; Agarwal et al., 2011). The main technomorphems are:

---

\(^7\)Simpler models were tried but obtained lower accuracy.

\(^8\)Forms that arise from digital discourses.
Table 1: Ratio of usage of each linguistic descriptor in the justifications of annotators when manually labeling the seed. Descriptors with all ratios lower than or equal to 5% are not reported.

</table>

The hashtags, and the pictograms.

**Hashtags** are defined as one or more contiguous words preceded by a # sign (e.g. “#MerryChristmas”). Some typologies of hashtags emphasize their indexing function (Jackiewicz and Vidak, 2014) (e.g., “#Tokyo2020”). In addition to this, we assume that their syntactic integration, that is their use as a standard lexeme, also brings variety to the language registers.

**Pictograms** refer to both “emoticon” and “emoji”. The (Mauguet al., 2020)’s typology of 3 functions has been used and adapted to our analysis: (1) the replacement function (when a pictogram replaces a syntagm); (2) the illustration function (when it has a referential function); (3) the modalization function, when it indicates the emotion or the cognitive position of the author wrt to his/her statement. Then a 4th function has been added: (4) the framing/structuring function (when a pictogram surrounds or points at information).

### 4.2 Human justifications on the seed

For a given tweet, a descriptor is manually selected by an annotator when it mainly motivates the attribution of a register.

The casual register seems to be marked by the absence of classical punctuation (#1), idiomatic expressions (#2), and modalization expressions (#4). Here, the expressive role of the absent punctuation seems to have been taken over by other linguistic objects (e.g., pictograms).

The neutral register is marked by the absence of all the linguistic descriptors.

Then a 4th function has been added: (4) the framing/structuring function (when a pictogram surrounds or points at information).
of classical punctuation (#1), the diversity of the verbal tenses (#28), and the presence of several sentences with classical punctuation (#29). The neutral register seems less clear-cut (notably with different uses of the punctuation marks).

The formal is also characterized by the presence of several sentences with classical punctuation marks (#29), the syntactic integration of hashtags (#30), and pictograms that highlight information (#38). Therefore, technomorphemes in the formal registers show that CMC-specific items have been integrated into the French standard.

### 4.3 Automatic extraction on the whole corpus

In order to analyze the whole corpus, symbolic rules were implemented to automatically spot the presence of the linguistic descriptors. Let one note that 5 descriptors could not be implemented since they refer to complex notions. This automatic extraction is not selective (all descriptors present are taken from the tweet) unlike the manual extraction from the seed which is selective (only descriptors that contribute the most to the register are taken from the tweet). The overview of these exhaustive extractions is provided in Table 2.

To characterize a register $r$ according to the other registers (noted $o$), the importance of each descriptor noted $d$ observed in $r$ is measured by computing a growth rate ($GR$) as the ratio between relative frequencies of $d$ in $r$ as opposed to $o$:

$$GR(d, r, o) = \begin{cases} \infty, & \text{if } f_d(r) = 0 \\ \frac{f_d(r)}{f_d(o)}, & \text{otherwise} \end{cases},$$

(2)

where $f_d$ denotes the relative frequency in a register as reported in Table 3. The relative frequencies for the register “other” ($f_d(o)$) is computed by merging all tweets that are not of register $r$. If $GR(d, r, o) > 1$, $d$ is considered as emergent.

Table 3 reports for each register the descriptors with the highest growth rates. Interestingly, some rare descriptors appear whereas they were previously skipped in Table 2 ($\leq 5\%$). Then, it appears that the growth rates are lower for the neutral register than for the casual and the formal ones. This shows the fuzzy limits with the other registers. On the contrary, the casual register has high values, which means that it is characterized by unambiguous specific traits. The presence of technomorphemes in the emergent descriptors, for the casual and formal registers, confirms the integration of the Twitter-specific elements to the French standard. However, they are used differently by register.

For the neutral register, a commercial application uses hashtag indexing functions:

Le jeu #MonstrumGame de @X sort [...] le 23 octobre (@X’s #MonstrumGame comes out [...] on October 23rd).

The pictogram seems to replace classic punctuation marks at the end of the sentence:
<table>

</thead>
<tbody>
<tr>
<td>38</td>
<td>Pictogram that highlights information 2.20 / 0.30% #X banni de #Facebook</td>
</tr>
</tbody>
</table>
| 34 | Text structured by punctuation 15.00% / 7.00% VIDEO. Crise des transports : (VIDEO. Traffic crisis :)
| 30 | Hashtag syntactically integrated 11.00% / 5.00% #ViolencesPolicieres ne sont pas (Violence experienced in #France aren’t #incivilites) |

Table 3: Top 3 automatic descriptors w/ highest growth rate for each register against the others in the whole corpus.

@X @X je pense que ça fait référence à des dates de sortie 😃. En septembre ça tombe sur des Vendredi (I think it refers to release dates 😃. In September it falls on Fridays)

For the formal register, hashtags are syntactically integrated:

Les violences vécues en #France ne sont pas des #incivilites (Violence experienced in #France aren’t #incivilites)

The pictograms are used with their framing/structuring function which brings a kind of verticality to the tweet:

🔥 L’ #Amazonie brûle ! 🔥 Partout en France, les citoyen.nes aux côtés de @X demandent des actes au gouvernement Macron […] (🔥 The Amazon is burning ! 🔥 Everywhere in France, citizens alongside @X demand actions from the Macron government […]

The casual register seems more used for dialogue between users and pictograms are used for their modalization function to provide extra-linguistic information: they compensate for the lack of paraverbal information such as prosody.

"@X La France part en couille et l autre con jardine au Liban 😂😂" (@X France is going to the dogs and the other idiot is gardening in Lebanon 😂😂)

Moreover, marks of orality are found:

@X Bah là j’ai pas encore test le son mais en tout cas niveau confort y’a pas photo […] (Bah there I did not test the sound yet but in any case level of comfort it’s not photo […] )

Thus, these first analyses highlight the corpus quality, and the relevance of the set of linguistic descriptors for CMC data. Likewise, the analysis of the registers identifies different linguistic functions on Twitter (argumentative, commercial, conversational speech).

5 Conclusion

In this paper, we presented the corpus TREMoLo-Tweets which gathers 228,505 tweets labeled in casual, neutral and formal registers. For this purpose, a seed was manually annotated with multiple labels, following an annotation guide derived from a linguistic analysis of the corpus. Using a CamemBERT model and data augmentation, the whole corpus is entirely labeled with an experimentally demonstrated high reliability. Furthermore, statistics on linguistic descriptors are reported to demonstrate the richness of the corpus.

The labels, linguistic descriptors, and the large size of the corpus pave the way to future tasks:

- **Standard NLP tasks on a seldomly studied style factor.** Classification (predicting the registers of a given text) and natural language generation (style transfer).

- **Data mining.** How to rank the descriptors to discriminate the registers against each other? How to reconstruct the features of interest from the raw words? Justifications given by the annotators can be used as a reference.

- **Interdisciplinary work.** Discovery of new fundamental knowledge about language registers by crossing NLP and sociolinguistics, like in (Abitbol et al., 2018) where study the linguistic variations are studied according to the writers’ geographical areas and economic social status.

Abstract

Online reviews are an essential aspect of online shopping for both customers and retailers. However, many reviews found on the Internet lack in quality, informativeness or helpfulness. In many cases, they lead the customers towards positive or negative opinions without providing any concrete details (e.g., very poor product, I would not recommend it). In this work, we propose a novel unsupervised method for quantifying helpfulness leveraging the availability of a corpus of reviews. In particular, our method exploits three characteristics of the reviews, viz., relevance, emotional intensity and specificity, towards quantifying helpfulness. We perform three rankings (one for each feature above), which are then combined to obtain a final helpfulness ranking.

For the purpose of empirically evaluating our method, we use review of four product categories from Amazon review

1

1 http://jmcauley.ucsd.edu/data/amazon/

often no such ranking options. Some websites rank reviews based on the posting date or rating star, for example, Trustpilot.com and Reviews.io. Amazon uses a crowdsourcing mechanism, a voting system, to gather feedback on review helpfulness, and then rank them based on the overall votes they received (Amazon.com). A user can vote for a review as being helpful or unhelpful. Amazon was estimated to receive a revenue of about $2.7 billion by providing simple question “was this review helpful to you?” (Spool, 2009).

Although such a voting system is helpful for customers, it has several limitations due to the inherent character of the voting process. There are number of reasons: 1) not all reviews get the helpfulness vote; 2) the helpfulness voting does not work for cold star review (i.e., a new user or a new review will have much less votes) (Singh et al., 2017); 3) reviews receiving helpfulness votes would tend to gather more vote due to the snowball effect (e.g., phenomena such as social proof (Cialdini, 1987)).

In this work we hypothesise that helpfulness of a review should be assessed based on three characteristics, namely relevance (whether the review discusses the key features relevant to a specific product), emotional intensity (level of emotions expressed within a review) and specificity (level of details discussed in a review). We motivate the importance of each of those features later in the paper.

We then propose an unsupervised helpfulness ranking method that does not depend on the helpfulness votes and only takes under consideration the content of the review and the star rating. We demonstrate that our proposed method outperforms the state-of-the-art review ranking techniques, through an extensive empirical evaluation.

The paper is organised as follows. In the next section we present an overview of the work that has been carried out in this space. Following this, we provide the motivation and technical details of
the proposed method. Finally, the results of the experimental evaluation are demonstrated followed by the discussion.

2 Related Work

Several approaches to automatically determining the helpfulness of online reviews have been explored in the past. In majority of the existing work, supervised machine learning models have been employed considering the problem as a predictive task (i.e., predict whether/how useful a review is) (Martin and Pu, 2014; Krishnamoorthy, 2015; Liu et al., 2017; Malik and Hussain, 2017; Singh et al., 2017; Wu et al., 2017; Enamul Haque et al., 2018; Lee et al.; Alsmadi et al., 2020). With supervised approaches, various types of features such as linguistic features (Krishnamoorthy, 2015; Malik and Hussain, 2017; Wu et al., 2017) or textual features (i.e., polarity, subjectivity, entropy and readability) (Singh et al., 2017; Lee et al.; Siering et al., 2018) are first extracted from the reviews, with machine learning methods used over such data to train a predictive model. In a few papers, unsupervised learning based approaches have been used to rank reviews based on their helpfulness or relevance (Tsur and Rappoport, 2006; Wu et al., 2011; Woloszyn et al., 2017). It is very apparent that the majority of work has been focused on using supervised machine learning and unsupervised learning has not been well explored in this space. Supervised learning methods depend on large, annotated datasets to train the model. Unfortunately, most of the publicly available online reviews datasets do not have labels related to their helpfulness. This makes the unsupervised learning based approaches much more attractive and hence it is the focus of our work.

A review ranking method based on unsupervised learning was proposed by Tsur and Rappoport (2006). The authors first created a corpus of core dominant terms for the reviews representing the key aspects relevant to a specific product. Dominant terms were obtained by computing the frequency of all terms in a reviews collection and re-ranking them by their frequency in the reference to the British National Corpus, a baseline corpus. They named the corpus as virtual core (VC) review and represented it as feature vectors. Following this, they ranked the reviews according to their distance from the virtual core review vector. They assumed that the smaller the distance between a review and the virtual core review, the more relevant/helpful the review is.

Wu et al. (2011) proposed a ranking method to detect low quality reviews by using link analysis techniques. Three ranking algorithms have been implemented in their study which are (1) PageRank algorithm (Page et al., 1999), (2) HITS algorithm (Kleinberg et al., 2011), and (3) Length algorithm. First, they construct a graph for each review of a product where the vertexes are sentences in a review. Two directional edges between two vertexes are induced if they are similar according to specific POS tag i.e., nouns, adjectives, and verb. They compute the centrality scores of sentences using the PageRank and the HITS algorithms. A score for each review was obtained by summing all the centrality scores of all the sentences in a review and then rank the review based on the high centrality scores. The Length algorithm was used to rank all reviews based on total number of words. They count the number of words for each review and rank it based on the high score. The authors conjecture that high-quality review should contain more words than poor reviews. Two baseline methods were used for comparison in their experimental evaluation. From the evaluation, it could however be observed that their results were only slightly inferior in comparison to the baselines.

Inspired by the work proposed in (Martin and Pu, 2014), Woloszyn et al. (2017) developed MRR (Most Relevant Review), a novel unsupervised algorithm to rank reviews based on their estimated relevance. MRR algorithm consists of three steps: (1) First, they construct a graph of reviews for each product where the nodes are the reviews and the edges are defined based on the similarity between pairs of reviews. Two similarity scores are considered: cosine similarity between TF-IDF vectors computed for each review, and similarity between rating scores of reviews (i.e., rating scores from 1 to 5 given by reviewers), (2) This is followed by graph pruning that works by removing all edges with the similarity scores lower than the minimum threshold value, (manually set as $\beta=0.8553$), (3) Finally, the centrality scores are calculated for each review using PageRank algorithm. The authors hypothesise that the more central reviews should be considered as most relevant. Two state-of-the-art unsupervised learning (Tsur and Rappoport, 2006; Wu et al., 2011) and two supervised learning methods (i.e., one of the method use the same features
as (Wu et al., 2011)) were adopted in the experimental evaluation for comparison. Although, their results were lower than those obtained by supervised learning methods, they outperformed the two unsupervised learning based approaches.

In this work, we propose a new unsupervised method for ranking online reviews based on their helpfulness. Apart from the relevance (as in case of the existing unsupervised techniques), our method also considers the emotional intensity and the specificity of the reviews while assessing their helpfulness; this makes it unlike any of the approaches discussed above. For the text representation, we apply the Roberta state-of-the-art language model as opposed to TF-IDF used by the existing unsupervised methods.

3 Methodology

The key novelty of the proposed method is that it incorporates three different characteristics of online reviews while ranking them according to their helpfulness. We hypothesise that the helpfulness of a review should be determined based on the following features:

a) Relevance. Relevance indicates how well a review matches with customer’s specific information needs (Liu et al., 2019). In other words, a helpful review should discuss the key features of a product, which are important for the future buyers (e.g., “The camera is easy to use, it is compact and perfect for travelling.”). Review’s relevance has been modelled by the existing work (Wu et al., 2011; Woloszyn et al., 2017) using graph composed of all reviews, their similarities and various centrality measures. It was assumed that the reviews that are the most central within the graph contain the most relevant information about the product. In our work, we take a similar approach, however, instead of graphs we used a simpler pair similarity based method.

b) Emotional Intensity. We hypothesise that emotions play an important part in a review process as they allow customers to express their feelings and experiences through opinions. Therefore, a good review should contain a good balance of both, facts and emotions. The relationship between helpfulness of online reviews and emotions have been explored by Malik and Hussain (2017) where they studied which emotions are important for helpfulness prediction. Martin and Pu (2014) used emotions to detect helpful reviews by applying different classification models (i.e., SVM, Random Forest, and Naive Bayes) and demonstrated that their approach outperformed methods using POS tagging features. Emotion information has not been considered by any of the existing unsupervised methods. In this work, we propose to consider the level of emotions contained within a review as one of the factors in determining their helpfulness.

c) Specificity. A review of a product will be considered as useful/informative if it discusses various features of the products. In other words, instead of just expressing satisfaction/dissatisfaction from a product (e.g. “I hate this camera and would not recommend it”), it is much more helpful if the review explains what good or bad there is about the product (e.g. “The battery life is too short and the zoom is rather poor.”). The greater number of different features is mentioned in a review, the more informative the review is for any potential buyer/customer. It should be noted that there is a distinct difference between the relevance and the specificity. With relevance, we assess whether the key characteristic of a product was discussed. While with specificity, we evaluate the level of details that was provided while discussing different features of a product. Following this reasoning, we propose to consider the number of different entities mentioned in the reviews while ranking the reviews based on their helpfulness. Such a specificity feature has also not been considered by any of the existing work.

Apart from the aforementioned characteristics, we also consider the star rating of the reviews in our ranking process. It has been demonstrated in the literature that the application of star rating is beneficial when evaluating the helpfulness of a review (Tsur and Rappoport, 2006; Schuff and Mudambi, 2010; Singh et al., 2017).

The pseudocode of our proposed methods is presented in Algorithm 1. The input to the method is a collection of reviews related to the same products. Each review contains the review text (r) and the star rating associated with this review (s). In the first step of the algorithm, the input reviews are ranked
separately on the basis of their relevance, emotional intensity and specificity. For the relevance ranking, we create a product-specific “summary document” (sum), which contains all individual reviews collated together. The summary document and each individual review are then converted into vectors using the RoBERTa pre-trained language model (Liu et al., 2019). For this part, any other embedding model (such as Word2Vec or Glove) can be considered. We used the RoBERTa model as it has recently received state-of-the-art results on many NLP benchmark datasets (Liu et al., 2019). Following this, the cosine similarity between each individual review and the summary document is calculated as its relevance score. It is worth noting that the proposed relevance ranking method is much simpler and faster than those of the baseline, which uses graphs to model similarity between reviews. With the second ranking, the reviews are ranked based on their emotional intensity. To identify different emotions in the reviews we used the DepecheMood++ (Araqe et al., 2018) lexicon that contains 187942 words with 8 emotions intensity value for each word; this could be replaced with any emotion lexicon. For each review, we first identify all words which are present in the lexicon. Following this, all the intensity values assigned to those words in the lexicon are added together. The final emotion score assigned to each review is the accumulation of intensity value by summing all emotion words within this review.

Finally, for the specificity ranking, we first apply name entity recognition and extract entities from the reviews using the NLTK library\(^2\). We calculate the specificity score for each review as the sum of all entities that it contains. All the reviews are then sorted separately based on the three scores. As the outputs of the aforementioned steps, we obtained three rankings of the reviews, which were constructed based on the relevance, emotional intensity, and specificity of the reviews (lines 15-17).

As mentioned earlier, we also consider the star rating in our ranking method as it is considered as an good indicator of reviews helpfulness (Tsur and Rappoport, 2006; Schuff and Mudambi, 2010; Singh et al., 2017). We process the star rating by calculating the absolute deviation. The use of star rating deviation as a feature has been demonstrated in (Jindal and Liu, 2008; Lim et al., 2010; Jiang et al., 2013; Xu, 2013; Savage et al., 2015; Saumya and Singh, 2018) and some of the authors apply absolute deviation for the star rating (Danescu-Niculescu-Mizil et al., 2009; Mukherjee et al., 2013a,b; Runa et al., 2017). First, we calculate the average of all star ratings of a product review (line 20). In the next step, for each review \(r_i\), we calculate its absolute deviation (RAD) from the average star rating as per Eq 1.

\[
AD_i = |s_i - \text{avg}|
\]

\[
RAD_i = (1 - \alpha) \ast AD_i
\]

where \(s_i\) is star rating for review \(r_i\), typically between 1 and 5. Finally we calculate the rating absolute deviation (RAD) (line 22) as per equation 1, where \(\alpha\) is used to balance the impact of the star rating on the final ranking and its value has been adopted from (Wooszyn et al., 2017), \(\alpha = 0.867168\).

The RAD value will be further included in the final ranking process together with the other three rankings as explained below. For combining the three rankings (i.e., relevance, emotional intensity and specificity), we applied the z-score minimization method (Standard score, 2021). First, the mean (\(\mu\)) and the standard deviation (\(\sigma\)) of the three ranking positions are computed for each review \(r_i \in R\). In the next step we calculate the z-score distance matrix calculating the z-score for each review and every possible ranking position according to the following formula (lines 21-26):

\[
z\text{-score} = |(p - \mu)/\sigma|
\]

where \(p\) is the proposed ranking position.

The intuition behind this is to find the most statistically best ranking position by minimizing the aggregate z-score distance globally. The idea is from (Du et al., 2019) where they used exhaustive process for all possible features combination to find the best combination for helpfulness prediction. However, instead of using exhaustive process, we use a faster approach. The rows of matrix represent the number of reviews for each product and the columns represent the number of possible positions in the ranking (i.e., this is a squared matrix). Each cell of the matrix \((c_{ij})\) contains a position score calculated for review \(r_i\) and position \(j\) using equation 2. The z-score tells us how far each of the proposed ranking positions is from the mean position of the review. We further add the previously calculated RAD value to the z-scores.
Algorithm 1: The proposed algorithm for ranking online reviews based on their helpfulness

Require: List of reviews and their star ratings $R = \{(r_i, s_i)\}_{i=1..n}$ related to a single product
Ensure: The reviews ranked according to their helpfulness

1: $\Join \_\text{review}$ = join all reviews in $R$
2: $\text{sum} = \text{convert} \ Join \_\text{review}$ into Roberta embedding
3: for each review $r_i$ in $R$ do
4: $r_i \_\text{embed} = \text{convert} \ r_i$ into Roberta embedding
5: $r_i \_\text{relevance} \_\text{score} = \text{CosineSimilarity} (\text{sum}, r_i \_\text{embed})$
6: for each word $w_j$ in $r_i$ do
7: if $w_j$ in DepecheMood++ then

27: $\text{sum} \_\text{score} = \text{sum} \_\text{score} + \text{position}[\text{row}][\text{column}]$
28: for $j$ in len(position) do
29: $\text{sum} \_\text{score} = \text{sum} \_\text{score} + \text{position}[\text{row}][\text{column}]$
30: end for
31: $\text{total} \_\text{score} = \text{sum} \_\text{score} - \text{min} (\text{position}[\text{row}][\text{column}])$
32: end for
33: select column where $\text{total} \_\text{score} = \text{max} (\text{total} \_\text{score})$
34: assign review at the position where $\text{position} \_\text{score} = \text{min} (\text{position} \_\text{score})$
35: delete the column and row and repeat step 28-37 until convergence

In the matrix. The final step is to find out which set of ranking positions of the reviews gives the lowest total $z$-score distance. For this purpose we use an iterative solution (lines 28-37) which is explained below. For each column, we sum its values and subtract the minimum value from this column, obtaining a score referred to as $\text{total} \_\text{score}$. Then, we select the column with the maximum $\text{total} \_\text{score}$. After that, we find the minimum value in that column. The corresponding review is then assigned to the position. The next step is to delete the column and row and repeat the same for the rest of reviews until all the positions are filled. For instance, if the largest $\text{total} \_\text{score}$ is at column 4 and the minimum position score on that column belongs to review 1, then assign the review 1 to that position, i.e. 4 which is now the re-ranked position of review 1.

4 Experimental Evaluation

4.1 Datasets

For the purpose of this study, we use dataset from Amazon three reviews (from May 1996 – July 2014) for four categories of products, namely (1) Electronics, (2) Books, (3) CDs Vinlys and (4) Movies TV products, with raw data size of 1.48 GB, 9.46 GB, 1.33 GB, and 1.93 GB respectively. In this study, we only use four features: ASIN as a unique product id, ReviewText for performing the three rankings, Overall in order to include the rating star in the final ranking and Helpfulness Votes for the evaluation purposes. All the data has been processed and filtered according to the following steps. First, the product should have minimum 30 reviews. Each review should contain minimum four sentences. The review should have minimum five helpfulness votes. The details regarding the size of each dataset before and after pre-processing are listed in Table 1.

</table>

Table 1: Amazon dataset
4.2 Baseline and Evaluation

As a baseline, we implemented the state-of-the-art unsupervised ranking method MRR (Woloszyn et al., 2017), which has been described in Section 2. This is the most recent work that has been done in this space using unsupervised learning. In the original paper (Woloszyn et al., 2017), the results were also compared with two other unsupervised approaches and supervised models and it was demonstrated that MRR outperformed others baseline (Tsur and Rappoport, 2006; Wu et al., 2011). Therefore, we only use MRR as the baseline.

For further evaluation, we also explored different variants of our proposed methods. We considered using the summary of the reviews instead of their full content. The summaries of the reviews were first obtained with the SUMY library\(^4\) and then provided as an input to the algorithm described in Algorithm 1. We also evaluated the performance of our method using only the relevance ranking. In this way we wanted to validate the usefulness of emotional intensity and specificity rankings in the process. Finally, we considered the performance of our method without application of the rating star.

For the evaluation, we use NDCG (Järvelin and Kekäläinen, 2002) metric. NDCG measures the quality of ranking or recommendation system using list positions. For the purpose of ranking evaluation with NDCG, we use the helpfulness vote’s feature as the relevance value to determine the ranking. The relevance value for the NDCG is calculated based on the helpfulness vote obtained from Amazon using the gold standard as in (Woloszyn et al., 2017). The gold standard formula is in Eq 3:

\[
H(r \in R) = \frac{vote_+(r)}{vote_+(r) + vote_-(r)}
\]

Where \(r\) is a review, \(vote_+\) is the number of customers who voted for the review as being helpful and \(vote_-\) is for the customers who votes it as being unhelpful. \(H(r \in R)\) is then used as the relevance value for the NDCG.

5 Result and Discussion

The results obtained by each of the evaluated methods on each of the four datasets are presented in Tables 2-5.

Each table demonstrates the result obtained by each of the methods with and without incorporating the star rating in the process. The first row in each of the tables refers to the results obtained by the state-of-the-art (MRR) unsupervised baseline (Woloszyn et al., 2017). Rows 2 and 3 show the results obtained by our method based on only the relevance ranking and using the full text or the summary of the reviews, respectively. The last two rows refer to the results obtained by the method when all three rankings were incorporated in the process. We evaluate our ranking quality using NDCG metrics and we take four different ranking positions. Those are NDCG@3, NDCG@5, NDCG@7, and NDCG@10 where the number after the NDCG@ represent the number of reviews taken for evaluation from the top rank position.

From the results presented in Tables 2-5 we can observe that for each of the four datasets, the proposed method performed better when all three ranking were incorporated. This indicated that the emotional intensity and the specificity of a review are useful when determining its helpfulness. It can also be noted that our method obtained better results when the star rating is used when creating the final ranking. The difference is particularly apparent for the Books dataset. Finally, we can see that the proposed method performed better when applied with the full review content (Relevance(full text)+emotion+specify) than with the summary (Relevance(summary)+emotion+specify) with three out of four datasets. The only case when using the summaries of the reviews made a positive difference is the CDs & Vinlys dataset. Looking at the overall results (Both with and without rating star) we can conclude that our proposed method performs best when each of the three rankings is performed on the full reviews’ content and when the rating star is considered.

When comparing the proposed method with the baseline (MRR), we can observe from Tables 2-5 that we obtained better results according to each of the evaluation scores (NDCG@3, NDCG@5, NDCG@7, NDCG@10) in all datasets. For example, Table 2 shows our combination ranking score (relevance+emotion+specify) at NDCG@3, NDCG@5, NDCG@7, NDCG@10 are 0.982, 0.977, 0.974, and 0.972, respectively which improves by 1% from the baseline. On other datasets, the improvement is showing up to 2% compare with the baseline at NDCG@5 on Books dataset and NDCG@3 on Movies & TV dataset. To further evaluate the proposed method in comparison to the baseline, we assess whether the differences in their

\(^4\)https://pypi.org/project/sumy/
performances are statistically significant using the T-test. According to 0.05 significance level, the difference was statistically significant in 11 out of 16 cases. As the 16 cases we consider four different performance measures. (NDCG@3, NDCG@5, NDCG@7, NDCG@10) calculated for each of the four datasets. The results obtained by our method on the books and CDs & Vinyls datasets are numerically superior in all four cases. As for electronic dataset, only NDCG@3 and NDCG@5 are statistically different, while on Movie & TV dataset, only one result that shows the difference in statistic, it is NDCG@10.

### 6 Conclusion

This paper addresses the problem of online reviews ranking according to their helpfulness. We propose an unsupervised method, which first ranks the reviews based on their relevance, emotional intensity and specificity and then combine them in order to obtain the final helpfulness ranking. The performance of the method on four datasets that were created for the purpose of this study was evaluated using the NDCG metric. It was demonstrated that the method outperformed the state-of-the-art unsupervised online review ranking method proposed in (Woloszyn et al., 2017) in every case. In the future, we want to improve our ranking system by applying different features and ranking method. Some features such as linguistic features, positive and negative emotion, or topic sentences may be explore in the ranking system. Moreover, different combination ranking method such as Schulze (Schulze, 2018) or Borda count (Emerson, 2013) or another ranking method could be explored to improve the performance.

Abstract
We present an extended version of a tool developed for calculating linguistic distances and asymmetries in auditory perception of closely related languages. Along with evaluating the metrics available in the initial version of the tool, we introduce word adaptation entropy as an additional metric of linguistic asymmetry. Potential predictors of speech intelligibility are validated with human performance in spoken cognate recognition experiments for Bulgarian and Russian. Special attention is paid to the possibly different contributions of vowels and consonants in oral intercomprehension. Using incom.py 2.0 it is possible to calculate, visualize, and validate three measurement methods of linguistic distances and asymmetries as well as carrying out regression analyses in speech intelligibility between related languages.

1 Introduction
1.1 Background
Individual (receptive) multilingualism is essential in the European cultural and economic area.¹ How can native speakers of L1 spontaneously understand Lx on the basis of L1-Lx relatedness? Common experience shows that the degree of success in intercomprehension differs between spoken and written modalities, due to various linguistic and non-linguistic factors (Gooskens, 2019). While in listening the time available for the auditory input processing is limited, in reading one can jump back at will (Möller and Zeevaert, 2015) during visual input processing. The latter scenario, however, excludes the possibility to check comprehension through interactive communicative feedback. Even though cross-lingual differences are a multidimensional phenomenon (van Heuven, 2008), a simple baseline prediction of speech intelligibility between related languages can be based on the similarity of their phoneme inventories and lexicons.

For example, both similarity of phoneme inventories and lexical similarity were identified as factors predicting the perceptual confusion ability (and, by implication, similarity) of languages in the Great Language Game (Skirgård et al., 2017). These authors report confusion asymmetries within the set of Slavic languages, i.e., cases of speakers of one language (e.g. Bulgarian) understanding another language (e.g. Russian) better than the other way round. Phonetic and lexical distances are also considered as determinants of mutual intelligibility in the work of Gooskens and colleagues, who use a game-like interface, MICReLa², to collect data for Germanic, Romance, and (six) Slavic languages (Gooskens and van Heuven, 2020).

Notions of entropy and surprisal (Shannon, 1948) are employed in the INCOMSLAV framework³ to measure information density and gauge how language users master high degrees of surprisal due to partial incomprehensibility of linguistic encodings. The key idea is that understanding an unknown but related Lx should be better when the L1 language model adapted for processing the unknown Lx exhibits relatively low average surprisal, or information density (Fischer et al., 2017; Jágrová et al., 2018; Stenger et al., 2017).

1.2 This Paper

In the present study we extend the incom.py toolbox\(^4\) (Mosbach et al., 2019) focusing on mutual intelligibility aspects in oral comprehension. First, we compare the available measuring methods for linguistic distances and asymmetries – i.e., Levenshtein distance and word adaptation surprisal – as predictors of mutual intelligibility in auditory perception and add word adaptation entropy as an additional metric for asymmetric intelligibility. At the same time, we consider phonetic aspects, in particular vowel and consonant (dis)similarities, as explaining variables in spoken word intelligibility tests. While the initial version of incom.py (Mosbach et al., 2019) provides a baseline to calculate linguistic distances and asymmetries between related languages in visual perception, the current modification, referred to here as incom.py 2.0, targets the mutual intelligibility in auditory perception. The contributions of this paper include:

- Evaluation of two metrics for computing distances and asymmetries based on symbolic phonetic notations, including vowel and consonant (dis)similarities.
- Implementation of word adaptation entropy as an additional predictor of asymmetric intelligibility on the word level.
- Validation of presented predictors and explaining variables in spoken word translation tasks for Bulgarian and Russian.

2 incom.py 2.0

We borrow notation from Mosbach et al. (2019) and let \(L\) denote a language such as Russian or Bulgarian. Each language \(L\) has an associated alphabet – a set of characters – \(A(L)\) which includes the special symbol \(\emptyset\). We use \(w \in L\) to denote a word in language \(L\) and \(c_i \in w\) to denote the \(i\)-th character in word \(w\). Similarly, we will use IPA\((w)\) to denote the symbolic phonetic representation of \(w\), with \(A_{IPA}(L)\) being the phonetic alphabet of \(L\) and \(s_i \in IPA(w)\) denoting the \(i\)-th sound in word \(w\). Moreover, let \(\mathcal{V}(IPA(w))\) denote the set of all vowels in \(w\) and \(C(IPA(w))\) the set of all consonants in \(w\), respectively.

LD and WAS Following Mosbach et al. (2019), incom.py 2.0 supports computing the Levenshtein distance (LD) and word-adaptation surprisal (WAS) as well as their normalized versions \(nLD\) and \(nWAS\) between a pair of words \(w_i, w_j\) on the orthographic level. We extend these to the phonetic level by computing \((n)LD\) and \((n)WAS\) between IPA\((w_i)\) and IPA\((w_j)\), \(\mathcal{V}(IPA(w_i))\) and \(\mathcal{V}(IPA(w_j))\) as well as \(C(IPA(w_i))\) and \(C(IPA(w_j))\). We refer to Mosbach et al. (2019) for the mathematical definitions an in-depth discussion of \((n)LD\) and \((n)WAS\).

Identical Phonetic Correspondences Additionally, incom.py 2.0 supports the computation of the number of identical phonetic correspondences between two words \(w_i\) and \(w_j\) based on their phonetic representations IPA\((w_i)\) and IPA\((w_j)\). We compute the number of identical phonetic correspondences by first applying the LD algorithm of Mosbach et al. (2019) to IPA\((w_i)\) and IPA\((w_j)\) to obtain their alignment and then simply counting the number of identical phonetic transcription agreements.

Word Adaptation Entropy Lastly, incom.py 2.0 supports the computation of the normalized word adaptation entropy (nWAE) between two words \(w_i\) and \(w_j\). Recall that given a character (sound) \(c \in A(L1)\) (\(c \in A_{IPA}(L1)\)) and another character (sound) \(t \in A(L2)\) (\(t \in A_{IPA}(L2)\)), the character (sound) adaptation surprisal between \(s\) and \(t\) is defined as follows: \(\text{CAS}(s, t) = -\log_2(P(t|s))\). Now, nWAE between two words \(w_i\) and \(w_j\) can be computed by first obtaining their aligned sequences \(\tilde{w}_i, \tilde{w}_j\) using the LD algorithm of Mosbach et al. (2019) followed by computing the average (phonetic) character entropy as follows:

\[
\text{nWAE}(\tilde{w}_i, \tilde{w}_j) = \frac{1}{L} \sum_{l=0}^{L-1} P(t_l|s_l) \times \text{CAS}(s_l, t_l)
\]

3 Experimental Setup

Via the INCOMSLAV platform\(^5\), we conducted a series of mutual intelligibility tests in the spo-

---

\(^4\)Our code is available online: \url{https://github.com/uds-lsv/incompy}

\(^5\)The website includes a large number of different online experiments in 11 Slavic languages (as well as
ken modality with isolated cognate (i.e., historically or etymologically related) words. Being a challenging task on its own, the context-free recognition of cross-lingual cognates is a precondition of successful oral intercomprehension (Gooskens and van Heuven, 2020). Here, we investigate the transparency of Bulgarian–Russian cognates with regard to diachronically motivated sound correspondences that appear to facilitate or hinder human performance. As we are interested in inherent intercomprehension, only people who speak their first language (L1) natively and who do not know the stimulus language (Lx) have been included in the analysis. After completing a background questionnaire, Bulgarian (BG) and Russian (RU) participants were asked to translate randomized 1206 oral7 BG and RU stimuli into their respective native language in two series of 60 stimuli each. The items were taken from the written intelligibility tests of Mosbach et al. (2019) in order to obtain a reliable baseline.

The number of RU participants is 29, aged between 16 and 48 years (average age 32)8 with 23 women, 5 men, and 1 not specified. The number of BG participants is 11, aged between 19 and 37 years (average age 27)9 with 10 females and 1 male. Even though these two groups differ considerably in size, statistical analyses based on fewer participants are particularly worthwhile for the practice of foreign language learning and teaching and in experiments involving specific target groups (Branets et al., 2020). In this study, when no statistical observations can be made, we report findings as percentages to indicate success rates based on collected material, bearing in mind that our results should be interpreted with caution as general trends.

During the experiments the participants listened to the stimuli one by one (each word was played twice), and had to provide a written translation within 10 seconds. The order of stimuli was randomized. The time limit was chosen based on the experience from other intercomprehension experiments (Golubović, 2016), and the results were automatically categorized as ‘correct’ or ‘wrong’ via pattern matching with pre-defined correct answers and acceptable alternatives. The responses were then manually checked for typographical errors in the final analysis. The mean percentage of correctly translated items constitutes the intercomprehension score in each language (Table 1). These results show that the RU participants understand BG words at 68.42% and that the BG participants understand RU cognates they are presented with at 65.58%. This suggests that the intelligibility of spoken BG and RU stimuli did not cause major problems for the respective native speakers. For comparison, the intelligibility scores presented in the study of Mosbach et al. (2019) for the written modality are slightly higher, e.g. 71.33% (BG for RU) respectively 74.67% (RU for BG).

## 4 Results

### 4.1 Available Measures

The statistical analyses in Mosbach et al. (2019) clearly supported the normalized Levenshtein distance (nLD) as a reliable predictor of orthographic intelligibility on the word level for BG and RU, while the predictive potential of normalized word adaptation surprisal (nWAS) was rather weak despite its modification. From a cross-linguistic perspective, the advantage of surprisal-based methods, in contrast to Levenshtein distance, is in capturing asymmetries (Stenger et al., 2020). In this study, we validate the correlation of nLD and nWAS with the intelligibility scores obtained in oral intercomprehension experiments.

10In total 13 participants took part at the experiments, two participants noticed the knowledge of Russian and were excluded from the analysis.
Levenshtein Distance. As the simplest version of the Levenshtein algorithm is based on binary differences between alignments, we use a modified version with vowels matched only to vowels and consonants only to consonants. However, it is not always clear how to assign the respective weights in modeling speech intelligibility (Gooskens, 2019). The optimal weighting differs for each language combination, taking into consideration the predictability and generalizability of sound correspondences as well as the human decoding process (Berthele, 2011; Gooskens et al., 2008; Kürschner et al., 2008; Möller and Zeevaert, 2015; Stenger and Avgustinova, 2020). The version that we use in this article is based on a cost matrix including communicatively relevant sound distances for speech intelligibility between BG and RU (Stenger and Avgustinova, 2020).

To reveal the relationship between speech intelligibility and nLD, we correlated the results of the spoken cognate recognition tests with the calculated nLD in each language group. The basic assumption is that small distances would correlate with high intelligibility scores, while large distances are expected to correlate with low intelligibility scores. Figure 1 shows a significant negative correlation in both directions: BG for RU: Pearson’s $r = -0.25$, $p = 0.0056$ and RU for BG: Pearson’s $r = -0.4$, $p = 5.7\times10^{-6}$. This means that cross-lingual spoken word intelligibility is predictable from the nLD between the stimulus and the native language. The larger the distances the more difficult it is to recognize the cognates of a related language. However, the nLD accounts for 16.08% ($R^2 = .16075$) of the variance in the intelligibility scores for BG listeners and for only 6.33% ($R^2 = .06325$) of the variance in the intelligibility scores for RU listeners, leaving the majority of the variance unexplained. Hence, for RU, the predictive potential of nLD in the oral modality is smaller than in the written one in Mosbach et al. (2019).

Word Adaptation Surprisal. We correlated the nWAS values with the intelligibility scores to find out whether surprisal can predict human performance in spoken cognate recognition. With smaller nWAS values we expect an easier cognate guessing effect. The correlations between nWAS and the intelligibility scores are shown in Figure 2. We found negative correlations between nWAS and the intelligibility scores for both written and spoken modalities. Additionally, we investigated to what extent (dis)similarities in vowels and consonants may contribute to the cognate recognition process between BG and RU. As Gooskens and van Heuven (2020, p. 376) point out, consonants are better predictors of speech intelligibility.
than vowels, e.g., in the intelligibility of Scandinavian dialects for speakers of Standard Danish, consonants are more important than vowels (Gooskens et al., 2008; van Heuven, 2008).

We calculated the normalized vowel and consonant distances (nLD; see Section 2) and correlated these metrics with the intelligibility scores (Figure 3). The negative correlations for the vowels were significantly stronger than for consonants: Pearson’s $r = -.222$ ($p < .05$) versus Pearson’s $r = -.127$ ($p = .167$) for BG–RU language pair and Pearson’s $r = -.390$ ($p = 1.04e-05$) versus Pearson’s $r = .019$ ($p = .835$) for RU–BG language pair. Although the correlations are lower than in the case of the full nLD (considering all classes of speech sounds), the vowel distances are significant in both language groups. The BG–RU consonant distance is still negative but not significant. In the opposite direction, the RU–BG consonant distance is not negative as assumed but again not significant. It might be the case that qualitative characteristics of the mismatched consonant correspondences in spoken word recognition are more decisive than their number. In spoken cognate recognition between BG and RU, vowels turn out to be empirically more important than consonants. The impact of the total number of vowels (V) and consonants (C) in the stimulus word and of the identical vowel (Vic) and consonant (Cic) correspondences between the stimulus and the target cognates in spoken word recognition are correlated as explaining variables with the obtained intelligibility scores. Table 2 provides an overview of the statistical results (Pearson’s r and p-value).

The statistical results show significantly positive correlations between the number of vowels and consonants in the stimulus cognates and the intelligibility score of the BG–RU language pair. The positive correlation for consonants is, in this case, significantly stronger than for vowels. However, the correlation for the identical vowel correspondences is significantly stronger, while the correlation for the identical consonant correspondences is positive, but insignificant.

For the RU–BG language pair, statistical results show significantly positive correlations of intelligibility scores with the number of consonants in the stimulus cognates and with identical vowel correspondences. The predictive potential of the number of vowels in auditory perception of RU cognates by BG participants is, however, small and insignificant. The correlation for identical consonant correspondences is not positive as assumed but again insignificant.

How to interpret these results? First of all, in our experimental material, the cognate BG words are slightly shorter than their RU equivalents (4.64 vs. 4.81). Looking at BG and RU sound inventories in more detail, we see an almost equal distribution of consonants between the two languages: 343 vs. 341 (2.86 per word in BG and 2.84 per word in RU). Consonants of the two languages include 224 identical correspondences (38.89%) and 122 mismatched correspondences (21.18%), including missing consonants. At the same time, the distribution of vowels is not so equally represented between BG and RU: 214 vs. 230 (1.78 per word in BG and 1.92 per word in RU), where vowels of the two languages represent only 53 identical correspondences (9.20%) and
177 mismatched correspondences (30.73%), including missing vowels. These facts partly explain the results obtained from correlations and the different contribution of vowels and consonants to understanding spoken cognates.

To conclude, the experimental subjects seemed to rely on the interplay between a vowel (dis)similarity effect and a larger number of consonants with a balanced distribution. On the other hand, it might be the case that participants are communicatively more or less tolerant (or sensible) to different phonetic details (Gooskens et al., 2015), in particular to the qualitative effect of sound correspondences in spoken cognate recognition (Stenger and Avgustinova, 2020).

### 4.3 Word Adaptation Entropy

Despite all dissimilarities, speech intelligibility between related languages appears to be possible mainly because of regular correspondences. Speakers of L1 can understand a word \( w_j \) from a related Lx insofar as they can predict which word \( w_i \) of L1 is the best equivalent for \( w_j \).

In the case of cognates, the prediction can be based on sound correspondences. Entropy, as the mean of surprisal, gives a quantification of the overall uncertainty involved in making a choice. Let us consider an example. From a RU perspective, the BG–RU cognate pair [dup]-[dup] “oak” gives us individual sound adaptation entropies of 0.567 for [d] (BG [d] potentially corresponds to RU [d] and [d’]), 1.689 for [v] (BG [v] potentially corresponds to RU [u], [e], [o] and [i]) and 0.523 for [p] (BG [p] potentially corresponds to RU [p] and [p’]). An aggregate measure for the entire word thus results in 2.778, which after normalization by the sound correspondence alignment gives us 0.926. From a BG perspective, on the other hand, the RU–BG cognate pair [dyp]-[dup] “oak” gives us individual sound adaptation entropies of 0.0 for [d] (RU [d] can only correspond to BG [d]) as well as for [p] (RU [p] can only correspond to BG [p]), but 1.296 for [u] (RU [u] potentially corresponds to BG [v], [a] and [u]). As an aggregate measure for the entire word we get 1.296 and eventually normalized value of 0.432.

Based on sound entropies we have calculated the normalized word adaptation entropy (nWAE) as an aggregate measure for entire words. We assume that the smaller the nWAE, the easier it is to guess the spoken cognate in a related language. We found negative but very low and not significant correlations in both directions: BG for RU: Pearson’s \( r = -0.078, p = .40 \) and RU for BG: Pearson’s \( r = -0.069, p = .46 \). The question is why the correlations are so low and not significant? Our analysis is based on a limited number of stimulus words (120 cognates in each direction) and this sample may be too limited for nWAE values (Moberg et al., 2006). Additional linguistic factors may influence the mutual intelligibility of related languages, e.g., the existence of
words that are very similar to the stimulus but differ only in one sound, which leads to disregarding the correct counterpart (Kürschner et al., 2008). We therefore assume that WAE needs to systematically account for such neighborhood density effects as a relevant factor for speech intelligibility.

By using the nWAE values, we can now quantify the uncertainty in the overall adaptation process of cognates. For BG and RU, we found that the mean nWAE for RU given BG (1.267) is higher than for BG given RU (0.807). This means that a RU listener may in general have more difficulties when exposed to BG than a BG speaker exposed to RU. There are 114 BG cognates with higher nWAE values in comparison to 114 RU cognates. This means that RU subjects listening to 114 BG stimuli cognates are predicted to deal with more uncertainty than BG subjects listening to 114 RU stimuli cognates. Only 6 RU cognates have higher nWAE values in comparison to BG cognates. In this case BG subjects adapting 6 RU stimuli cognates are predicted to face larger uncertainty than RU subjects trying to adapt 6 BG stimulus cognates.

To carry out comparative analyses with the small group of BG participants, we automatically extracted a corresponding sample of 11 RU subjects with matching intelligibility scores. We then calculate the difference in intelligibility between the two groups separately for all cognate pairs. The quantitative data show that 56 BG stimuli have higher intelligibility scores than their RU cognates, 50 RU stimuli have higher intelligibility scores than their BG cognates, and 14 cognate pairs have identical scores. Let us consider six cognate pairs with higher nWAE values for the stimuli, which imply larger difficulties for the listeners. There are indeed three BG stimuli with higher intelligibility scores than their RU cognates, cf. BG–RU [3gon]–[3gon] “flame/fire” (91% vs. 29%), [3ol]–[3ol] “salt” (100% vs. 90%) and [3lo][3a]–[3lo][3a] “knee” (45% vs. 29%). On the other hand, three RU stimuli have higher intelligibility scores than their BG cognates despite higher nWAS values, cf. RU–BG [4gerox]–[4grax] “pea” (50% vs. 27%), [4mto]–[4jatsc] “egg” (86% vs. 82%) and [4porox]–[4prax] ”gunpowder” (14.0% vs. 9.0%).

To recap, the obtained experimental results indicate that the calculated nWAE values can only partially explain the asymmetric intelligibility of spoken words between the two tested languages.

4.4 Regression Analyses

In this Section we present regression analysis results. The nLD correlates most strongly with intelligibility scores in both directions (see Section 4.1). The negative correlation between the intelligibility score and the nWAS is very small and significant only for BG listeners (see Section 4.1). However, in order to investigate whether the nWAS still has a significant additional contribution to speech intelligibility in case of BG and RU, a multiple regression analysis was performed. Note that even though the nWAE does not correlate significantly with the intelligibility scores in both directions (see Section 4.3) it is included as the third predictor in the regression analysis. Figure 4 and Figure 5 present the results of the regression analysis, conducted first with the method to identify the effect of two predictors in combination: nLD and nWAS, nLD and nWAE, and nWAS and nWAE.

The first regression model containing nLD and nWAS as two predictors could account for 16.12% ($R^2 = .16117, p = 3.421e–05$) of the variance in intelligibility of spoken RU words and for only 6.37% ($R^2 = .06370, p < .05$) of the variance in intelligibility of spoken BG words. The second model containing nLD and nWAE as two predictors explains the variance to a slightly better extent: RU for BG – 16.30% of the variance ($R^2 = .16296, p = 0.20338e–05$) and BG for RU – 6.59% ($R^2 = .06592, p < .05$). However, the third model of nWAS and nWAE does not explain the variance to a significant extent in both directions: RU for BG – 4.00% of the variance ($R^2 = .03999, p = .092$) and BG for RU – 1.64% of the variance ($R^2 = .01637, p = .381$). The final model includes all three predictors: nLD, nWAS and nWAE and this results in explaining 16.74% ($R^2 = .16742, p = 8.9276e–05$) of the variance in understanding of RU spoken cognates and in only 6.60% ($R^2 = .06600, p < .05$) of the variance in understanding of BG spoken cognates. A combination of nLD, nWAS and nWAE is only a slightly better predictor of speech intelligibility in case
of BG and RU than two predictors: nLD and nWAS or nLD and nWAE, and than nLD alone. Nevertheless, the amount of explained variance is low for all three predictors.

5 Conclusion and Outlook

We presented incom.py 2.0, the extended version of the incom.py toolkit for calculating similarities and asymmetries between closely related languages, with a focus on auditory perception. Our main conclusions are the following:

- Our statistical analyses clearly support nLD as a reliable predictor of speech intelligibility on the word level, although its predictive potential in the BG–RU setup is smaller for the oral modality when compared to the written one (Mosbach et al., 2019). The predictive potential of nWAS for speech intelligibility in case of BG and RU is rather weak and significant only for BG speakers, which is in line with the results for the written modality (Mosbach et al., 2019).

- Our special attention to the possibly different contributions of vowels and consonants in oral intercomprehension has shown that in the experimental material vowels are more important than consonants in recognizing cognates between BG and RU. A closer look at sound correspondences further reveals that a larger number of consonants with a balanced distribution between the two languages also plays a role in spoken word recognition.

- The additional linguistic asymmetry factor of nWAE quantifies the overall uncertainty involved in making a choice in spoken word recognition. We correlated nWAE with intelligibility scores and found negative correlations between the nWAE values and the intelligibility scores in both directions. However, the correlations are very low and not significant. Hence, nWAE can only partly explain or predict asymmetric intelligibility of spoken words between the two tested languages, which we attribute to the small empirical base of the present study.

- We carried out regression analyses to find out which combination of presented predictors served better to explain speech intelligibility in our experiments. We found out that the combination of nLD, nWAS and nWAE is a slightly better predictor of speech intelligibility in case of BG and RU than two predictors nLD and nWAS or nLD and nWAE and than nLD alone. Nevertheless, the amount of explained variance is low for three predictors.

As a next step, we plan to extend the range of the studied phenomena beyond mere word similarity and to include predictability of constructional similarity by focusing on cross-lingual correspondences of multi-component units in phrasal and sentential contexts. Additionally, we plan to integrate reaction times into the experiments in order to study the interaction of linguistic and cognitive aspects of human performance.

Not All Linearizations Are Equally Data-Hungry in Sequence Labeling Parsing

Abstract

Different linearizations have been proposed to cast dependency parsing as sequence labeling and solve the task as: (i) a head selection problem, (ii) finding a representation of the token arcs as bracket strings, or (iii) associating partial transition sequences of a transition-based parser to words. Yet, there is little understanding about how these linearizations behave in low-resource setups. Here, we first study their data efficiency, simulating data-restricted setups from a diverse set of rich-resource treebanks. Second, we test whether such differences manifest in truly low-resource setups. The results show that head selection encodings are more data-efficient and perform better in an ideal (gold) framework, but that such advantage greatly vanishes in favor of bracketing formats when the running setup resembles a real-world low-resource configuration.

1 Introduction

Dependency parsing (Mel’cuk et al., 1988; Kühbler et al., 2009) has achieved clear improvements in recent years, to the point that graph-based (Martins et al., 2013; Dozat et al., 2017) and transition-based (Ma et al., 2018; Fernández-González and Gómez-Rodríguez, 2019) parsers are already very accurate on certain setups, such as English news. In this line, Berzak et al. (2016) have pointed out that the performance on these setups is already on par with that expected from experienced human annotators.

Thus, the efforts have started to focus on related problems such as parsing different domains or multi-lingual scenarios (Sato et al., 2017; Song et al., 2019; Ammar et al., 2016), creating faster models (Volokh, 2013; Chen and Manning, 2014), designing low-resource and cross-lingual parsing techniques (Tiedemann et al., 2014; Zhang et al., 2019), or infusing syntactic knowledge into models (Strubell et al., 2018; Rotman and Reichart, 2019).

This work will lie in the intersection between fast parsing and low-resource languages. Recent work has proposed encodings to cast parsing as sequence labeling (Spoustová and Spousta, 2010; Strzyz et al., 2019; Gómez-Rodríguez et al., 2020; Li et al., 2018; Kiperwasser and Ballesteros, 2018). This approach computes a linearized tree of a sentence of length \( n \) in \( n \) tagging actions, providing a good speed/accuracy trade-off. Also, it offers a naïve way to infuse syntactic information as an embedding or feature (Ma et al., 2019; Wang et al., 2019). Such encodings have been evaluated on English and multi-lingual setups, but there is no study about their behaviour on low-resource setups, and what strengths and weaknesses they might exhibit.

Contribution We study the behaviour of linearizations for dependency parsing as sequence labeling in low-resource setups. First, we explore their data efficiency, i.e. if they can exploit their full potential with less supervised data. To do so, we simulate different data-restricted setups from a diverse set of rich-resource treebanks. Second, we shed light about their performance on truly low-resource treebanks. The goal is to determine whether tendencies from the experiments in the previous phase hold when the language is truly low-resource and when secondary effects of real-world low-resource setups, such as using predicted part-of-speech (PoS) tags or no PoS tags, impact more certain types of linearizations.

2 Related work

Low-resource parsing has been explored from perspectives such as unsupervised parsing, data augmentation, cross-lingual learning, or data-efficiency of models. For instance, on unsupervised parsing, Klein and Manning (2004) and Spitkovsky et al. (2010) have worked on generative models to determine whether to continue or stop attaching de-
pendents to a token, while others (Le and Zuidema, 2015; Mohananey et al., 2020) have studied how to use self-training for unsupervised parsing.

On data augmentation, McClosky et al. (2006) used self-training to annotate extra data, while others have focused on linguistically motivated approaches to augment treebanks. This is the case of Vania et al. (2019) or Dehouck and Gómez-Rodríguez (2020), who have proposed methods to replace subtrees within a given sentence.

On cross-lingual learning, authors such as Søgaard (2011) or McDonald et al. (2011) trained delexicalized parsers in a source rich-resource treebank, which are then used to parse a low-resource target language. Falenska and Çetinoğlu (2017) explored lexicalized versus delexicalized parsers and compared them on low-resource treebanks, depending on factors such as the treebank size and the PoS tags performance. Wang and Eisner (2018) created synthetic treebanks that resemble the target language by permuting constituents of distant treebanks. Naseem et al. (2012) and Täckström et al. (2013) tackled this same issue, but from the model side, training on rich-resource languages in such a way the model learns to detect the aspects of the source languages that are relevant for the target language. Recently, Mulcaire et al. (2019) used an LSTM to build a polyglot language model, which is then used to train on top of it a parser that shows cross-lingual abilities in zero-shot setups.

On data-efficiency, research work has explored the impact of the use of different amounts of data, motivated by the lack of annotated data or by the lack of quality of it. For instance, Lacroix et al. (2016a) showed how a transition-based parser with a dynamic oracle can be used without any modifications to parse partially annotated data. They found that this setup is useful to train low-resource parsers on sentence-aligned texts, from a rich-resource treebank to an automatically translated low-resource language, where only precisely aligned tokens are used for the projection in the target dataset. Lacroix et al. (2016b) studied the effect that pre-processing and post-processing has in annotation projection, and concluded that quality should prevail over quantity. Related to training with restricted data, Anderson and Gómez-Rodríguez (2020) showed that when distilling a graph-based parser for faster inference time, models with smaller treebanks suffered less. Dehouck et al. (2020) also distilled models for Enhanced Universal Dependencies (EUD) parsing with different amounts of data, observing that less training data usually translated into slightly lower performance, while offering better energy consumption. Garcia et al. (2018) showed, in the context of Romance languages, that peeking samples from related languages and adapting them to the target language is useful to train a model that performs on par with one trained on fully (but still limited) manually annotated data. Restricted to constituent parsing, Shi et al. (2020) analyzed the role of the dev data in unsupervised parsing. They pointed out that many unsupervised parsers use the score on the dev set as a signal for hyper-parameter updates, and show that by using a handful of samples from that development set to train a counterpart supervised model, the results outperformed those of the unsupervised setup. Finally, there is work describing the impact that the size of the parsing training data has on downstream tasks that use syntactic information as part of the input (Sagae et al., 2008; Gómez-Rodríguez et al., 2019).

3 Preliminaries

In what follows, we review the existing families of encodings for parsing as sequence labeling (§3.1) and the models that we will be using (§3.2).

3.1 Encodings for sequence labeling dependency parsing

Sequence labeling assigns one output label to every input token. Many problems are cast as sequence labeling due to its fast and simple nature, like PoS tagging, chunking, super tagging, named-entity recognition, semantic role labeling, and parsing. For dependency parsing, to create a linearized tree it suffices to assign each word $w_i$ a discrete label of the form $(x_i, l_i)$, where $l_i$ is the dependency type and $x_i$ encodes a subset of the arcs of the tree related to such word. Although only labels seen in the training data can be predicted, Strzyz et al. (2020) show that the coverage is almost complete. We distinguish three families of encodings, which we now review (see also Figure 1).

Head-selection encodings (Spoustová and Spousta, 2010; Li et al., 2018; Strzyz et al., 2019). Each word label component $x_i$ encodes its head as an index or an (abstracted) offset. This can be done by labeling the target word with the (absolute) index of its head token, or by using a relative offset that accounts for the difference between the dependent and head indexes. In this work, we
chose a relative PoS-based encoding (rpxb) that has shown to perform consistently better among the linearizations of this family. Here, each \( x_i \) is a tuple \((p_i, o_i)\), such that if \( o_i > 0 \) the head of \( w_i \) is the \( o_i \)th word to the right of \( w_i \) whose PoS tag is \( p_i \); if \( o_i < 0 \), the head of \( w_i \) is the \( o_i \)th word to the left of \( w_i \) whose PoS tag is \( p_i \). Among its advantages, we find the capacity to encode any non-projective tree and words being directly and only linked to its head, but on the other hand it is dependent on external factors (e.g. PoS tags).\(^1\)

**Bracketing-based encodings** (Yli-Jyrä and Gómez-Rodríguez, 2017). Each \( x_i \) encodes a sort of incoming and outgoing arcs of a given word and its neighbors, represented as bracket strings. More particularly, in Strzysz et al. (2019) each \( x_i \) is a string that follows the expression \((< \) ? (\( (\) \) x \( (\) \) x)) \( (> \) ?), where \( < \) means that \( w_{i-1} \) has an incoming arc from the right, \( k \) times \( \backslash \) means that \( w_i \) has \( k \) outgoing arcs towards the left, \( k \) times \( / \) means that \( w_{i-1} \) has \( k \) outgoing arcs to the right, and \( > \) means that \( w_i \) has an arc coming from the left. This encoding produces a compressed label set while not relying on external features, such as PoS tags. However, when it comes to non-projectivity, it can only analyze crossing arcs in opposite directions. To counteract this, it is possible to define a linearization using a second independent pair of brackets (denoted with \(*\)) to encode a 2-planar tree (Strzysz et al., 2020).\(^2\)

In this work we are considering experiments with both the restricted non-projective \((rxxb)\) and the 2-planar bracketing encodings \((2pb)\).

**Transition-based encodings** (Gómez-Rodríguez et al., 2020). Each \( x_i \) encodes a sub-sequence of the transitions to be generated by a left-to-right transition-based parser. Given a sequence of transitions \( t = t_1, \ldots , t_m \) with exactly \( n \) read transitions\(^3\), it splits \( t \) into \( n \) chunks and assigns the \( i \)th chunk to the \( i \)th word. Its main advantage is more abstract, allowing to automatically derive encodings relying on any left-to-right transition based parser (including dependency, constituency and semantic parsers). According to Gómez-Rodríguez et al. (2020), they produce worse results than the bracketing encodings, but we include them in this work for completeness. In particular, we consider mappings from arc-hybrid (Kuhlmann et al., 2011) \((ahxb)\) and Covington (2001) \((ctb)\), which are projective and non-projective transition-based algorithms.

To post-process corrupted predicted labels, we follow the heuristics described in each encoding paper.

### 3.2 Sequence labeling framework

**Notes** Let \( w \) be a sequence of words \([w_1, w_2, \ldots , w_{|w|}]\), then \( \vec{w} \) is a sequence of word vectors that will be used as the input to our models. Each \( \vec{w}_i \) will be a concatenation of: (i) a word embedding, (ii) a second word embedding computed through a char-LSTM, (iii) and optionally a PoS tag embedding (we will discuss more about this last point in §4).

We use bidirectional long short-term memory networks (biLSTMs; Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997) to train our sequence labeling parsers. BiLSTMs are a strong baseline used in recent work across a number of tasks (Yang and Zhang, 2018; Reimers and Gurevych, 2017). More particularly, we use two layers of biLSTMs, and each hidden vector \( \vec{h}_i \) from the last biLSTM layer (associated to each input vector \( \vec{w}_i \)) is fed to separate feed-forward networks that are in charge of predicting each of the label components of the linearization (i.e. \( x_i \) and \( l_i \)) using soft-maxes, relying on hard-sharing multi-task learning (MTL; Caruana, 1997; Ruder, 2017). Following

---

\(^1\)Other head-selection variants encode arcs based on word properties different than PoS tags (Lacroix, 2019).

\(^2\)An \( x \)-planar tree can be separated into \( x \) planes, where the arcs belonging to the same plane do not cross.

\(^3\)In left-to-right parsers, a read transition is an action that puts a word from the buffer into the stack. For algorithms such as the arc-standard or arc-hybrid this is only the shift action, while in the arc-eager both the shift and right-arc actions are read transitions. See also (Nivre, 2008).
§3.1, for all the encodings, except the 2-planar encoding, we will use a 2-task MTL setup: one task will predict $x_i$ according to each encoding specifics, and the other one will predict the dependency type, $l_i$. For the 2-planar bracketing encoding, which uses a second pair of brackets to predict the arcs from the second plane, we use instead a 3-task MTL setup, where the difference is that the prediction of $x_i$ is split into two tasks: one that predicts the first plane brackets and another task that predicts the brackets from the second plane.\(^4\)

It is worth noting that for this particular work we skipped computational expensive models, such as BERT (Devlin et al., 2019). There are three main reasons for this. First, the experiments in this paper imply training a total of 760 parsing models (see more details in §4), making the training on BERT (or variants) less practical. Second, there is not a multilingual or specific-language BERT model for all languages, and this could be the source of uncontrolled variables that could have an impact on the performance, and thereof on the conclusions.\(^5\)

Third, even under the assumption of all language-specific BERT models being available, these are pre-trained on different data that add extra noise, which could be undesirable for our purpose.

4 Methodology and experiments

We design two studies, detailed in §4.1 and 4.2:

1. We explore if some encodings are more data-efficient than others. To do so, we will simulate data-restricted setups, selecting rich-resource languages and using partial data. The goal is to test if some encodings are learnable with fewer data, or if other ones could obtain a better performance instead, but only under the assumption of very large data being available.

2. We focus on truly low-resource setups. This can be seen as a confirmation experiment to see if the findings under data-restricted setups hold for under-studied languages, and to confirm what sequence labeling linearizations are more recommendable under these conditions.

Experimental setups For experiments 1 and 2, we consider three setups that might have a different impact across the encodings:

1. Gold PoS tags setup: We train and run the models under an ideal framework that uses gold PoS tags as part of the input. The reason is that encodings such as $r^h_p$ rely on PoS tags to rebuild the linearized tree. This way, using gold PoS tags helps estimate the optimal data-efficiency and learnability of these parsers under perfect (but unreal) conditions.

2. Predicted PoS tags setup: Setup 1 cannot truly reflect the performance that the encodings would obtain under real-world data-restricted conditions. Predicted PoS tags will be less helpful because their quality will degrade. This issue can affect more to the $r^h_p$ encoding, since it requires them to rebuild the tree from the labels, and miss-predicted PoS tags could propagate errors during decoding. Here, we train taggers for each treebank, using the same architecture used for the parsers. To be coherent with the data-restricted setups, taggers will be trained on the same amount of data used for the parsers. Appendix A discusses the PoS taggers performance.

3. No PoS tags setup: We train the models without using any PoS tags as part of the input. It is worth noting that the setup is somewhat forced for the $r^h_p$ encoding, since we will still need to externally run the taggers to obtain the PoS tags and rebuild the tree. Yet, we include the PoS-based encoding for completeness, and to have a better understanding about how different families of encodings suffer from not (or minimally) using PoS tags. For instance, that is a simple way to obtain simpler and faster parsing models, as part of the pipeline does not need to be executed, and the input vectors to the models will be smaller, translating into faster executions too. Also, in low-resource setups, PoS tags might not be available or the tagging models are not accurate enough to help deep learning models (Zhou et al., 2020; Anderson and Gómez-Rodríguez, 2021).

4.1 Experiment 1: Encodings data-efficiency

Data We chose 11 treebanks from UD2.7 (Zeman et al., 2020) with more than 10000 training sentences: German\(_{HDT}\), Czech\(_{PDT}\), German\(_{HDT}\), Czech\(_{PDT}\),
Russian SynTagRus, Classical Chinese Kyoto, Persian PDT, Estonian EDT, Romanian Nonstandard, Korean Kaist, Ancient Greek PROIEL, Hindi HDTB and Latvian LVTB. They consider different families, scripts and levels of non-projectivity (see Appendix B). To simulate data-restricted setups, we created training subsets of 100, 500, 1 000, 5 000 and 10 000 samples, as well as the total training set. The training sets were shuffled before the division.

Setup To assess the data-efficiency, we proceed as follows. As the $\text{rp}^h$ encoding has showed the strongest performance in previous work for multi-lingual setups (Strzy et al., 2019; Gómez-Rodríguez et al., 2020), we are taking these models as the reference and an a priori upper bound. Then, we compute the difference of the mean UAS (across the 11 treebanks) between the $\text{rp}^h$ and each of the other linearizations, for all the models trained up to 10 000 sentences. The goal is to determine which encodings suffer more when training with limited data and monitor to what extent the tendency holds as more data is introduced. We compute the statistically significant difference between the $\text{rp}^h$ and the other encodings, using the p-value ($p < 0.05$) of a paired t-test on the scores distribution, following recommended practices for dependency parsing (Dror et al., 2018). Finally, we show specific results for the models trained on the whole treebanks. In this work, we will report UAS over LAS, since the differences in the encodings lie in how they encode the dependency arcs and not their types.

Results Tables 1, 2 and 3 show the difference of the mean UAS for each encoding with respect to the $\text{rp}^h$ one; for the gold PoS tags, predicted PoS tags and no PoS tags setups, respectively. For the gold PoS tags setup, the $\text{rp}^h$ encoding performs better than the bracketing ($\text{rx}^b$ and $\text{2p}^b$) and the transition-based ($\text{ah}^\text{tb}$ and $\text{ct}^\text{tb}$) encodings, for all the training splits. Yet, the gap narrows as the number of training sentence increases. For the predicted PoS tags setup, the relative PoS-based encoding performs better for the smallest set of 100 sentences, but slightly worse for the sets of 500 and 1 000 sentences with respect to $\text{rx}^b$ and $\text{2p}^b$. With more data, the tendency resembles the one from the gold PoS tags setup. Third, for the setup without PoS tags, the tendency reverses. The bracketing encodings perform better, particularly for the smallest test sets, but the gap narrows as the number of training sentences increases.

Table 1: Average UAS difference for the subsets of the rich-resource treebanks under the gold PoS tags setup. Blue and yellow cells show the UAS increase and decrease with respect to the $\text{rp}^h$ encoding, respectively.

Discussion The results from the experiments shed light about differences existing across different encodings and running configurations. First, under an ideal, gold environment, the $\text{rp}^h$ encoding makes a better use of limited data than the bracketing and transition-based encodings. Second, the predicted PoS tag setup shows that the performance of the PoS taggers can have a significant impact on the performance for the $\text{rp}^h$ encoding. More interestingly, weaknesses from different encodings seem to manifest to different extents depending on the amount of training data. For instance, when training data is scarce (100 sentences), bracketing encodings still cannot outperform the $\text{rp}^h$ encoding, despite the lower performance of the PoS taggers. However, when working with setups ranging from 500 to 1000 sentences, there is a slight advantage of the bracketing encodings with respect to $\text{rp}^h$, suggesting that with this amount of data, bracketing encodings could be the preferable choice, since they seem able to exploit their potential in a better way than the $\text{rp}^h$ encoding can exploit not fully accurate PoS tags. With more training samples, the relative PoS-based
encoding is again the best performing model across the board. In §4.2 we will discuss deeper how for truly low-resources languages the advantage in favour of bracketing representations exacerbates more for the predicted and no PoS tags setups.

Table 7: UAS for the low-resource treebanks for the gold PoS tags setup.

4.2 Experiment 2: Encodings performance on truly low-resource languages

**Data** We choose the 10 smallest treebanks (in terms of training sentences) that had a dev set: LithuanianHSE, MarathiUFAL, HungarianSzeged, TeluguMTG, TamilTTB, FaroeseFafPaHc, CopticScripturnium, MalteseMUDT, WolofWB and AfrikaansAfBooms (see Appendix B). Their sizes range between 153 and 1350 training sentences, most being around or between 500 and 1000 (see Appendix C).

**Setup** We rerun a subset of the experiments from §4.1, to check if the results follow the same trends, and conclusions are therefore similar.

**Results** Tables 7, 8 and 9 show the UAS for each encoding and treebank for the gold PoS tags setup, the predicted PoS tags setup and the no PoS tags setup, respectively. Again, under perfect conditions, the relative PoS-based encoding performs overall better, except for Telugu, which seems to

---

6Code switching treebanks and small treebanks of rich-resource languages were not considered.
be an outlier. For the predicted PoS tags setup, the bracketing-based encodings perform consistently better for most of the treebanks. For the no PoS tags setup, the bracketing-based encodings obtain, on average, more than 3 points than the relative PoS-head selection encoding, which even performs worse than the transition-based encodings.

**Discussion** These experiments help elaborate on the findings of §4.1. With respect to the ideal gold PoS tags setup, things do not change much, and the relative PoS-based encoding performs overall better. Still, this should not be taken as a ground truth about how the encodings will perform in real-world setups. For instance, for the predicted PoS tags setup, the bracketing-based encodings perform consistently better in most of the treebanks. This reinforces some of the suspicions found in the experiments of Table 2, where training on rich-resource languages, but with limited data, revealed that bracketing encodings performed better, although just slightly. Also, it is worth noting that most of the low-resource treebanks tested in this work have a number of training sentences in the range where the bracketing-based encodings performed better for the predicted PoS tags setup in Table 2, i.e. from 500 to 1000 sentences (see Appendix C). Yet, the better performance of bracketing encodings is more evident when running on real low-resource treebanks. This does not only suggest that the bracketing encodings are better for real low-resource sequence labeling parsing, but it could also pose more general limitations for other low-resource NLP tasks that are evaluated only on ‘faked’ low-resource setups, and that could lead to incomplete or even misleading conclusions.

Overall, the results suggest that bracketing encodings are the most suitable linearizations for real low-resource sequence labeling parsing.

**5 Conclusion**

We have studied sequence labeling encodings for dependency treebanks. First, we explored which encodings are more data-efficient under different conditions that include the use of gold PoS tags, predicted PoS tags and no PoS tags as part of the input. By restricting training data for rich-resource treebanks, we observe that although bracketing encodings are less data-efficient than head-selection ones under ideal conditions, this disadvantage can vanish when the input conditions are not gold and data is limited. Second, we studied their performance under the same running configurations, but on truly low-resource languages. These results show more clearly the greatest utility of bracketing encodings over the rest of the ones when training data is limited and the quality of external factors, such as PoS tags, is affected by the low-resource nature of the problem.

Abstract

Recently, pre-trained language representation models such as BERT and RoBERTa have achieved significant results in a wide range of natural language processing (NLP) tasks; however, it requires extremely high computational cost. Curriculum learning (CL) is one of the potential solutions to alleviate this problem. CL is a training strategy where training samples are given to models in a meaningful order instead of random sampling. In this work, we propose a new CL method which gradually increases the block-size of input text for training the self-attention mechanism of BERT and its variants using the maximum available batch-size. Experiments in low-resource settings show that our approach outperforms the baseline in terms of convergence speed and final performance on down-stream tasks.

1 Introduction

Recent years have seen a series of breakthroughs in pre-trained language representation models. The development of pre-training methods like BERT (Devlin et al., 2019) and its variants (Liu et al., 2019) have led to large improvements in many down-stream tasks such as paraphrase identification, sentence textual similarity, sentiment analysis, and natural language inference. One of the advantages in training these models is that they can leverage the unlabeled large-scale corpora which are more available compared to the labeled ones. However, training these models with large-scale corpora is pretty expensive in terms of computational time and memory footprint. In the literature, there are three main approaches that have been adopted to address this problem. These are architecture-based approach (Sanh et al., 2019; Voita et al., 2019; Sukhbaatar et al., 2019; de Wynter and Perry, 2020; Lan et al., 2020), task-based approach (Yang et al., 2019; Clark et al., 2020) and dataset-based approach (Elman, 1993; Bengio et al., 2009; Moore and Lewis, 2010; Gururangan et al., 2020). While the architecture-based and task-based methods have been extensively studied in the context of pre-training methods for natural language processing (NLP), dataset-based approach is relatively unexplored. To this end, we adopt a dataset-based method called Curriculum Learning (CL) which controls the order of training samples so that the model might converge faster with better performance.

The idea of CL-like approach was originally proposed by Elman (1993). The idea is based on the actual learning mechanism of humans and animals, where basic concepts are acquired first, then more complex ones are gradually learned. Bengio et al. (2009) formalized this concept as CL to train neural networks. Through experimental analysis, Bengio et al. (2009) showed the benefit of CL on convergence speed and performance in shape recognition and language modeling tasks. One of the most significant challenges when adapting CL to a new task is to figure out a criterion for measuring the difficulty of the training samples. For example, in object recognition task, the size of objects is a good measure of difficulty (Shi and Ferrari, 2016; Ionescu et al., 2016), and the presence of low-frequent words in input text is an indicator of difficulty in language modeling (Bengio et al., 2009). These criteria vary greatly depending on the task, thus, it is not easy to define a measure of difficulty which is suitable for a particular task.

Most studies in the field of CL for NLP have proposed variety of difficulty measure by leveraging heuristics of the target tasks with neural networks (Bengio et al., 2009; Kocmi and Bojar, 2017; Soviany et al., 2021; Spitkovsky et al., 2009; Cirik et al., 2016; Rajeswar et al., 2017). On the other hand, it is not clear how to design CL for language representation models such as BERT. In pre-training BERT, distributed word representations are learned through optimizing masked language
modeling (MLM) loss which is computed by predicting a masked word or token in an input text. The input to the model is not a single sentence but an arbitrary-length span of text called a block. This indicates that it is not obvious how to measure the difficulty of the training samples using CL-based approach proposed in the previous studies.

The key component of BERT is the multi-head self-attention mechanism that learns to compute token embeddings from its context (Devlin et al., 2019). The multi-head self-attention mechanism can be thought as a problem of searching for important token-pairs based on the relative magnitude of attention among all the token-pairs in an input text. This process can be served as a clue which leads us to speculate that it might be possible to formulate CL strategy by focusing on the effective training of the self-attention mechanism in BERT. Although each individual head of the multi-head self-attention mechanism can learn any dependency among tokens, most of the heads tend to pay more attention to local dependencies than global ones (Kovaleva et al., 2019; Brunner et al., 2019; Sukhbaatar et al., 2019; Jiang et al., 2020). It could be easier to train local self-attention in shorter blocks of input text than global self-attention in longer ones. Therefore, the block-size of input text can be used as the effective criterion to measure the difficulty-level of training samples for BERT.

In this paper, we introduce a new CL method which gradually increases the block-size of input text for pre-training BERT using the maximum available batch-size to accomplish convergence speedup, and also improve performance in the down-stream tasks. Since our approach is very simple, it is easy to apply it to BERT and its variants with little effort. Using a small-scale corpus, the experimental results demonstrated that our proposed approach outperforms the baseline on GLUE tasks with faster convergence speed.

2 Related Work

To reduce the memory footprint and improve the training speed of pre-trained language models, prior works have shown that architecture-based approaches are very useful. Sanh et al. (2019) proposed to leverage knowledge distillation to train a smaller version of BERT with faster training speed while maintaining comparative performance. Lan et al. (2020) used factorized embedding parameterization and cross-layer parameter sharing, which led to the reduction of parameter size and training time. de Wynter and Perry (2020) applied neural architecture search to select the optimal architecture of BERT and successfully compressed the size of the model. Task-based approaches have also been explored for pre-training language models with high training efficiency. Yang et al. (2019) introduced permutation language modeling which retains the benefits of autoregressive models and allows the models to capture bidirectional context. Instead of performing pre-training with MLM task, Clark et al. (2020) trained a BERT as a discriminator that determines whether each corrupted token was replaced by a generator model.

Recent studies have shown that CL is a successful approach for a wide range of machine learning applications (Soviany et al., 2021; Wang et al., 2021), including the fine-tuning of large-scale language models such as BERT (Xu et al., 2020). Some of large-scale language models like GPT-3 (Brown et al., 2020) and T5 (Raffel et al., 2020) adopted non-uniform mixing strategies which control the amount of training samples from multiple corpora. However, CL strategy has not directly been applied to pre-training large-scale language models. There exists many studies of CL which used the length of sentences or input sequences as a measure of difficulty in NLP tasks including neural machine translation (Kocmi and Bojar, 2017), sentiment analysis (Cirik et al., 2016), parsing (Spitkovsky et al., 2009), poem generation (Rajeswar et al., 2017) and reading comprehension task (Tay et al., 2019). In this work, we exploit the block-size of input text in the context of self-attention mechanism as a measure of difficulty for pre-training BERT.

3 Method

The overview of the proposed CL method is presented in Figure 1. The method is divided into two stages: (a) Splitting a corpus based on specific block-sizes and (b) Gradual training of BERT by increasing the block-size. In the first stage, we split the original corpus into a series of input blocks with the pre-defined length. In the second stage, we train a model by changing the training samples from the short block-size to the long one depending on the pre-defined number of training steps. In training, some tokens in a block are randomly masked to perform the MLM task. We describe the MLM task and the details of the two stages of our
CL approach in this section.

3.1 Masked Language Modeling (MLM)

Let \( x = x_1, x_2, \ldots, x_T \) denotes a sequence of original tokens, where \( T \) is a block-size. By randomly masking an arbitrary number of tokens, we obtain an input sequence \( \hat{x} \). Given the corrupted sequence \( \hat{x} \), MLM is a task of predicting the original sequence \( x \). The training objective is formulated as:

\[
\max_{\theta} \log p_\theta(x | \hat{x}) \approx \sum_{i=1}^{T} m_i \log p_\theta(x_i | x_{<i}, x_{>i})
\]

where \( x_i \) is the predicted token at position \( i \) and \( \theta \) is the parameters of a model. \( m_i \) indicates the presence of a masked token where \( m_i = 1 \) if \( x_i \) is masked, otherwise \( 0 \). For this objective, we optimize the model parameters using the cross-entropy loss. In the MLM task, models infer masked tokens from bi-directional context \( (x_{<i} \text{ and } x_{>i}) \). The block-size restricts the available context information in both directions and thus affects the MLM accuracy.

3.2 Splitting a Corpus Based on Block-sizes

In the first stage, we split the original corpus into training samples with the specified size. Each input text for training BERT is not a linguistically coherent unit like a sentence or multiple sentences, but a fixed span of contiguous text (Devlin et al., 2019) that we called a block. In other words, the input is not guaranteed to end with a period nor start with a first word in a sentence. Liu et al. (2019) argues that it is desirable to acquire the input sequence to be at most 512 tokens through the extensive experiments. We follow this setting to obtain the block of a specified length from the corpus as a training sample. We train a byte-level Byte-Pair Encoding (BPE) tokenizer as in (Radford et al., 2019) to split the raw text into a sequence of tokens. By using byte-level BPE, we can decompose all words including out-of-vocabularies, which are likely to appear at test time especially when using a small training dataset. In the experiment, we set the vocabulary size to 20,000.

3.3 Gradual Training

In the second stage, we train a model step-by-step with four different block-sizes which are 64, 128, 256, and 512. We first train the model with the shortest block-size, which is 64 in this case, for an arbitrary number of steps. Then, we retrain the model in the order of 128 and 256 block-sizes respectively for the same number of steps. Finally, we retrain the model with the longest block-size of 512 until it converges. For masking tokens, we use the fixed masking rate of 0.15. When restarting the training, we always initialize the learning rate. To accelerate training, we use the maximum available batch-size depending on the block-size. Since our proposed method is designed to limit the block-size in the early training phase, we employ larger batch-size with shorter block-size which improves the whole training efficiency.

4 Experiments

In the experiments, we evaluate our proposed CL approach in terms of the convergence speed and model performance. We use wikinet-2 (Merity et al., 2019)
Figure 2: Comparison of our approach and the baseline on the validation losses. Left (a): The result of CL which increases the block-size with the maximum available batch-size. Right (b): The result of CL which increases block-sizes with the fixed batch size (16). Black dotted lines indicates the points where the block-size of training samples is changed, and the red dotted line indicates each convergence point.

et al., 2016) for pre-training RoBERTa (Liu et al., 2019), which is a variant of BERT. For fine-tuning on down-stream tasks, we use the General Language Understanding Evaluation (GLUE) dataset (Wang et al., 2018). All the training and fine-tuning were carried out on a GeForce RTX3090 with 24GB memory.

4.1 Datasets

Wikitext-2: Although BERT and its variants (e.g. RoBERTa) are commonly trained with large-scale corpora which contain over 3 billion words, we use wikitext-2 (Merity et al., 2016) which is a small corpus to enable pre-training with a limited computational resource. Wikitext-2 is one of the standard corpora for language models, and consists of 720 good-quality articles from English Wikipedia. It has about 2M tokens for training, and 217K and 245K tokens for validation and testing respectively.

GLUE Benchmarks: We fine-tune our models on the GLUE benchmarks (Wang et al., 2018). GLUE consists of nine datasets for measuring the generalization performance of pre-trained language models. We use only 7 datasets (SST-2, MRPC, QQP, MNLI-m, QNLI, RTE, and WNLI) out of the 9 GLUE benchmarks. CoLA and STS-B are removed due to a tendency to fall into over-fitting which stems from the small-scale pre-training.

4.2 Training Details

We perform both curriculum training and anti-curriculum training in the pre-training of RoBERTa. In curriculum training, we increase the block-size of training samples from the shortest to the longest. On the other hand, in anti-curriculum training, training samples with the longest block-size are first given to the model as the most difficult ones, then the difficulty-level of training samples is gradually reduced by shortening the block-size in the training process. By comparing curriculum training with anti-curriculum training, which follows the opposite sampling order, we show that increasing block-size is an effective CL method for pre-trained language representation models.

For all the models, we use the same RoBERTa-base architecture which has 12 layers with a hidden size of 768. Each layer has 12 attention heads. We
use AdamW (Loshchilov and Hutter, 2017) with a learning rate of 1e-5 in the pre-training with four different batch-sizes depending on the block-sizes as shown in Table 2. In fine-tuning, we also use the same optimizer as used in pre-training and set a learning rate to 5e-5 and batch-size to 64 for all task except for QNLI where we use learning rate of 2e-5 and batch-size of 16 due to the memory limitation.

We define the training time of the overall curriculum training as a total of the training time for every training phase corresponding to each block-size. In both curriculum training and anti-curriculum training, our models are trained for 10,000 steps with each block-size except for the last block-size where we continue the training until the convergence of the models. For comparative evaluation, we train RoBERTa without CL by using random sampling as the baseline model.

### 4.3 Results

#### 4.3.1 Convergence Speed

Figure 2(a) shows the comparison of our curriculum model which increases the block-size with the maximum available batch-size and the baseline on the validation losses throughout pre-training. Compared to the loss of the baseline model that converged at around 5.0, the loss of curriculum model decreased steadily and achieved the faster convergence speed outperforming the baseline by about 2 points in validation loss. The learning curve of the baseline model were plateau until 35K steps, and then the loss finally restarted to descend. On the other hand, the loss of the curriculum model stably decreased every time we switched the difficulty-level of training samples. To analyze the effect of increasing a batch-size on convergence speed, we demonstrated an ablation study by fixing the batch-size to 16 (which is the maximum size when block-size is set to 512). Figure 2(b) shows the result of the curriculum model which increases block-size with the fixed batch-size. Compared to the our proposed curriculum model (Figure 2(a)), it required about 60K steps to converge, which is the same training time as the baseline. This result indicates that CL improves final performance but does not contribute to the convergence speedup in case the batch-size is fixed.

Table 1 presents the statistical information about the training of the baseline and each curriculum phase. While the baseline model converged after about 60K steps, our curriculum model required just 40K steps in total, which is about 1.5 times faster than the baseline. Although using the large batch-size depending on the small block-size tended to take long training time, it allows training a large number of training samples and the total training time was reduced by about 1.0 hours. Table 2 represents the comparison of training efficiency between the baseline and our curriculum model. With respect to the training samples per second, curriculum model achieved better training efficiency, which is 5 times as higher as the baseline, and also resulted in much better validation loss.

#### 4.3.2 GLUE Results

Table 3 shows the GLUE scores on development datasets. For all 6 down-stream tasks, our curriculum model at the bottom of the table outperformed the baseline model at the top. Especially, performances on STS-2, MRPC, QQP, MNLI-m and QNLI were higher than the baseline by a large margin (+4.47 on SST-2, +3.19 on MRPC, +6.48 F1 score and +3.37 accuracy on QQP, 8.89 on MNLI-m, and 15.74 on QNLI) while accuracy on RTE and WNLI were extremely low in both curriculum and baseline. Although each scores of our model is not high due to the small-scale pre-training, relative improvements of scores by CL were generally observed.

4.3.3 Comparison with Anti-Curriculum

Compared with our curriculum model, performances of anti-curriculum model were lower on every down-stream tasks. This result indicates that not decreasing but increasing a block-size is the effective for improving the generalization performances. Interestingly, the performances of anti-curriculum were better or equal to the baseline in all tasks except for QNLI. One possible reason for this result is that generating training samples with various block-sizes may have the same impact as data augmentation. Anti-curriculum model, however, failed to learn the QNLI task because the model is optimized for short text like 64 tokens at the end while the input of QNLI contains samples whose input length is longer than 64.

4.3.4 Ablation Study

As an ablation study, we tested two types of models including 3-stage curriculum and 2-stage curriculum. For the 3-stage curriculum, we removed a specific block-size from our training schedule and conducted the CL with the rest of block-sizes. For 2-stage curriculum, we trained the model only with the shortest block-size (64 tokens) and longest one (512 tokens).

As Table 3 shows, our curriculum model with the full training schedule is equal to or slightly better than the 2-stage or 3-stage models on each down-stream tasks. However, for tasks where performance gaps are not significant, the 2-stage and 3-stage curricula are more advantageous because of the shorter training time. As in the case of the anti-curriculum, the curriculum model without block-size of 512 tokens, that was not optimized for the largest block-size, had lower performance in QNLI. The 2-stage curriculum, which requires the least amount of training time, achieved almost the same accuracy as the normal curriculum in MRPC and MNLI-m, but relatively poor performance in tasks such as SST-2. These experiments show that there is room to further speed-up of CL by modifying the curriculum schedule on the block-size. Moreover, the result also indicates that the impact of CL on the performance will be different depending on each down-stream task.

5 Conclusion

In this paper, we proposed a new CL method for pre-training BERT, which progressively increase a block-size of input text. Our approach is very simple and thus handy to implement. Experiments in the low-resource setting have shown that proposed method leads to faster convergence speed and better performances in down-stream tasks. In further research, we expand the corpus and validate the scalability of our approach. In addition, we speculate that it is important to investigate when the difficulty-level should be changed through the training and how it affect model performances.

Abstract

With the emergence of the COVID-19 pandemic, the political and the medical aspects of disinformation merged as the problem got elevated to a whole new level to become the first global infodemic. Fighting this infodemic is currently ranked very high on the list of priorities of the World Health Organization, with dangers ranging from promoting fake cures, rumors, and conspiracy theories to spreading xenophobia and panic. With this in mind, we studied how COVID-19 is discussed in Bulgarian social media in terms of factuality, harmfulness, propaganda, and framing. We found that most Bulgarian tweets contain verifiable factual claims, are factually true, are of potential public interest, are not harmful, and are too trivial to fact-check; moreover, zooming into harmful tweets, we found that they spread not only rumors but also panic. We further analyzed articles shared in Bulgarian partisan pro/con-COVID-19 Facebook groups and found that propaganda is more prevalent in skeptical articles, which use doubt, flag waving, and slogans to convey their message; in contrast, concerned ones appeal to emotions, fear, and authority; moreover, skeptical articles frame the issue as one of quality of life, policy, legality, economy, and politics, while concerned articles focus on health & safety.

1 Introduction

The ongoing global COVID-19 pandemic has brought an unprecedented situation with a lot of uncertainty: as this was a new disease, very little was known about it. This created an information void, where there was a lot of demand but little supply of reliable new information: a perfect breeding ground for all kinds of rumors and conspiracy theories, whose spread was facilitated by social media, which in turn optimized for user engagement (yet, later, they did put serious efforts in trying to limit the spread of false claims about COVID-19).

Unlike previous events that attracted a lot of disinformation, the emergence of the COVID-19 pandemic gave rise to a new powerful blending of medical and political disinformation, which resulted in the first global infodemic. Indeed, shortly after having declared the COVID-19 outbreak a pandemic, the World Health Organization had to engage in counter-measures against the growing infodemic, which it ranked among its top priorities in the fight against the COVID-19 pandemic.¹

Figure 1 shows some tweets that demonstrate how COVID-19 is discussed in Bulgarian social media. We can see that the problem goes beyond factuality: while some tweets spread rumors (Figure 1a), other discuss cure (Figure 1b). Indeed, the infodemic quickly extended to promoting bad cure, instilling panic, xenophobia, racism, and distrust in authorities, among others. (Alam et al., 2021b)

Figure 1: Bulgarian tweets with English translation.
Thus, it is important to analyze social media posts in terms of factuality, harmfulness, checkworthiness, etc. It is also useful to understand whether the post is propagandistic, what propaganda techniques are used, and how the issue is framed. While there have been studies focusing on (some of) these issues for high-resource languages such as English and Arabic (Barrón-Cedeño et al., 2020; Hossain et al., 2020; Li et al., 2020; Alam et al., 2021b; Nakov et al., 2021a,c), there has been less work for low-resource languages such as Bulgarian (Dinkov et al., 2019; Alam et al., 2021d; Shaar et al., 2021b,c). Here, we aim to bridge this gap by analyzing tweets and Facebook posts about COVID-19 in Bulgarian, with focus on factuality, harmfulness, propaganda, and framing.

Our contributions can be summarized as follows:

- We create a dataset of tweets and Facebook posts related to COVID-19.\(^2\)
- We perform analysis from various perspectives (factuality, harmfulness, propaganda, and framing), and we discuss some interesting observations from our analysis.

The rest of the paper is organized as follows: Section 2 offers a brief overview of previous work. Section 3 describes the dataset. Section 4 discusses our methodology. Section 5 discusses the findings. Finally, Section 7 concludes and points to possible directions for future work.

2 Related Work

Below, we discuss work relevant to our analysis, focusing on factuality, check-worthiness, propaganda, framing, and fighting the COVID-19 infodemic.

2.1 Factuality

A variety of task formulations have been proposed to address the spread of misinformation and disinformation online, and for each formulation, a number of approaches have been developed. Some good readings on the topic include surveys such as that by Shu et al. (2017), who adopted a data mining perspective on “fake news” and focused on social media. Another survey (Zubiaga et al., 2018) studied rumor detection in social media. The survey by Thorne and Vlachos (2018) took a fact-checking perspective on “fake news” and related problems. Li et al. (2016) covered truth discovery in general. Lazer et al. (2018) offered an overview and discussion on the science of “fake news”. Vosoughi et al. (2018) focused on the proliferation of true and false news online. Other recent surveys focused on stance detection (Küçük and Can, 2020), propaganda (Nakov et al., 2021b), social bots (Ferrara et al., 2016), false information (Zannettou et al., 2019), and bias on the Web (Baesa-Yates, 2018).

Some very recent surveys featured stance for misinformation and disinformation detection (Hardalov et al., 2021), automatic fact-checking to assist human fact-checkers (Nakov et al., 2021b), predicting the factuality and the bias of entire news outlets (Nakov et al., 2021d), and multimodal disinformation detection (Alam et al., 2021a). A large body of research has focused on developing automatic systems for fact-checking to limit the spread of disinformation and misinformation (Li et al., 2016; Hardalov et al., 2016; Shu et al., 2017; Lazer et al., 2018; Mihaylova et al., 2018; Vosoughi et al., 2018; Nguyen et al., 2020). This includes development of datasets (Wang, 2017; Augenstein et al., 2019), and organizing evaluation campaigns (Derczynski et al., 2017; Nakov et al., 2018; Da San Martino et al., 2019; Elsayed et al., 2019; Gorrell et al., 2019; Mihaylova et al., 2019; Barrón-Cedeño et al., 2020; Nakov et al., 2021c; Shaar et al., 2021b). However, there are credibility issues with automated systems (Arnold, 2020). Hence, another research direction has emerged: building tools to facilitate human fact-checkers (Nakov et al., 2021b).

2.2 Check-Worthiness Estimation

Most work on check-worthiness focused on political debates and speeches. This includes the ClaimBuster (Hassan et al., 2015) and the ClaimRank systems (Jaradat et al., 2018), shared tasks at CLEF (Atanasova et al., 2018, 2019, 2020, 2021c), modeling the context of the claim (Gencheva et al., 2017; Patwari et al., 2017; Shaar et al., 2021a), and multi-task learning from the decisions of multiple fact-checking organizations (Vasileva et al., 2019).

There has been less research on identifying check-worthy claims in social media posts. Previous work in this direction includes check-worthiness estimation of COVID-19 and political tweets (Alam et al., 2021d,b; Shaar et al., 2020, 2021b,c).
More directly related to our work here is the work of Alam et al. (2021d) and Alam et al. (2021b), who developed a multi-question annotation schema to annotate tweets about COVID-19, organized around seven questions that model the perspective of journalists, fact-checkers, social media platforms, policymakers, and the society. In our experiments, we use their schema and data to train classifiers for part of our analysis.

2.3 Propaganda

Propaganda is a communication tool, deliberately designed to influence the opinions and the actions of other people in order to achieve a predetermined goal. Computational propaganda is defined as the use of automated approaches to intentionally disseminate misleading information on social media platforms (Woolley and Howard, 2018).

Most research on propaganda detection has focused on analyzing textual content (Barrón-Cedeno et al., 2019; Rashkin et al., 2017; Da San Martino et al., 2019, 2020a). Rashkin et al. (2017) developed the TSHP-17 corpus, which uses document-level annotation and is labeled with four classes: trusted, satire, hoax, and propaganda. They trained a model using word n-gram representation with logistic regression and reported that the model performed well only on articles from sources that the system was trained on. Barrón-Cedeno et al. (2019) developed the QProp corpus with two labels: propaganda vs. non-propaganda. They also experimented on TSHP-17 and QProp corpora, where for the TSHP-17 corpus, they binarized the labels: propaganda vs. any of the other three categories. Similarly, Habernal et al. (2017, 2018) developed a corpus with 1.3k arguments annotated with five fallacies, including ad hominem, red herring, and irrelevant authority, which directly relate to propaganda techniques.

A more fine-grained propaganda analysis was done by Da San Martino et al. (2019), who developed a corpus of news articles annotated with 18 propaganda techniques. Subsequently, the Prta system was released (Da San Martino et al., 2020b), and improved models were proposed, focusing on interpretability (Yu et al., 2021) or addressing the limitations of transformers (Chernyavskiy et al., 2021). Very recently, multimodal content was explored in memes using 22 fine-grained propaganda techniques (Dimitrov et al., 2021a,b).

2.4 Framing

Framing is a strategic device and a central concept in political communication, for representing different salient aspects and perspectives for the purpose of conveying the latent meaning about an issue (Entman, 1993). It is important for news media as the same topics can be discussed from different perspectives, which can influence our understanding, beliefs, and attitudes regarding what is happening in our society. There has been recent work on automatically identifying media frames, which includes developing coding schemes and datasets such as the Media Frames Corpus (Card et al., 2015), developing systems to automatically detect media frames (Liu et al., 2019; Zhang et al., 2019), large scale automatic analysis of New York Times Articles (Kwak et al., 2020), and a semi-supervised approach to detecting frames in online news sources (Cheeks et al., 2020).

2.5 COVID-19 Research

Since the beginning of the COVID-19 pandemic, there has been a large number of work on fighting the COVID-19 infodemic. Most notable work includes developing multi-question annotation schemas of tweets about COVID-19 (Alam et al., 2021d,b), studying credibility (Cinelli et al., 2020; Pulido et al., 2020; Zhou et al., 2020), racial prejudices and fear (Medford et al., 2020; Vidgen et al., 2020), situational information, e.g., caution and advice (Li et al., 2020), as well as on detecting mentions and stance with respect to known misconceptions (Hossain et al., 2020).

Another less relevant research line is on the development of datasets of tweets about COVID-19 (Cinelli et al., 2020; Song et al., 2021; Zhou et al., 2020; Haouari et al., 2021)

3 Dataset

Tweets: Using the Twitter API, we collected 30k tweets from January 2020 till November 2020. We performed search by specifying the target language to be Bulgarian and asking for the tweet to contain the following keywords and hashtags related to COVID-19 (English translations are shown in bleu color):

#корона, #коронавирус, коронавирус, корона
#corona, #coronavirus, coronavirus, corona
We only selected original tweets (no retweets or replies), we removed duplicates using a similarity-based approach (Alam et al., 2021c), and we filtered out tweets with less than five words. Finally, we selected the most frequently liked and retweeted tweets for annotation. For our analysis, we manually annotated 4k of them using the multi-question annotation schema from (Alam et al., 2021b), with three annotators per tweet (a total of 11k annotations). This Bulgarian data is also used in (Alam et al., 2021d) and for the CLEF 2021 CheckThat! lab task 1 (Shaar et al., 2021).

**Articles in Facebook posts:** We further collected articles posted in Bulgarian Facebook groups that discuss COVID-19. We focused on concerned, skeptical, and conspiracy groups; the list is shown in Figure 3. We collected the links to articles posted in these groups, and we manually annotated each article as skeptical or concerned.

**4 Method**

Figure 2 shows our analysis pipeline. Below, we discuss each element of the pipeline in more detail.

**4.1 Manual Annotation**

The manual tasks consist of multi-question disinformation annotation of tweets and also of skeptical vs. concerned articles posted on Facebook.

**Concerned**

(10.9k) Covid-19: факти срещу слухове
(10.9k) Covid-19: facts against rumors
(2.4k) Коронавирус/COVID-19 - само валидирана информация
(2.4k) Coronavirus / COVID-19 - validated information only
(1.0k) Здрав разум за здрава държава
(1.0k) Common sense for a healthy state

**Skeptical**

(14.8k) Аз подкрепям доцент Мангъров
(14.8k) I support Associate Professor Mangarov

(0.2k) Crown virus COVID-19 or major manipulation

Figure 3: Facebook groups we collected articles from.

**4.1.1 Disinformation Annotation for Tweets**

For the disinformation analysis, we used the holistic approach in (Alam et al., 2021b). It is formulated into seven questions, asking whether a tweet (Q1) contains a verifiable factual claim, (Q2) is likely to contain false information, (Q3) is of interest to the general public, (Q4) is potentially harmful to a person, a company, a product, or society, (Q5) requires verification by a fact-checker, (Q6) poses harm to society and why, or (Q7) requires the attention of policy makers and why. Three annotators worked on each tweet, following the annotation guidelines in (Alam et al., 2021b).
The annotators were fluent in Bulgarian, two were male and one was female, with qualifications ranging from undergraduates to people with a MSc degree. For disagreed annotations, a final consolidator participated in the discussion to decide the final label. We computed the inter-annotator agreement between the annotators and the final consolidated label using Fleiss Kappa ($\kappa$) as shown in Table 1. We can see that there was moderate to substantial agreement between the human annotators across the questions, according to the range of values for $\kappa$ suggested in (Landis and Koch, 1977).

<table>

Table 1: Inter-annotator agreement using Fleiss Kappa for the 7-level annotation for disinformation in tweets.

4.1.2 Skeptical vs. Concerned Annotation for Articles Posted on Facebook

The same annotators further annotated the Facebook articles as skeptical or concerned. This was a fairly straightforward task, with almost no disagreement. Note that we analyzed each article manually to decide whether it is skeptical or concerned (rather than using distant supervision to propagate the label for the group to label articles automatically, even though the vast majority of articles could be labeled with the label of the group).

4.2 Automatic Classification

For the analysis of propaganda and framing, both for tweets and for news articles, we used the automatic models discussed below.

4.2.1 Propaganda Analysis

For this analysis, we used Proppy and Prta.

Proppy (Barrón-Cedeño et al., 2019) uses a fragment-level and a sentence-level classifier. They were trained on a corpus of 350K tokens. The performance of the sentence-level classifier is 60.71 in terms of F1 score. The fragment-level classifier identifies the text fragments and the propaganda techniques that occur in them. They consider the following 18 techniques: (i) loaded language, (ii) name calling or labeling, (iii) repetition, (iv) exaggeration or minimization, (v) doubt, (vi) appeal to fear/prejudice, (vii) flagwaving, (viii) causal oversimplification, (ix) slogans, (x) appeal to authority, (xi) black-and-white fallacy, dictatorship, (xii) thought-terminating cliché, (xiii) whataboutism, (xiv) reductio ad Hitlerum, (xv) red herring, (xvi) bandwagon, (xvii) obfuscation, intentional vagueness, confusion, and (xviii) straw man.

Note that both Proppy and Prta only support English. To prepare their input, we translated the Bulgarian text to English using Google.

4.2.2 Framing

We used the Tanbih Framing Bias Detection system (Zhang et al., 2019), trained on the Media Frames Corpus (11k training news articles) by fine-tuning BERT to detect topic-agnostic media frames, achieving accuracy of 66.7% on the test set (1,138 news articles). It can predict the following 15 frames: (i) economy, (ii) capacity and resources, (iii) morality, (iv) fairness and equality, (v) legality, constitutionality and jurisprudence, (vi) policy prescription and evaluation, (vii) crime and punishment, (viii) security and defense, (ix) health and safety, (x) quality of life, (xi) cultural identity, (xii) public opinion, (xiii) politics, (xiv) external regulation and reputation, and (xv) other.

5 Results and Discussion

Below, we present the results of our analysis.

5.1 Disinformation Analysis

Figure 4 shows a detailed distribution for each question. We can see that (i) most tweets contain a verifiable factual claim, (ii) about half of the tweets are factually true, (iii) most of them are of general interest to the public, (iv) about half of the tweets are not harmful to the society, to a person, a company, or a product, (v) many tweets are trivial to fact-check, (vi) some tweets spread rumors, panic, or make a joke.
5.2 Propaganda Analysis

**Propaganda** Figure 5 shows the results for the propaganda analysis of tweets associated with check-worthiness and harmfulness. We can see that check-worthy tweets are more propagandistic (right-side bars in Figure 5a). A large portion of them (left-side bars) are neither check-worthy nor propagandistic. On Figure 5b, we can see that harmful tweets (i.e., such spreading rumors, conspiracy, and panic) are (somewhat) more propagandistic than non-harmful ones.

Figure 5c shows the propaganda analysis for articles posted in Facebook groups. We can see that skeptical articles are more propagandistic.

**Propaganda Techniques** A more fine-grained analysis is important in order to understand the type of content that is shared/posted in social media. Thus, we analyzed tweets by categorizing them using propaganda techniques. Figure 6 shows a propaganda technique analysis for the tweets, which are also labeled for check-worthiness and harmfulness.
5.3 Framing

Our analysis of framing in tweets shows that *economy* is the dominant perspective, *health and safety* come second, and *legality* is third. Figure 7 reports the distribution of tweets manually annotated for check-worthiness and harmfulness and automatically analyzed for framing. Figure 7a shows that the most frequent check-worthy tweets are associated with *health, legality, crime and punishment*, whereas non-check-worthy are associated with *economy, politics, and quality of life*. Figure 7b reports the distribution of the framing and the harmfulness labels. Frames labeled as *economy* are non-harmful; *cultural identity, crime and punishment* are associated with rumor/conspiracy, while *health and safety* frames show panic.

Figure 7c reports the distribution of articles manually categorized as skeptical vs. concerned and automatically analyzed for framing. The plot shows that skeletal articles are associated with *quality of life, policy, legality, economy*, and *politics*, whereas concerned articles are associated with *health and safety*, and *cultural identity*.

6 Limitations

**Manual annotations** Our manual annotation for disinformation in tweets shows moderate to substantial agreement across the questions. We believe that this is reasonable given the complexity of the task.

**Automatic analysis** The performance of the automatic analysis varies across the different tasks (e.g., for propaganda analysis vs. framing), which can introduce noise in the results.

**Translation** We needed to translate the text from Bulgarian to English, which can add noise in case of translation errors. Although we performed a qualitative analysis on a sample of propaganda annotations and we found a good quality for our model’s predictions, in future work, we would like to train a model directly for Bulgarian.

7 Conclusion and Future Work

We presented our analysis of COVID-19 in Bulgarian social media with focus on tweets and on news articles posted in Facebook groups, which we collected in different time frames starting from January till November 2020. Then, we manually and automatically analyzed them using different aspects of disinformation, propaganda, and framing.
Figure 6: Propaganda techniques.

We believe that the kind of analysis we perform here would help in better understanding various trends in social media about COVID-19. See also a related study about COVID-19 and vaccines in Qatar (Nakov et al., 2021a).

There are a number of interesting research directions that could be pursued using the approaches we used in this study. While we only focused on Twitter and Facebook, similar analysis can be done on other platforms e.g., WhatsApp, Gab, Reddit.
Figure 7: Framing.

Acknowledgments

We would like to thank the Atlantic Club in Bulgaria and DataBee for helping us with the manual analysis of Bulgarian tweets and of news articles posted on Facebook. We further thank the anonymous reviewers for their constructive comments.

This research is part of the Tanbih mega-project (http://tanbih.qcri.org), developed at the Qatar Computing Research Institute, HBKU, which aims to limit the impact of “fake news”, propaganda, and media bias by making users aware of what they are reading, thus promoting media literacy and critical thinking.

Abstract

While COVID-19 vaccines are finally becoming widely available, a second pandemic that revolves around the circulation of anti-vaxxer “fake news” may hinder efforts to recover from the first one. With this in mind, we performed an extensive analysis of Arabic and English tweets about COVID-19 vaccines, with focus on messages originating from Qatar. We found that Arabic tweets contain a lot of false information and rumors, while English tweets are mostly factual. However, English tweets are much more propagandistic than Arabic ones. In terms of propaganda techniques, about half of the Arabic tweets express doubt, and 1/5 use loaded language, while English tweets are abundant in loaded language, exaggeration, fear, name-calling, doubt, and flag-waving. Finally, in terms of framing, Arabic tweets adopt a health and safety perspective, while in English economic concerns dominate.

1 Introduction

During the COVID-19 pandemic, social media have become one of the main communication channels for information dissemination and consumption, and many people rely on them as their primary source of news (Perrin, 2015), attracted by the broader choice of information sources. Unfortunately, over time, social media have also become one of the main channels to spread disinformation. To tackle this issue, a number of (mostly manual) fact-checking initiatives have been launched, and there are over 200 fact-checking organizations currently active worldwide. 1 However, these efforts are insufficient, given the scale of disinformation, which, in the time of COVID-19, has grown into the First Global Infodemic (according to the World Health Organization).

Figure 1: Tweets about COVID-19 and vaccines.

(a) rumor in Arabic and English

Military helicopters spray pesticides against Coronavirus. This is rumor!

(b) action taken

Qatar has signed a deal with @moderna_tx to buy its COVID-19 #vaccine when it is approved and released for global use.

(c) panic

Modernina COVID vaccine has caused side effect for those with cosmetic facial fillers foxnews.com/ue/moderna-cov... #FoxNews

(d) joke

I’ve just been informed that although the Covid vaccine won’t contain microchips, it will have the new U2 album

(e) bad cure

Nameste Twitter 😁

Today I wanna share something useful & effective for all of us 😊

GOOD NEWS!!! Wuhan’s Corona virus can cure itself by a bowl of freshly boiled garlic water. The old Chinese doctor proved its effectiveness. Many patients have also proven it to be effective.

Figure 1 shows examples of how online users discuss COVID-19 and vaccines. We can see that the problem goes beyond factuality: there are tweets spreading rumors, discussing action taken, instilling panic, making jokes, and promoting bad cure.

1 http://tiny.cc/zdlfnz
For the tweets in Figure 1, we might want to know whether they are factual, harmful, calling for action, etc. (see Section 4.1). It is also important to understand whether the content of the tweet is propagandistic (Section 4.2), what propaganda techniques are used, as well as the way the issue is framed (Section 4.3). Doing this in a timely manner is crucial to help organizations channel their efforts, and to counter the spread of disinformation, which may cause panic, mistrust, and other problems.

With this in mind, we performed an extensive analysis of Arabic and English tweets about COVID-19 and vaccines, with focus on messages originating from Qatar. Our analysis focuses on (i) COVID-19 disinformation, (ii) propaganda and its techniques, and (iii) framing.

Our contributions can be summarized as follows:

- We build and release a dataset of tweets related to COVID-19 and vaccines in Arabic and English.²
- We analyze the tweets from various perspectives (factuality, harmfulness, propaganda, and framing), and we discuss some interesting observations from our analysis.

2 Related Work

Below, we discuss relevant research directions.

2.1 Factuality

Work on fighting disinformation and misinformation online has focused on fact-checking and fake news detection (Li et al., 2016; Hardalov et al., 2016; Shu et al., 2017; Karadzhov et al., 2017; Lazer et al., 2018; Mishaylova et al., 2018; Vosoughi et al., 2018; Vo and Lee, 2018; Atanasova et al., 2019; Baly et al., 2019; Zlatkova et al., 2019; Baly et al., 2020; Nguyen et al., 2020; Shaar et al., 2020a). Research was further enabled by the emergence of datasets (Wang, 2017; Augenstein et al., 2019), often released as part of evaluation campaigns (Derczynski et al., 2017; Nakov et al., 2018; Da San Martinot et al., 2019; Elsayed et al., 2019; Gorrell et al., 2019; Mishaylova et al., 2019; Barrón-Cedeño et al., 2020; Nakov et al., 2021c,d; Shaar et al., 2021b). As automated systems have credibility issues (Arnold, 2020), another research direction has emerged: building tools to facilitate human fact-checkers (Nakov et al., 2021b).

2.2 Check-Worthiness Estimation

Given the volume of claims appearing in social media posts or in political statements, a problem that is crucial for fact-checkers is to identify which claims should be prioritized for fact-checking. The ClaimBuster system (Hassan et al., 2015) was a pioneering work in that direction. It categorized a political statement as non-factual, unimportant factual, or check-worthy factual. Gencheva et al. (2017) also focused on the 2016 US Presidential debates, for which they obtained binary (check-worthy vs. non-check-worthy) labels based on the fact-checking decisions of nine fact-checking organizations. An extension of this work was the ClaimRank system, which supports both English and Arabic (Jaradat et al., 2018). Note that political debates and speeches require modeling the context of the target sentence to classify. Indeed, context was a major focus for most research in the debates domain (Gencheva et al., 2017; Patwari et al., 2017; Vasileva et al., 2019; Shaar et al., 2021a). For example, Vasileva et al. (2019) modeled context in a multi-task learning neural network that predicts whether a sentence would be selected for fact-checking by each fact-checking organization (from a set of nine such organizations).

There has also been research on detecting check-worthy claims in social media (as opposed to the above research, which targeted political debates and speeches), featuring tweets about COVID-19 or general topics in Arabic and English (Hasanain et al., 2020; Shaar et al., 2020b, 2021c).

More directly related to our work here is the work of Alam et al. (2021c) and Alam et al. (2021a), who developed a multi-question annotation schema of tweets about COVID-19, organized around seven questions that aim to model the perspective of journalists, fact-checkers, social media platforms, policymakers, and the society. In our experiments, we use their schema and data to train classifiers for part of our analysis.

2.3 Propaganda

Propaganda is a communication tool that is deliberately designed to influence the opinions and the actions of other people in order to achieve a predetermined objective. When automatic means are being used to spread such influencing messages on social media platforms, this is referred to as computational propaganda (Woolley and Howard, 2018).

Research on propaganda detection has focused on textual content (Barrón-Cedeno et al., 2019; Rashkin et al., 2017; Da San Martino et al., 2019; Da San Martino et al., 2020a). Suitable datasets were made available by Rashkin et al. (2017) and Barrón-Cedeno et al. (2019), where the documents (news articles) were annotated using distant supervision, according to the reputation of their source, as judged by journalists. Rashkin et al. (2017) focused on analyzing the language of propaganda (vs. trusted, satire, and hoaxes) based on LIWC lexicons, while Barrón-Cedeno et al. (2019) studied a variety of stylistic features.

Habernal et al. (2017, 2018) developed a corpus annotated with five fallacies, including ad hominem, red herring, and irrelevant authority. Fine-grained propaganda analysis was done by Da San Martino et al. (2019), who developed a corpus of news articles annotated with 18 propaganda techniques. Subsequently, the Prta system was released (Da San Martino et al., 2020b), and improved models were proposed, focusing on interpretability (Yu et al., 2021) or addressing the limitations of transformers (Chernyavskiy et al., 2021). Finally, multimodal content was explored in memes using 22 propaganda techniques (Dimitrov et al., 2021a,b).

2.4 Framing

Framing refers to representing different salient aspects and perspectives for the purpose of conveying the latent meaning about an issue (Entman, 1993). Recent work on automatically identifying media frames includes developing coding schemes and semi-automated methods (Boydston et al., 2013), datasets such as the Media Frames Corpus (Card et al., 2015), and systems to automatically detect media frames (Liu et al., 2019; Zhang et al., 2019), large-scale automatic analysis of news articles (Kwak et al., 2020), and semi-supervised approaches (Cheeks et al., 2020).

2.5 Fighting the COVID-19 Infodemic

Related work on fighting the COVID-19 infodemic includes developing multi-question annotation schemes of tweets about COVID-19 (Alam et al., 2021c,a), studying credibility (Cinelli et al., 2020; Pulido et al., 2020; Zhou et al., 2020), racial prejudices and fear (Medford et al., 2020; Vidgen et al., 2020), situational information, e.g., caution and advice (Li et al., 2020), as well as detecting mentions and stance with respect to known misconceptions (Hossain et al., 2020).

3 Dataset

We collected Arabic tweets from February 2020 till March 2021. For the English tweets, we had two separate time periods (before and after COVID-19 vaccines became available): (i) from February till August 2020 (644 tweets), and (ii) from November 2020 till January 2021 (1,945 tweets). We used the following keywords to collect the tweets:

**English:** #covid19, #CoronavirusOutbreak, #Coronavirus, #Corona, #CoronaAlert, #CoronaOutbreak, Corona, covid-19, COVID vaccine, Covid-19 vaccine, #covidvaccine, corona vaccine, #vaccinate, #vaccine, vaccine

**Arabic:** كورونا, كورونا الجديد, #فيروس كورونا المستجد, #فيروس كورونا, #فیروس کورونا, #فیروس کورونا, #فیروس کورونا, #کورونا, #کورونا الجدید, لقاء, معلومات, تطعيم, لقاءات.

We collected original tweets (no retweets or replies), we removed the duplicates using the similarity-based approach in Alam et al. (2021b), and we filtered out tweets with less than five words. Finally, we kept the most frequently liked and retweeted tweets for annotation. Our final corpus consists of 606 Arabic and 2,589 English tweets.

4 Method

Figure 2 shows the architecture of our system. Below, we discuss each analysis step in detail.

4.1 Disinformation Analysis

For disinformation analysis, we used the dataset from (Alam et al., 2021c,a), which is organized around seven questions: asking whether the tweet (Q1) contains a verifiable factual claim, (Q2) is likely to contain false information, (Q3) is of interest to the general public, (Q4) is potentially harmful to a person, a company, a product, or the society, (Q5) requires verification by a fact-checker, (Q6) poses harm to society, or (Q7) requires the attention of policy makers. The dataset consist of 504 English and 218 Arabic tweets, and we used it to train an SVM classifier, whose hyper-parameters we optimized using 10-fold cross-validation. Table 1 shows the performance of the classifier for English and Arabic for all questions. Note the multiclass nature of the tasks and the skewed class distribution for Q2 to Q6 (Alam et al., 2021a).
The **Prta system** offers a fragment-level and a sentence-level classifiers. They were trained on a corpus of 350K tokens. The performance of the sentence-level classifier is 60.71 in terms of F1 score. The fragment-level classifier identifies the text fragments and the propaganda techniques that occur in them. They consider the following 18 techniques: (i) Loaded language, (ii) Name calling or labeling, (iii) Repetition, (iv) Exaggeration or minimization, (v) Doubt, (vi) Appeal to fear/prejudice, (vii) Flag-waving, (viii) Causal oversimplification, (ix) Slogans, (x) Appeal to authority, (xi) Black-and-white fallacy, dictatorship, (xii) Thought-terminating cliché, (xiii) Whataboutism, (xiv) Reductio ad Hitlerum, (xv) Red herring, (xvi) Bandwagon, (xvii) Obfuscation, intentional vagueness, confusion, and (xviii) Straw man.

Note that both Proppy and Prta were developed for English. Thus, for the classification of Arabic content, we first translated it to English using the Google translation API, and then we ran the tools.

### 4.3 Framing

We used the **Tanbih Framing Bias Detection system** (Zhang et al., 2019), trained on the Media Frames Corpus (11k training news articles) by fine-tuning BERT to detect topic-agnostic media frames, achieving accuracy of 66.7% on the test set (1,138 news articles). It can predict the following 15 frames: (i) Economy, (ii) Capacity and resources, (iii) Morality, (iv) Fairness and equality, (v) Legality, constitutionality and jurisprudence, (vi) Policy prescription and evaluation, (vii) Crime and punishment, (viii) Security and defense, (ix) Health and safety, (x) Quality of life, (xi) Cultural identity, (xii) Public opinion, (xiii) Politics, (xiv) External regulation and reputation, and (xv) Other.

### 5 Results and Discussion

#### 5.1 Disinformation Analysis

**Arabic:** Figure 3 shows the distribution for the questions for Arabic. We can see that (i) most tweets contain a verifiable factual claim, (ii) about half of the tweets contain false information, (iii) most tweets are of general interest to the public, (iv) about half of the tweets are harmful to the society, a person, a company, or a product (Question 6), (v) many tweets are worth fact-checking, (vi) most tweets are not harmful to the society, and many spread rumors, and (vii) some tweets discuss possible cure, and very few spread panic.
English: Figure 4 shows the distribution for the English tweets from February till August 2020. We can see that most tweets contain a verifiable factual claim, contain no false information, are of general interest to the public, are not harmful, and are worth fact-checking. Moreover, many tweets contain jokes, some contain rumors, and some blame the authorities.

We also analyzed the English tweets from November 2020 till January 2021. The results are shown in Figure 5, and follow a very similar trend.

Summary: Arabic tweets contain relatively more false information and rumors, some discuss possible cure, and very rarely spread panic. English tweets contain mostly factual statements, many make jokes, and rarely spread rumors.

5.2 Propaganda Analysis

Figure 6 shows the propaganda analysis in Arabic vs. English tweets. We can see that Arabic propagandistic tweets are extremely rare, while for English they about 33% of all tweets.
We also analyzed English tweets collected from November 2020 till January 2021, to cover tweets about COVID-19 vaccines, and we found that there were fewer propagandistic tweets: about 25%.

**Fine-Grained Propaganda Analysis** Next, we aimed to detect the specific propaganda techniques used in the tweets. Figure 7 shows the top propaganda techniques for Arabic and English.

We can see that, for Arabic, 50% of the tweets express doubt, and 20% use loaded language.

For English, we see a different distribution: about 33% of the tweets use loaded language, while each of the following techniques appears in about 10% of the tweets: exaggeration, fear, name-calling, doubt, and flag-waving.

Yet another trend is observed for English tweets collected from November 2020 till January 2021 (discussing vaccines): 50% of the tweets use loaded language, and each of the following four techniques appears in about 10% of the tweets: flag-waving, name-calling, and exaggeration.
5.3 Framing

Finally, we performed analysis in terms of framing, which reflects the perspective taken in the COVID-19 related tweets we analyzed. The results are shown on Figure 8.

We can see that in the Arabic tweets health and safety is the dominant frame, with economy coming second, and cultural identity being third.

For English, in both studied time periods, economy is the primary frame, and health and safety comes second.

We speculate that the difference in framing between Arabic and English tweets reflects the perspective of Qatari locals (who tweet primarily in Arabic) vs. that of expats (who tweet primarily in English). Thus, it is to be expected that the former are concerned primarily with health aspects (e.g., COVID-19 vaccination, social distancing, and other measures to keep one safe during the pandemic), while the latter worry more about the economic consequences of the pandemic (and respectively, about the security of their jobs).
6 Conclusion and Future Work

We have presented our analysis of COVID-19 tweets in Arabic and English aiming to help in the fight against the global infodemic, which emerged as a result of the COVID-19 pandemic. In particular, we collected tweets in different time frames starting from February 2020 till January 2021, and we analyzed them using different aspects of disinformation, propaganda, and framing. We believe that such analysis should help in better understanding the trends over time and across languages.

Many interesting directions could be pursued in future work. For example, the analysis could be applied to other languages; in fact, we already did a related study for Bulgarian (Nakov et al., 2021a). Moreover, while here we focused on tweets, the approach is applicable to other social media platforms such as Facebook and WhatsApp.

Abstract

Distantly supervised datasets for relation extraction mostly focus on sentence-level extraction, and they cover very few relations. In this work, we propose cross-document relation extraction, where the two entities of a relation tuple appear in two different documents that are connected via a chain of common entities. Following this idea, we create a dataset for two-hop relation extraction, where each chain contains exactly two documents. Our proposed dataset covers a higher number of relations than the publicly available sentence-level datasets. We also propose a hierarchical entity graph convolutional network (HEGCN) model for this task that improves performance by 1.1% F1 score on our two-hop relation extraction dataset, compared to some strong neural baselines.

1 Introduction

The idea of distant supervision (Mintz et al., 2009) eliminates the need for manual annotation for obtaining training data for relation extraction. Previously, this idea is used mostly to create sentence-level datasets. However, the assumption of distant supervision, that the two entities of a tuple must appear in the same sentence, is overly strict. We may not find an adequate number of evidence sentences for many relations as both entities do not appear in the same sentence. The relation extraction models built on such data can find relations only for a small number of relations and the relations of most knowledge bases (KBs) will be out of the reach of such models.

To address this issue, we propose a multi-hop relation extraction task where the subject and object entities of a tuple can appear in two different documents, and these two documents are connected via some common entities. We can create a chain of entities from the subject entity to the object entity of a tuple via the common entities across multiple documents. Each link in this chain represents a relation between the entities located at the endpoints of the link. We can determine the relation between the subject and object entities of a tuple by following this chain of relations. This approach can give training instances for more relations than sentence-level distant supervision. Following the proposed multi-hop approach, we create a two-hop relation extraction dataset for the task. Each instance of this dataset has two documents, where the first document contains the subject entity and the second document contains the object entity of a tuple. These two documents are connected via at least one common entity. This idea can be extended to create an N-hop dataset.

We also propose a hierarchical entity graph convolutional network (HEGCN) model for the task. Our proposed model has two levels of graph convolutional networks (GCNs). The first-level GCN of the hierarchy is applied to the entity mention level graph of every document to capture the relations among the entity mentions within a document. The second-level GCN of the hierarchy is applied on a unified entity-level graph, which is built using all the unique entities present in the document chain. This entity-level graph can be built on the document chain of any length and it can capture the relations among the entities across the multiple documents in the chain. Our proposed HEGCN model improves the performance on our two-hop dataset. To summarize, the following are the contributions of this paper:

(1) We propose a multi-hop relation extraction task and create a two-hop dataset. This dataset has more relations than other popular distantly supervised sentence-level or document-level relation extraction datasets.

∗ This work was done when the first author was a PhD student at the National University of Singapore.
(2) We propose a novel hierarchical entity graph convolutional network (HEGCN) for multi-hop relation extraction. Our proposed model improves the F1 score by 1.1% on our two-hop dataset, compared to strong neural baselines.\footnote{The source code and data for this paper are available at https://github.com/nusnlp/MHRE.git}

2 Task Formalization

Multi-hop relation extraction can be defined as follows. Consider two entities, a subject entity $e_s$ and an object entity $e_o$, and a chain of documents $D = \{D_s \rightarrow D_1 \rightarrow D_2 \rightarrow \ldots \rightarrow D_n \rightarrow D_o\}$ where $e_s \in D_s$ and $e_o \in D_o$. There exists a chain of entities $e_s \rightarrow c_1 \rightarrow c_2 \rightarrow \ldots \rightarrow c_{n+1} \rightarrow e_o$ where $c_1 \in \{D_s, D_1\}, c_2 \in \{D_1, D_2\}, \ldots, c_{n+1} \in \{D_n, D_o\}$. The task is to find the relation between $e_s$ and $e_o$ from a pre-defined set of relations $R \cup \{\text{None}\}$, where $R$ is the set of relations and None indicates that none of the relations in $R$ holds between $e_s$ and $e_o$. A simpler version of this task is two-hop relation extraction where $D_s$ and $D_o$ are directly connected by at least one common entity. In this paper, we focus on two-hop relation extraction.

3 Related Work

3.1 Relation Extraction Datasets

Distantly supervised datasets are very popular for relation extraction (Nayak et al., 2021). Riedel et al. (2010) (NYT10) and Hoffmann et al. (2011) (NYT11) mapped Freebase tuples to New York Times (NYT) articles to obtain such datasets. The NYT10 and NYT11 datasets have been used extensively by researchers for relation extraction. TACRED (Zhang et al., 2017) is another dataset created from the TAC KBP evaluations. FewRel 2.0 (Gao et al., 2019) is a few-shot relation extraction dataset. All these datasets are created at the sentence level. DocRED (Yao et al., 2019) is a document-level relation extraction dataset created using Wikipedia articles and Wikidata items. To the best of our knowledge, there does not exist any relation extraction dataset which involves multiple documents.

3.2 Relation Extraction Models

Neural models have performed well on distantly supervised datasets for relation extraction. Zeng et al. (2014, 2015) used convolutional network with max-pooling on word embeddings for this task, whereas Shen and Huang (2016); Jat et al. (2017); Nayak and Ng (2019) used word-level attention model for single-instance sentence-level relation extraction. Lin et al. (2016); Vashishth et al. (2018); Ye and Ling (2019) used neural networks in a multi-instance setting to find a relation from a bag of independent sentences. Recently, graph convolutional network-based (GCN) (Kipf and Welling, 2017) models have become popular for many NLP tasks. These models work on non-linear graph structures. Zhang et al. (2018); Vashishth et al. (2018); Guo et al. (2019); Zeng et al. (2020) used graph convolution networks for relation extraction. They consider each token in a sentence as a node in the graph and use a syntactic dependency tree to create a graph structure among the nodes. Recently, neural joint extraction approaches (Takanobu et al., 2019; Nayak and Ng, 2020) were proposed for this task.

3.3 Multi-hop QA versus Multi-hop RE

Welbl et al. (2018) proposed a multi-hop QA dataset (WikiHop) where the answer can only be found using more than one document. Several neural models have been proposed (Song et al., 2018; Cao et al., 2019; De Cao et al., 2019; Kundu et al., 2019) to solve this task. We have created a two-hop relation extraction dataset (THRED) from this WikiHop dataset. The major difference between these two datasets is that THRED contains many None relations, whereas in the WikiHop dataset, every instance has a correct answer. Extracting the None relation is challenging, since None occurs when no relations in $R$ exist. When the number of relations in $R$ increases, it becomes more difficult to predict the relations. As such, we believe the multi-hop RE task is more challenging than the multi-hop QA task.

4 Dataset Construction

We create a two-hop relation extraction dataset from a multi-hop question-answering (QA) dataset WikiHop (Welbl et al., 2018). Welbl et al. (2018) defined the multi-hop QA task as follows: Given a set of supporting documents $D_s$ and a set of candidate answers $C_a$ which are mentioned in $D_s$, the goal is to find the correct answer $a^* \in C_a$ for a question by drawing on the supporting documents. They used Wikipedia articles and Wikidata (Vrandečić and Krötzsch, 2014) tuples for creating this dataset. Each positive tuple $(e_s, e_o, r_p)$ in
WikiHop test data is blind and not released. We find that 76% of the selected positive samples and 82% of the selected negative samples are accurate.

### 4.1 Dataset Statistics

The training, validation, and test data of the WikiHop dataset are created using distant supervision, but the validation and test data are manually verified. WikiHop test data is blind and not released. We use their validation data to create the test data for our task and use their training data for our training and validation purposes. We include the statistics of our two-hop relation extraction dataset.

\[ (e_s, a^*, r_p) \]

is the positive tuple for relation extraction. For any other candidate answer \( e_w \in C_a - \{a^*\} \), the entity pair \((e_s, e_w)\) is considered as a None tuple if there exists no relation among the four pairs \((e_s, e_w), (e_w, e_s), (e_w, e_o)\), and \((e_o, e_w)\) in Wikidata. We check for the no relation condition for these four entity pairs involving \(e_w, e_s, e_o\) to reduce the distant supervision noise in the dataset for None tuples. We create a None candidate set \(C_n\) with each \(e_w \in C_a - \{a^*\}\). We first find all possible pairs of documents from the supporting document set \(D_s\) such that the first document of the pair contains the subject entity \(e_s\) and the second document of the pair contains either the entity \(a^*\) or one of the entities from \(C_n\). We discard those pairs of documents that do not contain any common entity. The document pairs where the second document contains the entity \(a^*\) are considered as a document chain for the positive tuple \((e_s, a^*, r_p)\) where \(r_p \in R\). All other document pairs where the second document contains an entity from the set \(C_n\) are considered as a document chain for None tuple \((e_s, e_w, None)\) where \(e_w \in C_n\). In this way, using distant supervision, we can create a dataset for two-hop relation extraction. Each instance of this dataset has a chain of documents \(D = \{D_s \rightarrow D_o\}\) of length 2 that is the textual source of a tuple \((e_s, e_o, r)\). The document \(D_s\) contains the subject entity \(e_s\) and the document \(D_o\) contains the object entity \(e_o\). The two documents are connected with at least one common entity \(c\). There exists at least one entity chain \(e_s \rightarrow c \rightarrow e_o\) in the document chain. The goal is to find the relation \(r\) between \(e_s\) and \(e_o\) from the set \(R \cup \{None\}\). We refer to this two-hop dataset as THRED (two-hop relation extraction dataset) in the remaining sections of this paper. We manually checked 100 randomly selected positive samples and 100 randomly selected negative samples, and found that 76% of the selected positive samples and 82% of the selected negative samples are accurate.

\[ D = \{D_s \rightarrow D_o\}\]
Table 1: A multi-hop question-answer instance from the WikiHop dataset. The tuple (Doc1, Zoo Lake, Doc2, Gauteng, located_in_administrative_entity) constitutes a positive instance in the THRED dataset. The tuple (Doc1, Zoo Lake, Doc3, Tanzania, None) constitutes a negative instance in the THRED dataset.

5 Proposed HEGCN Model

We propose a hierarchical entity graph convolutional network (HEGCN) for multi-hop relation extraction. We encode the documents in a document chain using a bi-directional long short-term memory (BiLSTM) layer (Hochreiter and Schmidhuber, 1997). On top of the BiLSTM layer, we use two graph convolutional networks (GCN), one after another in a hierarchy. In the first level of the GCN hierarchy, we construct a separate entity mention graph on each document of the chain using all the entities mentioned in that document. Each mention of an entity in a document is considered as a separate node in the graph. We use a graph convolutional network (GCN) to represent the entity mention graph of each document to capture the relations among the entity mentions in the document. We then construct a unified entity-level graph across all the documents in the chain. Each node of this entity-level graph represents a unique entity in the document chain. Each common entity between two documents in the chain is represented by a single node in the graph. We use a GCN to represent this entity-level graph to capture the relations among the entities across the documents. We concatenate the representations of the nodes of the subject entity and object entity and pass it to a feed-forward layer with softmax for relation classification.

5.1 Documents Encoding Layer

We use two types of embedding vectors: (1) word embedding vector $w \in \mathbb{R}^{d_w}$ (2) entity token indicator embedding vector $z \in \mathbb{R}^{d_z}$, which indicates if a word belongs to the subject entity, object entity, or common entities. The subject and object entities are assigned the embedding index of 2 and 3, respectively. The common entities in the document chain are assigned embedding index in an...
increasing order starting from index 4. The same entities present in two documents in the chain get the same embedding index. Embedding index 0 is used for padding and 1 is used for all other tokens in the documents. A document is represented using a sequence of vectors \( \{x_1, x_2, \ldots, x_n\} \) where \( x_t = w_t||z_t. \) \( || \) represents the concatenation of vectors and \( n \) is the document length. We concatenate all documents in a chain sequentially by using a document separator token. These token vectors are passed to a BiLSTM layer to capture the interaction among the documents in a chain. \( \tilde{h}_t \in \mathbb{R}^{(d_w+d_z)} \) and \( \tilde{h}_t \in \mathbb{R}^{(d_w+d_z)} \) are the output at the \( t \)th step of the forward LSTM and backward LSTM respectively. We concatenate them to obtain the \( t \)th BiLSTM output \( h_t \in \mathbb{R}^{2(d_w+d_z)} \).

5.2 Hierarchical Entity Graph Convolutional Layers

Kipf and Welling (2017) proposed graph convolutional networks (GCN) which work on graph structures. Here, we describe the GCN which is used in our model. We represent a graph \( G \) with \( m \) nodes using an adjacency matrix \( A \) of size \( m \times m \). If there is an edge between node \( i \) and node \( j \), then \( A_{ij} = A_{ji} = 1 \). We also add self loops, \( A_{ii} = 1 \), in the graph \( G \). We normalize the adjacency matrix \( A \) by using symmetric normalization proposed by Kipf and Welling (2017). A diagonal node degree matrix \( D \) of size \( m \times m \) is used in the normalization of \( A \). \( \text{deg}(v_i) \) is the number of edges that are connected to the node \( v_i \) in \( G \) and \( \hat{A} \) is the corresponding normalized adjacency matrix of \( G \). Each node of the graph receives the hidden representation of its neighboring nodes from the \( (l-1) \)th layer and uses the following operation to update its own hidden representation.

\[
D_{ij}^{-\frac{1}{2}} = \begin{cases} \frac{1}{\sqrt{\text{deg}(v_i)}} & \text{if } i = j \\ 0 & \text{otherwise} \end{cases}
\]

\[
\hat{A} = D^{-\frac{1}{2}} A D^{-\frac{1}{2}}
\]

\[
g_l^i = \text{ReLU}(\sum_{j=1}^m \hat{A}_{ij} W_l^i g_{j, l-1}^j)
\]

\( W_l \) is the trainable weight matrix of the \( l \)th layer of the GCN. \( g_l^i \) is the representation of the \( i \)th node of the graph at the \( l \)th layer. If \( g_l^i \) has the dimension of \( d_g \), then the dimension of the weight matrix \( W_l \) is \( d_g \times d_g \). \( g_0^i \) is the initial input to the GCN.

5.2.1 Entity Mention Graph Layer

We construct an entity mention graph (EMG) for each document in the chain on top of the document encoding layer. An entity string may appear at multiple locations in a document and each appearance is considered as an entity mention. We add a node in the graph for each entity mention. We connect two entity mention nodes if they appear in the same sentence (EMG type 1 edge). We assume that since they appear in the same sentence, there may exist some relation between them. We also connect two entity mention nodes if the strings of the two entity mentions are identical (EMG type 2 edge). Let \( e_1, \ldots, e_l \) be the sequence of entity mention nodes listed in the order of their appearance in a document. We connect nodes \( e_i \) and \( e_{i+1} \) \((1 \leq i < l)\) with an edge (EMG type 3 edge). EMG type 3 edges create a linear chain of the entity mentions and ensure that the graph is connected. We
use a graph convolutional network on this graph topology to capture the relations among the entity mentions in a document.

We obtain the initial representations of the entity mention nodes from the hidden representations of the document encoding layer. We concatenate the hidden vector of the first token of an entity mention, the hidden vector of its last token, and a context vector to obtain the entity mention node representation. The context vector is obtained using an attention mechanism on the tokens of the sentence in which the entity mention appears.

\[ p = h_b || h_e, \quad s_t = \tanh(p^T W)h_t \]

\[ a = \text{softmax}([s_1, s_2, \ldots, s_k]^T) \]

\[ c = \sum_{t=1}^{k} a_t h_t, \quad q = p || c \]

\[ h_b \in \mathbb{R}^{2(d_w+d_z)} \text{ and } h_e \in \mathbb{R}^{2(d_w+d_z)} \] are the hidden vectors from the document encoding layer of the first and last token of an entity mention. \( W \in \mathbb{R}^{4(d_w+d_z) \times 2(d_w+d_z)} \) is a trainable weight matrix, \( h_t \in \mathbb{R}^{2(d_w+d_z)} \) is the hidden vector of the \( t \)th token of the sentence in which the entity mention is located, and \( a_t \) is the normalized attention score for the \( t \)th token with respect to the entity mention. \( k \) is the length of the sentence in which the entity mention is located, and \( c \in \mathbb{R}^{2(d_w+d_z)} \) is the context vector. The entity mention node vector \( q \in \mathbb{R}^{2(d_w+d_z)} \) of the \( i \)th node in the graph is passed to the GCN as \( g_i^0 \). The parameters of this GCN are shared across the documents in a chain. This layer of the model is referred to as entity mention-level graph convolutional network or EMGCN.

### 5.2.2 Entity Graph Layer

We construct a unified entity graph (EG) on top of the entity mention graphs. First, we construct an entity graph for each document, where each unique entity string is represented as an entity node in the graph. We add an edge between two entity nodes if the strings of the two entities appear together in at least one sentence in the document (EG type 1 edge). We also form a sequence of entity nodes based on the order of appearance of the entities in a document, where only the first occurrence of multiple occurrences of an entity is kept in the sequence. We connect two consecutive entity nodes in the sequence with an edge (EG type 2 edge). This ensures that the entire entity graph remains connected.

We construct one entity graph for each document in the document chain. We unify the entity graphs of multiple documents by merging the nodes of common entities between them. The unified entity graph contains all the nodes from the multiple entity graphs, but the common entity nodes which appear in two entity graphs are merged into one node in the unified graph. There is an edge between two entity nodes in the unified entity graph if there exists an edge between them in any of the entity graphs of the documents.

We obtain the initial representations of the entity nodes from the GCN outputs of the entity mention graphs. For the common entities between two documents, we average the GCN outputs of the entity mention nodes that have an identical string as the entity from the entity mention graphs of the two documents. For other entity nodes that appear only in one document, we average the GCN outputs of the entity mention nodes that have an identical string as the entity from the entity mention graph of that document. Each entity vector is passed to another graph convolutional network as \( g_i^1 \) which represents the initial representation of the \( i \)th entity node in the unified entity graph. We use a graph convolutional network on this graph topology to capture the relations among the entities across the documents in the document chain. This layer of the model is referred to as entity level graph convolutional network or EGCGN.

### 5.3 Relation Classifier

We concatenate the EGCGN outputs of the nodes corresponding to the subject entity \( e_s \in \mathbb{R}^{6(d_w+d_z)} \) and object entity \( e_o \in \mathbb{R}^{6(d_w+d_z)} \), and pass the concatenated vector to a feed-forward network (FFN) with softmax to predict the normalized probabilities for the relation labels.

\[ r = \text{softmax}(W_r(e_s || e_o) + b_r) \]

\( W_r \in \mathbb{R}^{(|R|+1) \times 2(d_w+d_z)} \) is the weight matrix, \( b_r \in \mathbb{R}^{|R|+1} \) is the bias vector of the FFN, and \( r \) is the vector of normalized probabilities of relation labels.

### 6 Experiments

#### 6.1 Baselines

We implement four neural baseline models for comparison with our proposed HEGCN model. Similar to our proposed model, we represent the tokens in the documents using pre-trained word embedding
vectors and entity token indicator vectors. We use a document separator token when concatenating the vectors of two documents in a chain.

(1) CNN: We apply the convolution operation on the sequence of token vectors with different kernel sizes. A max-pooling operation is applied to choose the features from the outputs of the convolution operation. This feature vector is passed to a feed-forward layer with softmax to classify the relation.

(2) BiLSTM: The token vectors of the document chain are passed to a BiLSTM layer to encode its meaning. We obtain the entity mention vectors of the subject entity and the object entity by concatenating the hidden vectors of their first and last token. We average the entity mention tokens of the corresponding entity to obtain the representation of the subject entity and the object entity. These two vectors are concatenated and passed to a feed-forward layer with softmax to find the relation between them.

(3) BiLSTM-CNN: This is a combination of the BiLSTM and CNN model described above. The token vectors of the documents are passed to a BiLSTM layer and then we use the convolution operation with max-pooling with different convolutional kernel sizes on the hidden vectors of the BiLSTM layer. The feature vector obtained from the max-pooling operation is passed to a feed-forward layer with softmax to classify the relation.

(4) LinkPath: This model uses the explicit paths (Kundu et al., 2019) from the subject entity $e_s$ to the object entity $e_o$ via the common entities to find the relation. As we consider only two-hop relations, each path from $e_s$ to $e_o$ will be of the form $e_s \rightarrow c \rightarrow e_o$, where $c$ is a common entity. Since there can be multiple common entities between two documents and these common entities as well as the subject and object entities can appear multiple times in the two documents, there exist multiple paths from $e_s$ to $e_o$. Each path is formed with four entity mentions: (i) entity mentions of the subject entity and common entity in the first document. (ii) entity mentions of the common entity and object entity in the second document. We concatenate the BiLSTM hidden vectors of the start and end token of an entity mention to obtain its representation. Each path is constructed by concatenating all the four entity mentions of the path. This can be extended from two-hop to multi-hop relations by using a recurrent neural network that takes the path entity mentions as input, and outputs the hidden representation of the path. We average the vector representations of all the paths and pass it to a feed-forward layer with softmax to find the relation.

6.2 Parameter Settings
We use GloVe (Pennington et al., 2014) word embeddings of dimension $d_w$ which is set to 300 in
our experiments, and update the embeddings during training. We set the dimension $d_z$ to be 20 for the entity token indicator embedding vectors. The hidden vector dimension of the forward and backward LSTM is set at 320. The dimension of BiLSTM output is 640. We use 500 different convolution filters with kernel width of 3, 4, and 5 for feature extraction. We use one convolutional layer in both entity mention-level GCN and entity-level GCN in our final model. Dropout layers (Srivastava et al., 2014) are used in our network with a dropout rate of 0.5 to avoid overfitting. We train our models with a mini-batch size of 32 and use negative log-likelihood as our objective function. We optimize the network parameters using the Adagrad optimizer (Duchi et al., 2011). For evaluation, we use precision, recall, and F1 score. We do not include the None relation in the evaluation. A confidence threshold that achieves the highest F1 score on the validation dataset is used to decide if the relation of a test instance belongs to the set of relations $R$ or None.

6.3 Experimental Results

We include the median of five runs of the models on the THRED dataset in Table 5. We see that adding a BiLSTM in the document encoding layer improves the performance by close to 5% in F1 score. The BiLSTM, BiLSTM_CNN, and LinkPath models achieve similar F1 scores. When we add our proposed hierarchical entity graph convolutional layer on top of the BiLSTM layer, we get another 1.1% F1 score improvement over the next best BiLSTM model. We perform a statistical significance test using bootstrap resampling to compare each baseline and our HEGCN model, and have ascertained that the higher F1 score achieved by our model is statistically significant ($p < 0.001$).

7 Conclusion

In this paper, we propose how the idea of distant supervision can be extended from sentence-level extraction to multi-hop extraction to cover more relations. We propose a general approach to create multi-hop relation extraction datasets. Following this approach, we create a two-hop relation extraction dataset that covers a higher number of relations from knowledge bases than other distantly supervised relation extraction datasets. We also propose a hierarchical entity graph convolutional network for this task. The two levels of GCN in our model help to capture the relation cues within documents and across documents. Our proposed model improves the F1 score by 1.1% on our two-hop dataset, compared to a strong neural baseline, and it can be readily extended to N-hop datasets.

Abstract

Distantly supervised models are very popular for relation extraction since we can obtain a large amount of training data using the distant supervision method without human annotation. In distant supervision, a sentence is considered as a source of a tuple if the sentence contains both entities of the tuple. However, this condition is too permissive and does not guarantee the presence of relevant relation-specific information in the sentence. As such, distantly supervised training data contains much noise which adversely affects the performance of the models. In this paper, we propose a self-ensemble filtering mechanism to filter out the noisy samples during the training process. We evaluate our proposed framework on the New York Times dataset which is obtained via distant supervision. Our experiments with multiple state-of-the-art neural relation extraction models show that our proposed filtering mechanism improves the robustness of the models and increases their F1 scores.

1 Introduction

The task of relation extraction is about finding relation or no relation between two entities. This is an important task to fill the gaps of existing knowledge bases (KB). Open information extraction (OpenIE) (Banko et al., 2007) is one way of extracting relations from text. They consider the verb in a sentence as the relation and then find the noun phrases located to the left and right of that verb as the entities. But this process has two serious problems: First, the same relation can appear in the text with many verb forms and OpenIE treats them as different relations. This leads to the duplication of relations in KB. Second, OpenIE treats any verbs in a sentence as a relation which can generate a large number of insignificant tuples which cannot be added to a KB.

Supervised relation extraction models, on the other hand, do not have these problems. But they require a large amount of annotated data which is difficult to get. Mintz et al. (2009), Riedel et al. (2010), and Hoffmann et al. (2011) used the idea of distant supervision to automatically obtain the training data to overcome this problem. The idea of distant supervision is that if a sentence contains both the entities of a tuple, it is chosen as a source sentence of this tuple. Although this process can generate some noisy training instances, it can give a significant amount of training data which can be used to build supervised models for this task. They map the tuples from existing KBs such as Freebase (Bollacker et al., 2008) to the text corpus such as Wikipedia articles (Mintz et al., 2009) or New York Times articles (Riedel et al., 2010; Hoffmann et al., 2011).

Based on distantly supervised training data, researchers have proposed many state-of-the-art models for relation extraction. Mintz et al. (2009), Riedel et al. (2010), and Hoffmann et al. (2011) proposed feature-based learning models and used entity tokens and their nearby tokens, their part-of-speech tags, and other linguistic features to train their models. Recently, many neural network-based models have been proposed to avoid feature engineering. Zeng et al. (2014) and Zeng et al. (2015) used convolutional neural networks (CNN) with max-pooling to find the relation between two given entities. Shen and Huang (2016), Jat et al. (2017), Nayak and Ng (2019) used attention framework in their neural models for this task.

But the distantly supervised data may contain many noisy samples. Sometimes sentences may contain the two entities of a positive tuple, but they may not contain the relation specific information. These kinds of sentences and entity pairs are considered as positive noisy samples. Another set of noisy samples comes from the way samples for
None relation are created. If a sentence contains two entities from the KB and there is no positive relation between these two entities in the KB, this sentence and entity pair is considered as a sample for None relation. But knowledge bases are not complete and many valid relations among the entities in the KBs are missing. So it may be possible that the sentence contains information about some positive relation between the two entities, but since the relation is not present in the KB, this sentence and entity pair is incorrectly considered as a sample for None relation. These kinds of sentences and entity pairs are considered as negative noisy samples.

We include examples of clean and noisy samples generated using distant supervision in Table 1. The KB contains many entities out of which four entities are Barack Obama, Hawaii, Karkuli, and West Bengal. Barack Obama and Hawaii have a birth_place relation between them. Karkuli and West Bengal are not connected with any relations in the KB. So we assume that there is no valid relation between these two entities. The sentence in the first sample contains the two entities Barack Obama and Hawaii, and it also contains information about Obama being born in Hawaii. So this sentence is a correct source for the tuple (Barack Obama, Hawaii, birth_place). So this is a positive clean sample. The sentence in the second sample contains the two entities, but it does not contain the information about Barack Obama being born in Hawaii. So it is a positive noisy sample. In the case of the third and fourth samples, according to distant supervision, they are considered as samples for None relation. But the sentence in the third sample contains the information for the relation located_in between Karkuli and West Bengal. So the third sample is a negative noisy sample. The fourth sample is an example of a negative clean sample.

The presence of the noisy samples in the distantly supervised data adversely affects the performance of the models. Our goal is to remove the noisy samples from the training process to make the models more robust for this task. We propose a self-ensemble based noisy samples filtering method for this purpose. Our framework identifies the noisy samples during the training and removes them from training data in the following iterations. This framework can be used with any supervised relation extraction model. We run experiments with several state-of-the-art neural models, namely Convolutional Neural Network (CNN) (Zeng et al., 2014), Piecewise Convolutional Neural Network (PCNN) (Zeng et al., 2015), Entity Attention (EA) (Shen and Huang, 2016), and Bi-GRU Word Attention (BGWA) (Jat et al., 2017) with the distantly supervised New York Times dataset (Hoffmann et al., 2011). Our framework improves the F1 score of these models by 2.1%, 1.1%, 2.1%, and 2.3% respectively.

datasets are used for training relation extraction models. But the presence of noisy samples negatively affects their performance. In this work, we try to identify these noisy samples during training and filter them out from the subsequent training process to improve the performance of the models.

3 Self-Ensemble Filtering Framework

Figure 1 shows our proposed self-ensemble filtering framework. This framework is inspired from the work by Nguyen et al. (2020). We start with clean and noisy samples and assume that all samples are clean. At the end of each iteration, we predict the labels of the entire training samples. Based on the predicted label and the label assigned by distant supervision, we decide to filter out a sample in the next iteration. After each iteration, we consider the entire training samples for the filtering process. The individual models at each iteration can be very sensitive to wrong labels, so in our training process, we maintain a self-ensemble version of the models which is a moving average of the models of previous iterations. We hypothesize that the predictions of the ensemble model are more stable than the individual models. So the predictions from the ensemble model are used to identify the noisy samples. These noisy samples are removed from the training samples of the next iteration. We consider the entire distantly supervised training data for prediction and filtering so that if a sample is filtered out wrongly in an iteration, it can be included again in the training data in the subsequent iteration.

3.1 Self-Ensemble Training

We use the student-teacher training mechanism proposed by Tarvainen and Valpola (2017) for our self-ensemble model learning. A student model can be any supervised learning model such as a neural network model. A teacher model is the clone of student model with same parameters. The weights of parameters of this teacher model is the exponential moving average of the weights of parameters of the student model. So this teacher model is the self-ensemble version of the student model. An additional consistency loss is used to maintain the consistency of the predictions of the student model and the teacher model. Following is the step-by-step algorithm to train such an self-ensemble model:

1. First, a student model $M^t_s$ is initialized. This can be any supervised relation extraction model such as CNN, PCNN, Entity Attention (EA) or Bi-GRU Word Attention (BGWA) model.

2. A teacher model $M^t_i$ is cloned from the student model $M^t_s$. We completely detach the weights of the teacher model from the student model.

3. A gradient descent based optimizer is selected to update the parameters of the student model.

4. Loss is calculated based on the cross-entropy loss of the student model for the classification task and a consistency loss between the student model and teacher model.

5. In each training iteration or epoch:

   • In each step or mini-batch:
     - Update the weights of the student model $M^t_s$ using the selected optimizer and the loss function.
     - Update the weights of the teacher model $M^t_i$ as an exponential moving average of the student weights.
   • Evaluate the performance of the teacher model $M^t_i$ on a validation dataset. If we decide to continue the training after evaluation, we use a filtering strategy at this point to remove the noisy samples from the training data. This clean training data is used in the next iteration of the training process.

6. Return the best teacher model $M^t_i$. This teacher model is the self-ensemble version of the student model.

3.2 Loss Function & Updating the Student

We use the negative log-likelihood loss of the relation classification task from the student model ($L_{ce}$) and a mean-squared error based consistency loss between the student and teacher model ($L_{mse}$) to update the student model.

\[
L_{ce} = -\frac{1}{B} \sum_{i=1}^{B} \log(p(r_i|s_i, e^1_i, e^2_i, \theta_s))
\]
\[
L_{mse} = \frac{1}{B} \sum_{i=1}^{B} \sum_{j=1}^{C} (y^i_{s,j} - y^i_{t,j})^2
\]
\[
L = L_{ce} + L_{mse}
\]
For \( L_{ce}, p(r_i|s_i, e^1_i, e^2_i, \theta_s) \) is the conditional probability of the true relation \( r_i \) when the sentence \( s_i \), two entities \( e^1_i \) and \( e^2_i \), and the model parameters of the student \( \theta_s \) are given. For \( L_{mse}, y^{j,i}_s \) and \( y^{j,i}_t \) are the softmax output of the \( j \) th relation class of \( i \) th training sample in the batch from the student model and the teacher model respectively. \( C \) is number of relation class in the dataset and \( B \) is the batch size. The parameters of the student model \( \theta_s \) are updated based on the combined loss \( L \) using an gradient descent based optimizer. The consistency loss (\( L_{mse} \)) makes sure that output softmax distribution of the student model and teacher model are close to each other, thus maintain the consistency of the output from both models.

3.3 Updating the Teacher

We update the parameters of teacher model \( \theta_t \) based on the exponential moving average of the all previous optimization steps of the student model.

\[
W(\theta^l_t) = \alpha W(\theta^{l-1}_t) + (1 - \alpha) W(\theta^l_s)
\]

where \( W(\theta^l_t) \) and \( W(\theta^l_s) \) are the weights of the parameters of the teacher model and student model respectively after the \( l \) th global optimization step. \( W(\theta^{l-1}_t) \) is the weights of the teacher model parameters up to the \( l - 1 \) th global optimization step. \( \alpha \) is a weight factor to control the contribution of the student model of the current step and the teacher model up to the previous step. At the initial optimization steps of the training, we keep the value of \( \alpha \) low as the self-ensemble model or teacher model is not stable yet and the student model should contribute more. As the training progress and the self-ensemble model becomes stable, we slowly increase the value of \( \alpha \) so that we take the majority contribution from the self-ensemble model itself. We use the following Gaussian curve (He et al., 2018) to ramp up the value of \( \alpha \) from 0 to \( \alpha_{max} \) which is a hyper-parameter of the model.

\[
T = E \times \left\lceil \frac{L}{B} \right\rceil \\
p = 1 - \min(\text{step_idx}, T) \\
\alpha = e^{-5p^2 \alpha_{max}}
\]

Here \( E \) is the epoch count to ramp up the \( \alpha \) from 0 to \( \alpha_{max} \). \( E \) is a hyper-parameter of the model and generally, this is lower than the total number of epochs of the training process. \( L \) is the size of distant supervised training data at the beginning of training, \( B \) is the batch size, and \( \text{step_idx} \) is the current global optimization step count of the training. \( T \) represents the number of global optimization steps required for \( \alpha \) to reach its maximum value \( \alpha_{max} \).

3.4 Noise Filtering Strategy

After each iteration, we use a validation dataset to determine to stop or to continue the training. If we decide to continue the training, then we use the self-ensemble model or the teacher model to filter out noisy samples from the initial training data. This clean training data is used in the next training iteration. We use the self-ensemble model to predict the relation on initial training data for
the filtering process after each iteration. We use the entire initial training data for prediction so that if a training sample is filtered out wrongly in an iteration as a noisy one, it can be used again in subsequent training iterations if the subsequent self-ensemble model predicts the sample as a clean one.

Generally, distantly supervised datasets contain a largely high number of None samples than the valid relation samples. For this reason, we choose a strict filtering strategy for None samples and a lenient filtering strategy for valid relation samples. We consider a None sample as clean if teacher models predict the None relation. Otherwise, this sample is considered as noisy and filtered out from the training set of next iteration. For the valid relations, we consider a sample as clean if the relation assigned by distant supervision belongs to the top $K$ predictions of the teacher model. This clean training data is used in the next training iteration.

4 Student Models

We have used the following state-of-the-art neural relation extraction models as the student model in our filtering framework. These models use three types of embedding vectors: (1) word embedding vector $w \in \mathbb{R}^{d_w}$ (2) a positional embedding vector $u^1 \in \mathbb{R}^{d_u}$ which represents the linear distance of a word from the start token of entity 1 (3) another positional embedding vector $u^2 \in \mathbb{R}^{d_u}$ which represents the linear distance of a word from the start token of entity 2. The sentences are represented using a sequence of vectors $\{x_1, x_2, ..., x_n\}$ where $x_t = w_t || u^1_t || u^2_t$. $\parallel$ represents the concatenation of vectors and $n$ is the sentence length. These token vectors $x_t$ are given as input to all the following models.

4.1 CNN (Zeng et al., 2014)

In this model, convolution operations with max-pooling are applied on the token vectors sequence $\{x_1, x_2, ..., x_n\}$ to obtain the sentence-level feature vector.

\[ c_t = f^T(x_t \parallel x_{t+1} \parallel ... \parallel x_{t+k-1}) \]
\[ c_{\text{max}} = \max(c_1, c_2, ..., c_n) \]
\[ v = [c_{1\text{max}}, c_{2\text{max}}, ..., c_{K\text{max}}] \]

$f$ is a convolutional filter vector of dimension $k(d_w + 2d_u)$ where $k$ is the filter width. The index $i$ moves from 1 to $n$ and produces a set of scalar values $\{c_1, c_2, ..., c_n\}$. The max-pooling operation chooses the maximum $c_{\text{max}}$ from these values as a feature. With $f_k$ number of filters, we get a feature vector $v \in \mathbb{R}^{f_k}$. This feature vector $v$ is passed to feed-forward layer with softmax to classify the relation.

4.2 PCNN (Zeng et al., 2015)

Piecewise Convolutional Neural Network (PCNN) is a modified version of the CNN model described above. Similar to the CNN model, convolutional operations are applied to the input vector sequence. But CNN and PCNN models differ on how the max-pooling operation is performed on the convolutional outputs. Rather than applying a global max-pooling operation on the entire sentence, three max-pooling operations are applied on three segments/pieces of the sentence based on the location of the two entities. This is why this model is called the Piecewise Convolutional Neural Network (PCNN). The first max-pooling operation is applied from the beginning of the sequence to the end of the entity appearing first in the sentence. The second max-pooling operation is applied from the beginning of the entity appearing first in the sentence to the end of the entity appearing second in the sentence. The third max-pooling operation is applied from the beginning of the entity appearing second in the sentence to the end of the sentence. These max-pooled features are concatenated and passed to a feed-forward layer with softmax to determine the relation.
4.3 Entity Attention (EA) (Shen and Huang, 2016)

This model combines the CNN model with an attention network. First, convolutional operations with max-pooling are used to extract the global features of the sentence. Next, attention is applied to the words of the sentence based on the two entities separately. The word embedding of the last token of an entity is concatenated with the embedding of every word. This concatenated representation is passed to a feed-forward layer with tanh activation and then another feed-forward layer with softmax to get a scalar attention score for every word for that entity. The word embeddings are averaged based on the attention scores to get the attentive feature vectors. The CNN-extracted global feature vector and two attentive feature vectors for the two entities are concatenated and passed to a feed-forward layer with softmax to determine the relation.

4.4 Bi-GRU Word Attention (BGWA) (Jat et al., 2017)

This model uses a bidirectional gated recurrent unit (Bi-GRU) (Cho et al., 2014) to capture the long-term dependency among the words in the sentence. The tokens vectors $x_t$ are passed to a Bi-GRU layer. The hidden vectors of the Bi-GRU layer are passed to a bi-linear operator which is a combination of two feed-forward layers with softmax to compute a scalar attention score for each word. The hidden vectors of the Bi-GRU layer are multiplied by their corresponding attention scores for scaling up the hidden vectors. A piecewise convolution neural network (Zeng et al., 2015) is used on top of the scaled hidden vectors to obtain the feature vector. This feature vector is passed to a feed-forward layer with softmax to determine the relation.

5 Experiments

5.1 Datasets

To verify our hypothesis, we need training data that is created using distant supervision, thus noisy and test data which is not noisy, thus human-annotated. If the test data is also noisy, then it will be hard to derive any conclusion from the results. So, we choose the New York Times (NYT) corpus of Hoffmann et al. (2011) for our experiments. This dataset has 24 valid relations and a None relation. The statistics of the dataset is given in Table 2. The training dataset is created by aligning Freebase tuples to NYT articles, but the test dataset is manually annotated. We use 10% of the training data as validation data and the remaining 90% for training.

<td>24</td>
</tr>
<tr>
<td>#None relation instances</td>
<td>235,172</td>
<td>930</td>
</tr>
</tbody>
</table>

Table 2: The statistics of the NYT dataset.

5.2 Evaluation Metrics

We use precision, recall, and F1 scores to evaluate the performance of models on relation extraction after removing the None labels. We use a confidence threshold to decide if the relation of a test instance belongs to the set of valid relations $R$ or None. If the network predicts None for a test instance, then it is considered as None only. But if the network predicts a relation from the set $R$ and the corresponding softmax score is below the confidence threshold, then the final predicted label is changed to None. This confidence threshold is the one that achieves the highest F1 score on the validation data.

5.3 Parameter Settings

We run word2vec (Mikolov et al., 2013) on the NYT corpus to obtain the initial word embeddings with a dimension of $d_w = 50$ and update the embeddings during training. We set the dimension positional embedding vector at $d_e = 5$. We use $f_k = 230$ convolutional filters of kernel size $k = 3$ for feature extraction whenever we apply the convolution operation. We use dropout in our network with a dropout rate of 0.5, and in convolutional layers, we use the tanh activation function. We train our models with a mini-batch size of 50 and optimize the network parameters using the Adagrad optimizer (Duchi et al., 2011). We want to keep the value of $\alpha_{\text{max}}$ high because when the training progress, we want to increase the contribution of the self-ensemble model compare to the student model. So we set the value of $\alpha_{\text{max}}$ at 0.9. We experiment with $E = \{5, 10\}$ epochs to ramp up the value of $\alpha$ from 0 to $\alpha_{\text{max}}$. We also experiment with $K = \{3, 5\}$ for filtering the valid relation samples during the filtering process after each training iteration. The performance of the self-ensemble model does not vary much with these choices of $E$ or $K$. So we use $E = 5$ and $K = 3$ for final experiments.
Table 3: Precision, Recall, and F1 score comparison of the student models on NYT dataset when trained with self-ensemble filtering framework (SEF column) and when trained independently (Student column). We report the average of five runs with standard deviation. ↑ column shows the absolute % improvement of F1 score over the Student models.

5.4 Results

We include the results of our experiments in Table 3. We run the CNN, PCNN, EA, and BGWA models 5 times with different random seeds and report the average with standard deviation in the ‘Student’ column in Table 3. The column ‘SEF’ (Self-Ensemble Filtering) is the average results of 5 runs of CNN, PCNN, EA, and BGWA models with the self-ensemble filtering framework. We see that our SEF framework achieves 2.1%, 1.1%, 2.1%, and 2.3% higher F1 score for the CNN, PCNN, EA, and BGWA models respectively compared to the Student models. If we compare the precision and recall score of the four models, we see that our self-ensemble framework improves the recall score more than the corresponding precision score in each of these four models. These results show the effectiveness of our self-ensemble filtering framework in a distant supervised dataset.

5.5 Self-Ensemble without Filtering

We experiment with how the self-ensemble version of the student models behave without filtering the noisy samples after each iteration. So in this setting, we use the entire distant supervised training data at every iteration. The results are included in Table 4 under the ‘SE’ (Self-Ensemble) column. This result shows that the performance of the four neural models under self-ensemble training without filtering is not much different from the ‘Student’ performance of Table 3. This shows that the filtering of the noisy samples from the training dataset helps to improve the performance of our proposed self-ensemble framework.

Table 4: Precision, Recall, and F1 score of the self-ensemble version of the student models on NYT dataset without noise filtering. We report the average of five runs with standard deviation. ↓ column shows the absolute % decline of F1 score respect to the SEF models (Table 3).

5.6 Ensemble vs Self-Ensemble Filtering

Since our SEF framework has an ensemble component, we compare its performance with the ensemble versions of the independent student models. The ‘Ensemble’ column in Table 5 refers to the ensemble results of the 5 runs of each student model. We use the five runs of the models on the test data and average the softmax output of these runs to decide the relation. We see that our SEF framework outperforms the ensemble results for CNN, PCNN, EA, and BGWA with 1.6%, 0.5%, 0.7% and 2.6% F1 score respectively. Here, we should consider the fact that to build an ensemble model, the student models must be run multiple times (5 times in our case). In contrast, self-ensemble models can be built in a single run with little cost of maintaining the moving average of the student model.

6 Related Work

There are two approaches for relation extraction (Nayak et al., 2021): (i) Pipeline approaches (Zeng et al., 2014, 2015; Jat et al., 2017; Nayak and Ng, 2019) (ii) Joint extraction approaches (Takanobu et al., 2019; Nayak and Ng, 2020). Most of these models work with distantly supervised noisy datasets. Thus noise mitigation is an important dimension in this area of research. Multi-instance relation extraction is one of the popular methods for noise mitigation. Riedel et al. (2010), Hoffmann et al. (2011), Surdeanu et al. (2012), Lin et al. (2016), Yaghoobzadeh et al. (2017), Vashishth et al. (2018), Wu et al. (2019), and Ye and Ling (2019) used this multi-instance learning concept in their proposed relation extraction models. For each entity pair, they used all the sentences that contain these two entities to find the relation between them. Their goal was to reduce the effect of noisy samples using this multi-instance setting. They used different types of sentence selection mechanisms to give importance to the sentences that contain relation specific keywords and ignore the noisy sentences. But this idea may not be effective if there is only one sentence for an entity pair. Ren et al. (2017) and Yaghoobzadeh et al. (2017) used the multi-task learning approach for mitigating the influence of the noisy samples. They used fine-grained entity typing as an additional task in their model.

Wu et al. (2017) used an adversarial training approach for the same purpose. They add noise to the word embeddings to make the model more robust for distantly supervised training. Qin et al. (2018a) used the generative adversarial network (GAN) to address this issue of the noisy samples in relation extraction. They used a separate binary classifier as a generator in their model for each positive relation class to identify the true positives for that relation and filter out the noisy ones. Qin et al. (2018b) used reinforcement learning to identify the noisy samples for the positive relations and then use the identified noisy samples as unlabelled data in their model. Shang et al. (2020) used a clustering approach to identify the noisy samples. They assign the correct relation label to these noisy samples and use them as additional training data in their model. Different from these approaches, we propose a student-teacher framework that can work with any supervised neural network models to address the issue of noisy samples in distantly-supervised datasets.

7 Conclusion

In this work, we propose a self-ensemble based noisy samples filtering framework for distantly supervised relation extraction. Our framework identifies the noisy samples during training and removes them from the training data in the following iterations. This framework can be used with any supervised relation extraction models. We run experiments using several state-of-the-art neural models with this proposed filtering framework on the distantly supervised New York Times dataset. The results show that our proposed framework improves the robustness of these models and increases their F1 score on the relation extraction task.

Abstract

Biomedical Named Entities are complex, so approximate matching has been used to improve entity coverage. However, the usual approximate matching approach fetches only one matching result, which is often noisy. In this work, we propose a method for biomedical NER that fetches multiple approximate matches for a given phrase to leverage their variations to estimate entity-likeness. The model uses pooling to discard the unnecessary information from the noisy matching results, and learn the entity-likeness of the phrase with multiple approximate matches. Experimental results on three benchmark datasets from the biomedical domain, BC2GM, NCBI-disease, and BC4CHEMD, demonstrate the effectiveness. Our model improves the average F-measures by up to 0.21 percentage points compared to a BioBERT-based NER.

1 Introduction

In the biomedical field, obtaining labelled data is very costly. Biomedical Named Entities (NEs) are complex and new NEs are continuously increasing in significant numbers, leading to unknown-word issues in Biomedical Named Entity Recognition (BioNER) tasks. One reason why biomedical NEs are complex is that they have many variations with the interchangeability of Roman numbers and Latin characters, spaces and hyphens, etc. The number of new biomedical research papers is increasing, wherein approximately two papers per minute, resulting in more than 1 million papers each year, are added to the PubMed database (Landhuis, 2016). With this number of publications, new NEs are constantly being reported.

In the last few years, NER using pre-trained language models (LMs), such as BERT (Devlin et al., 2018), ELMo (Peters et al., 2018), and Flair (Akbik et al., 2019), has shown state-of-the-art performance. In the biomedical domain, pre-trained LMs such as BioBERT (Lee et al., 2019a) and BioELMo (Jin et al., 2019), which are BERT and ELMo trained on a biomedical domain text, have achieved the state-of-the-art performance in many biomedical natural language processing tasks including NER. However, only using previously trained LMs cannot cover the continuously increasing new entities due to complex characteristics of biomedical NEs, lead to unknown words problem. Despite being used as approaches to avoid unknown words problem, subword segmentation (Sennrich et al., 2015; Kudo and Richardson, 2018) methods consider subwords represented as unique IDs, but not words or their synonyms. therefore, it is difficult for subword or character based LMs to cover biomedical NEs, which are complex and contain various of expression described in section 3. Moreover, LM pre-training is costly, time-consuming, and computationally expensive. Training BioBERT on biomedical corpora based on the BERT model requires 10 to 23 days on eight NVIDIA V100 GPUs (Lee et al., 2019a).

To deal with the complex and continuously increasing entities, the use of dictionary-based approaches can be an effective approach in previous works (Collobert et al., 2011; Rijhwani et al., 2020). In contrast to pre-training models, we can cover new NEs by adding entries to the dictionary, without needing time-consuming pre-training. There are two types of dictionary application methods: exact matching and approximate matching. Exact matching has been incorporated into neural NER (Collobert et al., 2011; Chiu and Nichols, 2016; Wu et al., 2018) and non-neural NER methods (Uchimoto et al., 2000) to improve accuracy.

Exact matching cannot totally cover all of the complex and newly-created NEs. In the biomedical domain, new NEs are created by modifying the endings of the existing one. For example, the new gene TAAR7P was named by modifying the
ending of the existing gene TAAR8. To improve the coverage of entities, approximate matching has been used to manage new NEs in non-neural NER (Cohen and Sarawagi, 2004). However, the approximate matching approach fetches only one matching result, which cannot cover all variations of NEs. For example, NEs “Type-1 angiotensin II receptor-associated protein” have many variations such as “Type I angiotensin II receptor associated protein”, “Type-1 angiotensin 2 receptor associated protein”, and “Type 1 angiotensin II receptor-associated protein”. Also, approximate matching results are often noisy.

In this paper, we propose a method to improve neural BioNER by learning the entity-likeness of a given input sentence using multiple approximate matches of the input sentence with a dictionary. We define the entity-likeness as the degree to which a certain input sentence is likely to appear in the dictionary. It is estimated from matching results between the input sentence and entities in the dictionary.

We evaluated our method with three biomedical domain benchmarks, i.e., BC2GM, NCBI-disease, and BC4CHEMD dataset. The experimental results show the effectiveness of our approach. It improves F-measures by up to +0.21 points on the biomedical benchmark, and +2.2 points when probing the biomedical ELMo (Jin et al., 2019), which is a recent state-of-the-art pre-training method.

2 Related Work

For the NER task, previous studies have examined the application of dictionaries in machine learning. Dictionary matching was employed in SVM-based NER (Ratinov and Roth, 2009) and partial matching computed by distance feature between a token and entity in dictionary was considered in semi-Markov extraction processes (Cohen and Sarawagi, 2004).

Dictionary matching is also used in Neural NER approaches. Liu et al. added a pre-trained module that softly matches the gazetteers to the semi-Markov CRF-based segmental NER task. Soft matching of gazetteers is also used in the work of Rijhwani et al. (2020) for low-resource NER. Exact matching was used by Collobert et al. (2011) they use a network layer to map words of dictionary into feature vectors by a lookup table operation and train the features as input in their model. Chiu and Nichols proposed the use of the longest matching, including partial lexicon matching in neural networks. Each word vector has dimensions to express dictionary matching.

In the CRF-based sequence labeling model for NER, the clustering results of phrases in the search engine query logs were used as features by Lin and Wu (2009). To improve word representation, a word embedding learning method that leverages information from relevant lexicons to phrase embedding was proposed by Passos et al. (2014). Hand-crafting features obtained from gazetteers were also incorporated to model additional information in the named entity (Wu et al., 2018; Shang et al., 2018).

Related to approaches employing approximate string matching in Biomedical NER, Tsuruoka and Tsujii proposed a method to recognize entity candidates by approximate searching and filtering out false positives using a binary classifier. Yang et al. used approximate string matching and added pre- and post-keywords for each bio-entity name to expand the coverage of the dictionary. Xu et al. constructed a dictionary attention layer to incorporate exact dictionary matching and a document-level attention mechanism to improve disease NER.

Approaches based on neural network were also applied for Biomedical NER (Habibi et al., 2017; Crichton et al., 2017; Wang et al., 2018). For a transformer-based approach, Khan et al. used a shared transformer encoder to capture the embedding vector of each token in input sentence and task specific linear layers to generate representations of multi-tasks including Biomedical NER.

Differing from these works, we propose a method to learn the entity-likeness of a sentence by leveraging multiple approximate matches of the sentence with one or multiple dictionaries. Recent approaches based on pre-training for specific domains, such as biomedical (Lee et al., 2019a; Jin et al., 2019), clinical (Huang et al., 2019) and scientific (Beltagy et al., 2019), have shown high levels of accuracy; our method is complementary to these approaches.

3 NEs in Biomedical Domain

Biomedical NEs are complex and ambiguous due to the following characteristics:

**Variation of Expression** Biomedical NEs have various synonyms, including abbreviations, interchangeability of Roman numbers and Latin characters, insertions and deletions of hyphens and spaces, and changes in word order. For example, the gene
“Angiotensin II Receptor Type 1” has the official name “AGTR1”, as well as more than ten other names, e.g., AGTR-1, Type-1 Angiotensin II Receptor, Angiotensin Receptor 1B, and AT1 Receptor. Even if the dictionary is further expanded, exact matching cannot entirely cover all possible variations of NEs.

**Composite Mentions** NEs in the biomedical domain are frequently connected by “and,” “or” in a single span which refers to more than one entity. For example, “alpha and beta globin” refers to “alpha globin” and “beta globin”.

**Nested NEs** Nested NEs (Kim et al., 2003; Ringland et al., 2019), where one NE is completely contained by the other, are also commonly used in biomedical data. For example, both “adenylate cyclase activating polypeptide 1” and “adenylate cyclase” are the names of proteins.

**Entity ambiguity** The same mention may often refer to many different entities depending on context. For example, “VHL” can be either a disease name “Von Hippel–Lindau (VHL) disease” or a gene name “VHL gene” depending on context.

NEs in the biomedical domain are continuously increasing in number every year. When using exact matching or pre-trained LMs for BioNER, it is difficult to sufficiently cover all possible combinations of NEs, leading to the omission of NE recognition.

4 Learning Entity-likeness with Multiple Approximate Matches

The concept of our approach is that the entity-likeness of a given input sentence can be estimated by its maximal similarity to entities in a dictionary. Our motivation is to assign the entity-likeness to each word of the input sentence.

The overall flow of the proposed approach is as follows:

1. Given an input sentence, we first fetch matching results between the input sentence and a specified dictionary.

2. We create matching patterns based on the matching results, and assign them to each word in the input sentence. The matching pattern is a label that indicates how each word matches with the dictionary.

3. For each word in the input sentence, we build a vector for predicting entity-likeness from the multiple matching patterns by a pooling operation.

4. We build an NER model learning both vector of entity-likeness and contextual embedding derived from pre-trained LMs.

4.1 Creating Multiple Approximate Matches

Given an input sentence, we first fetch the matching results between the input sentence and entities in a dictionary. Since we cannot specify which part of the input sentence contains the entity, we calculate the string similarity of all continuous word level N-grams ($N \leq 5$) in the input sentence with all dictionary entries. The matching returns entries whose similarity with the $N$-gram is larger than a specified threshold $\tau$. We regard a match of $N$-gram with an entity with threshold 1.0 as an exact matching.

By employing the multiple approximate matchings of $N$-gram with the dictionary, it is possible to obtain useful information about the multiple matches for estimating the entity-likeness of the $N$-grams, especially in the case of predicting a new NE which is similar to the existing one. For example, we can obtain information on the interchange-ability of Greek or Roman characters in NEs from dictionary entries “beta-1 Adrenergic Receptor”, “β-1 Adrenergic Receptor” and other synonyms. The information is useful for recognizing the unknown NE “α-1 Adrenergic Receptor”.

4.2 Creating Dictionary Matching Patterns

Based on the matching results of $N$-grams ($N \leq 5$) with a dictionary obtained in section 4.1, we create a set of dictionary matching patterns that includes the information of the dictionary that is used, the types of matching, and the matching position; this information is assigned to each word in the input sentence. The type of matching is set to “Exact” if the $N$-gram exactly matches the dictionary entry, otherwise it is set to “Approximate”. There are three types of matching positions (B (Beginning), I (Inside), and E (Ending)) which indicate the position of the word in the $N$-gram.

For example, as shown in Figure 1, the input sentence “EGFR is epidermal growth factor receptor” is matched with a gene/protein dictionary. The gene/protein dictionary includes entries such as “epidermal growth factor receptor substrate 1”.

Note that an $N$-gram can be matched with one or multiple dictionaries when we have two or more dictionaries.
15,” “epidermal growth factor receptor GRB-7,” etc. As shown in Figure 1, 3-gram \textbf{N1} with the beginning word \(w_0\) “epidermal” exactly matches with gene/protein dictionary entry \	extbf{M1} and it approximately matches with entries \	extbf{M3}, \	extbf{M4} and \textbf{M5}. The matching result of the 3-gram \textbf{N1} assigns matching patterns: “Gene-Exact-B” and “Gene-Approximate-B” to \(w_0\).

In the same way, 4-gram \textbf{N2} approximately matches with dictionary entries \textbf{M6} and \textbf{M7}. In this case, the word “epidermal” is inside the \textbf{N2} and therefore the matching result of the \textbf{N2} assigns matching patterns: “Gene-Approximate-I” to \(w_0\).

Based on matching results between all \(N\)-grams of the input sentence and the dictionary, we can obtain a set of matching patterns for each word in the input sentence. The possible matching patterns for each word are \{Number of dictionaries\} \times \{Exact, Approximate\} \times \{B, I, E\}. For example, in Figure 1, a set of matching patterns with the Gene dictionary for the third word “epidermal” are \{“Gene-Exact-B,” “Gene-Approximate-B,” “Gene-Approximate-I”\}.

4.3 Representation of Multiple Matching Patterns

After creating sets of dictionary matching patterns corresponding to each word, we build a representation for the dictionary matching patterns.

Suppose each word \(w_i\) corresponds to a subset of matching patterns \(S_i \subset S\), where \(S\) is the possible matching patterns, \(S_i\) is obtained in section 4.2. Here, \(S_i\) represents the likeliness of that the word forms a part of entities. \(E_i\) corresponds to embeddings of \(S_i\):

\[
E_i = \{\text{emb}(s) | s \in S_i\} \tag{1}
\]

where \(\text{emb}(\cdot)\) indicates an embedding operation. In experiments, embedding \(\text{emb}(s)\) is randomly initialized from a normal distribution but not fine-tuned.

Next, we build a vector representation \(D_i\) of entity-likeness by pooling the embeddings \(E_i\); \(D_i\) has the same dimension as \(E_i\):

\[
D_i = f_{pool}(E_i) \tag{2}
\]

where \(f_{pool}\) is a pooling operation.

The aim of the pooling is to aggregate information for learning from various matching patterns. In order to investigate the effect of various pooling functions, we consider four types of pooling: Sum, Max, Average and Convolution.

**Sum Pooling** It is expected that summarizing all features of the possible matching pattern embeddings gives information for estimating entity-likeness of words.

\[
f_{sum}(E_i) = \sum_{v \in E_i} v \tag{3}
\]
Figure 2: Illustration of the proposed model architecture. $T_i$ and $D_i$ are the corresponding contextual word embedding module and dictionary matching pattern module for each word $w_i$ in the input sentence, respectively. $V_i$ represents interaction between each word and its entity-likeness. The model predicts the token-level NE label, $l_i$. $am_1 B$, $am_1 I, ...$ are embeddings of matching patterns.

Max Pooling Instead of sum pooling, we use max pooling to compose the set of matching pattern embeddings:

$$f_{\text{max}}(E_i) = \max(E_i) \quad (4)$$

Average Pooling In the same way, we consider the average variation of the pooling method:

$$f_{\text{avg}}(E_i) = \text{avg}(E_i) \quad (5)$$

Convolution As a way to combine embeddings, we apply 1-D convolution over the set of matching pattern embeddings to build the dictionary matching embedding:

$$f_{\text{conv}}(E_i) = \text{Conv1d}(E_i) \quad (6)$$

4.4 Learning Representations of Entity-likeness with NER

Figure 2 shows the overview of our method. Given the output of the contextual word embedding $T_i$, and vector representation of entity-likeness $D_i$, the label prediction module predicts the IOB2 labels of input sentence $w_i$. By learning $T_i$ and $D_i$ together, it is possible to recognize new NEs which were not in the dictionary or training data of LMs. For the pre-trained LMs, we use BioBERT (Lee et al., 2019a) or BioELMo (Jin et al., 2019) depending on experiments.

The layer numbers and the internal details of the label prediction layer vary depending on the used pre-trained LMs. We follow the settings of the original studies (Lee et al., 2019a; Jin et al., 2019). In the case of BioBERT, we use a single linear layer to compute token level IOB2 probabilities. In the case of BioELMo, we follow the probing settings in the work of Jin et al. (2019). We use several linear layers to compute the probabilities.

5 Experiments

In this section, we conduct three experiments. Experiment 1 confirms the effectiveness of learning both entity-likeness and contextual embedding for BioNER. Also, we want to confirm if applying appropriate pooling operations can reduce noise in the case of approximate matching. Experiment 2 confirms portability by using our method with different pre-trained LMs. Experiment 3 confirms the effectiveness of our method not only in the biomedical domain but also in the general domain.

For pre-trained LMs, we employed BioBERT and BioELMo trained on PubMed and PMC biomedical articles. For experiments on a general domain dataset, we applied the pre-trained BERT base cased LMs.

5.1 Datasets

In this study, the results were obtained by adopting the proposed and BioBERT-based methods to three benchmark biomedical datasets, BC2GM, NCBI-disease, and BC4CHEMD, which are exclusively annotated with protein, disease, and chemical entities, respectively. For the general domain, we used the CoNLL 2003 dataset (Tjong Kim Sang and De Meulder, 2003). Table 1 shows the size of the datasets. All datasets are publicly available.

5.2 Dictionary

We consider the dictionary as a set of names including synonyms of the entities, e.g., Gene, Disease, and Drug. In the biomedical domain, there are several publicly available databases that can be used to create dictionaries. The dictionaries are built from

2https://github.com/cambridgeltl/MTL-Bioinformatics-2016

</table>

the databases. Therefore, we do not need to create and maintain dictionaries from scratch.

We construct dictionaries for genes/proteins, diseases, and drugs, to train the proposed model on the BC2GM, NCBI-disease, and BC4CHEMD datasets, respectively. Further, three dictionaries of person (PER), location (LOC), and organization (ORG) are built to train the proposed model on the CoNLL 2003 dataset.

**Gene/protein dictionary** We created a gene/protein dictionary from public databases: Human Gene Nomenclature (HGNC) and NCBI Entrez Gene (Maglott et al., 2019). HGNC is a database containing unique names and alias names for human genes. NCBI Entrez Gene is the National Center for Biotechnology Information (NCBI)’s database for gene-specific information (Maglott et al., 2011). We extracted gene names, their symbols, alias symbols, and alias names to build our gene/protein dictionary. The dictionary contains 292,853 gene entity surfaces.

**Disease dictionary** We built a disease dictionary based on Human Disease Ontology (LM et al., 2019). Our disease dictionary is built from disease names and their synonyms based on the ontology with 30,426 disease entities.

**Drug dictionary** For the drug dictionary, we used DrugBank Vocabulary ³ from DrugBank (DS et al., 2019). We entered common names and synonyms as drug names into the dictionary. The dictionary contains 26,235 drug entities.

**PER, LOC, and ORG dictionaries** We constructed three dictionaries on person (PER), location (LOC), and organization (ORG) from the DBpedia database ⁴ to train the proposed model on the CoNLL 2003 dataset. We used categories from the 2019-8-30 Version and extracted categories that include keywords such as “Person,” “Organization,” and “Places” to construct the dictionaries. The dictionary consists of 710,492 PER, 37,687 ORG, and 69,028 LOC entities.

### 5.3 Experimental Setting

To obtain multiple approximate matches of the input sentence and dictionary, we used Simstring (Okazaki and Tsujii, 2010), an approximate string matching library that searches for similarities between a set of characters (e.g., “cosine,” “jaccard”) with a query string length exceeding a specified threshold. Simstring is known as a fast and efficient algorithm for approximate dictionary matching.

We used Simstring to obtain matching results for N-gram (N ≤ 5) with the dictionary. The cosine similarity threshold between N-grams of the input sentence and dictionary entries was empirically set to 0.8. This is because the threshold value of 0.8 revealed good results during preliminary experiments. Next, we created a set of matching patterns based on the matching results.

For hyperparameter tuning, entity-likeness representation dimension sizes of 50, 100, and 300, and batch sizes of 16 and 32, were selected. Therein, we decided the parameter for entity-likeness representation and batch size are 100 and 32, respectively. Contextual word embedding derived from the pre-trained model is concatenated with 100-dimensional entity-likeness representation embeddings, and then fed into a label prediction layer. We trained for 20 epochs and the NER results were averaged over five seeds.

All experiments were conducted using a single NVIDIA GeForce RTX 16 GB GPU. Pytorch version was 1.4.0. We used the HuggingFace PyTorch implementation of (Wolf et al., 2019) ⁵ to conduct the experiments.

**Experiment 1: Learning Entity-likeness with BioBERT** We followed the recipe of Lee et al. (2019a) to train the model with the following hyperparameters: learning rates of 1e-5; batch sizes of 32; and weight-decay of 0.001. We used the pre-trained model BioBERT v1.0 (Wiki + Books + PubMed 200K + PMC 270K) ⁶ as a contextual word embedding.

⁴https://downloads.dbpedia.org/repo/lts/generic/
⁵https://github.com/huggingface/transformers
⁶https://github.com/naver/biobert-pretrained
For the approach using the approximate matching result, we compared our method with Liu et al. (2019). They proposed a pre-training sub-tagger softdict that softly matches a sentence with gazetteers for NER. This sub-tagger plays the role of an approximate dictionary look-up. Softdict is trained on gazetteers and non-entity N-grams sampled from the corpus.

They sampled 1 million non-entity N-grams from 14,987 sentences in the CoNLL 2003 training data. For each dataset, we sampled non-entity N-grams using the same ratio of data size and sample size. Following the settings in their work, we used pre-trained 50-dimensional Glove word embedding (Pennington et al., 2014), contextualized ELMo embedding, a convolutional character encoder and the pre-trained softdict to train the NER model.

Experiment 2: Learning Entity-likeness with BioELMo and Bio_word2vec We confirmed the performance of the proposed method with other pre-trained LMs. We conducted experiments using contextual embeddings from pre-trained models BioELMo (Jin et al., 2019) \(^7\) and Bio_word2vec (Pyysalo et al., 2013) \(^8\). We kept the default hyperparameters settings in Jin et al.’s work, with a batch size of 32, Adam learning rate of 0.002, and training for 10 epochs. The embedding derived from BioELMo or Bio_word2vec is concatenated with 100-dimensional entity-likeness representation embeddings and then are fed to four feed-forward layers and a CRF output layer.

Experiment 3: Learning Entity-likeness with BERT For experiments on the CoNLL 2003 dataset, a pre-trained BERT-based case was used instead of BioBERT. Hyperparameters were set the same as for learning entity-likeness with Experiment 1.

5.4 Results

For learning entity-likeness with BioBERT, we evaluated the accuracy of the results with an entity-level F-measures. For learning entity-likeness with BioELMo and Bio_word2vec, we used the official evaluation codes of BC2GM, which contain multiple ground-truth tags to calculate F-measures, following the work of Jin et al. (2019).

The experimental results are presented in Tables 2, 3 and 4. In Table 2, the F-measures were obtained in the experiments conducted based on the Pytorch implementation library of (Wolf et al., 2019); the best scores are denoted in bold. The scores are almost the same with scores reported in (Lee et al., 2019b), which are not the scores reported in the original BioBERT papers (Lee et al., 2019a).

The difference in scores of the original paper (Lee et al., 2019a) and (Lee et al., 2019b) is due to the neural network implementation library (Pytorch-based or TensorFlow-based), the implementation framework (HuggingFace, etc.), and the GPU architecture and setting of the random seed.

Table 3: Results of learning entity-likeness by probing BioELMo and Bio_word2vec on the BC2GM dataset. Cells represent Precision, Recall and F-measure with standard deviation. Exa and App denote Exact and Approximate, respectively.

As listed in Tables 2, 3 and 4, learning both exact matching and approximate matching outperforms BioBERT-based methods and improves F-measures by up to +0.13, +0.21 and +0.06 points on the three biomedical benchmarks BC2GM, NCBI-disease and BC4CHEMD, respectively; BioELMo and Bio_word2vec improve F-measures by up to +2.2 and +4.9 points on BC2GM; BERT-based methods improve F-measures by up to +0.25 points on CoNLL 2003.

6 Discussion

The experimental results indicate that, in the case of exact matching, F-measures are not highly different for the four types of pooling. As shown in Table 2, 3 and 4, sum pooling obtains the best results in the case of approximate matching. It is considered to be more informative for summarizing all features of the possible approximate matching patterns to estimate entity-likeness. Precision is improved in exact matching while recall is improved in approximate matching. In approximate matching, even though the matching results are noisy, tuning to select the appropriate pooling can help minimize noise. Our approach has effectiveness for small datasets such as NCBI-disease, and multi-category datasets such as CoNLL 2003, where F-measures improved by up to +0.21 and +0.25 points, respectively.

In Table 2, the improvement of F-measures is not significant on the BC4CHEMD dataset. It is thought that this is because approximate matching of N-gram (N ≤ 5) returns only dictionary entries which approximately match with N-gram only up to 5-words, while there are drug names whose length are much longer than 5-gram in BC4CHEMD dataset. For datasets containing long NEs, it is necessary to set N-grams with larger values.

Our approach has effectiveness for small datasets with complicated NEs. In reality, obtaining large-scale domain specific data like BC2GM and BC4CHEMD is very costly, while NEs in the biomedical domain are complex and continuously increasing every year.

7 Conclusion

In this paper, we proposed a new approach: learning the entity-likeness of phrases in sentences by using multiple approximate matching results. The experiments show three properties. The approach has portability with various pre-trained LMs. Our Sum pooling methods efficiently filter noisy approximate matching results for learning entity-likeness. Our approach effectively works particularly on small datasets, not only in the biomedical area but also in more general domains. Moreover, our approach does not require expensive computation. We hope that the proposed approach can contribute to identifying NEs in such cases.

Abstract

We present an adaptation of the Text-to-Picto system, initially designed for Dutch, and extended to English and Spanish. The original system, aimed at people with an intellectual disability, automatically translates text into pictographs (Sclera and Beta). We extend it to French and add a large set of Arasaac pictographs linked to WordNet 3.1. To carry out this adaptation, we automatically link the pictographs and their metadata to synsets of two French WordNets and leverage this information to translate words into pictographs. We automatically and manually evaluate our system with different corpora corresponding to different use cases, including one for medical communication between doctors and patients. The system is also compared to similar systems in other languages.

1 Introduction

Augmentative and Alternative Communication (AAC) is used by disabled people to help them to communicate in daily life and to be more independent in their interactions with others (Beukelman and Mirenda, 1998). As such, AAC technologies also improve the social inclusion of disabled people, including those with an Intellectual Disability (ID), which are the focus of this paper.

One of the characteristics of AAC is to represent the natural language in the form of pictures or pictographs, to support the communication of people with language impairment. Several sets of pictographs have been designed specifically for people with an ID to express their basic needs to their family, friends, teachers, or healthcare professionals. Pictures can be used by these persons for communication in various situations such as for social media (Vandeghinste et al., 2015), access to school (Vaschalde et al., 2018), or in the (pre-)hospital setting (Vaz, 2013; Eadie et al., 2013).

Recent research focuses on applications with pictographs for medical settings and people with or without disabilities such as foreigners and allophone patients. This is the case for the Smartwatch prototype of Wolk et al. (2017) and the BabelDr project (Bouillon et al., 2017; Norré et al., 2021a,b). Current systems are often limited and do not always use NLP techniques, especially the applications available for the general public. My Symptoms Translator (Alvarez, 2014; Alvarez and Fortier, 2014) and MediPicto AP-HP1 are examples of mobile app for medical communication with images between doctors and patients.

This article focuses on the Text-to-Picto system, which automatically translates text into pictographs for people with an ID (Sevens, 2018; Vandeghinste et al., 2015). The system was originally designed for Dutch, and later extended to English and Spanish (Sevens et al., 2015). In this work, we adapt it to French. In addition, we extend the system by linking it to a third pictograph set, namely Arasaac2. Until now, two pictograph sets had been used in Text-to-Picto: Sclera3 and Beta4, but adding Arasaac was relevant in view of its growing popularity and coverage (more than 15,000 coloured pictographs, which are specifically designed for people with an ID).

This paper first refers to some related work (Section 2), before introducing the methodology used to adapt Text-to-Picto to French (Section 3). Then, we automatically and manually evaluate the French translation system with the three pictograph sets, using three corpora corresponding to different use cases of AAC. Results are also compared to those of similar systems (Section 4). Finally, we discuss the different evaluations of the system (Section 5).

2 Related Work

In this section, we present some work about text-to-pictograph translation systems integrating various NLP techniques for different languages.

In their translation system, Mihalcea and Leong (2008) used the WordNet resource (Miller, 1995), but without exploiting the relations between concepts. In addition, their system aimed to translate only the content words (nouns and verbs). The Glyph automatically translated patient instructions using NLP (e.g. preprocessing stage, including sentence splitter, word and synonym normalization, etc.), terminology or medication databases, but also computer graphics techniques (Zeng-Treitler et al., 2014; Bui et al., 2012). This application was not designed or tested with disabled people unlike the work of Sevens (2018) and Vandeghinste et al. (2015) on the Dutch Text-to-Picto system, later extended to English and Spanish in the framework of the Able to Include project. The Text-to-Picto system had a certain success: Kultsova et al. (2017) integrated it in an assistive mobile application for travel and communication in Russian, intended for people with an ID, whereas Nandy (2019) adapted it for Indian languages. Other systems were also developed recently such as AraTraductor, an application for Spanish using NLP to improve its pictograph translations (Bautista et al., 2017) or the system of Imam et al. (2019) for English, which uses WordNet and ImageNet (Deng et al., 2009).

For French, Vaschalde et al. (2018) implemented a speech-to-picto tool with an automatic speech recognition module. It includes a system to automatically translate text into Arasaac pictographs, the set of images for AAC used for this study. Based on the work of Vandeghinste et al. (2015), Vaschalde et al. (2018) also evaluated their prototype by testing word sense disambiguation and automatic simplification for the passive structures or the deletion of some grammatical words. All these techniques were already tested by Sevens (2018), but only for translation from Dutch. Sevens et al. (2017) developed a rule-based module for simplification of twelve syntactic phenomena (relative clause, non subject-verb-object order, etc.), including compression. For pictograph translation, Sevens et al. (2016) also used a Dutch word sense disambiguation tool. It is worth mentioning that for the French language, there are not many large resources (e.g. sense-annotated corpus) – compared for example to English – for these NLP tasks.

3 Methodology

In this section, we describe how we automatically linked the pictographs to lexical-semantic resources. The Princeton WordNet or PWN (Miller, 1995) is one of the largest lexical databases for English. It classifies verbs, nouns, adjectives and adverbs into sets of cognitive synonyms, called synsets, which are linked by semantic relations. Its latest versions are the PWN 3.0 and the PWN 3.1, whose synsets do not have the same numeric identifiers.

For French, we found the WOrdnet Libre du Francais or WOLF (Sagot and Fisler, 2008) and the WoNeF (Pradet et al., 2014), two automatic translations of PWN 3.0 that differ in the way they were built. In this work, we use the WOLF 1.0b4 (2014) and the three versions of WoNeF 0.1 (2012): coverage (c), fscore (f), and precision (p). The WOLF is considered as the standard French WordNet and is cited more often than WoNeF. Compared to the 117,659 synsets of PWN 3.0, it contains 56,475 synsets with at least one lemma translated into French (see Table 1). As regards the WoNeF, the high coverage version contains 109,447 pairs (literal, synset), the main WoNeF has a F-score of 70.9%, and the high precision version has a precision of 93.3%. In addition, as a result of optimizing the three metrics, the coverage version includes 55,697 synsets, the fscore version has 53,440 and the precision has only 15,482 (Pradet et al., 2014).

Table 1: Number of non-empty synsets of French WordNets and percentage compared to PWN 3.0 per POS.
The Text-to-Picto system was designed to be language independent and easily extensible to other languages. For the Dutch version, Vandeghinste and Schuurman (2014) had manually linked 5,710 Sclera pictographs and 2,760 Beta pictographs to Cornetto WordNet before linking them automatically to PWN 3.0 for English and to MCR WordNet 3.0 for Spanish (Sevens et al., 2015).

To extend the Text-to-Picto system to French and to the Arasaac pictograph set, we could not get access to the links between the PWN 3.0 and 800 Arasaac pictographs of Schwab et al. (2020). We therefore used the Arasaac API to get JSON data, including the manual links to the PWN 3.1, different pictograph filenames (i.e. the lemmas), and their numeric identifiers (allowing to access the pictograph url). The pictograph filenames are available for at least 30 languages, including English, Spanish, Dutch, Russian, Arabic, etc. The other data of Arasaac API are the same for all languages.

Using OpenRefine (Verborgh and De Wilde, 2013), we cleaned the data: sort, deletion, preprocess duplicate filenames (renamed by adding numbers to distinguish the pictographs in the reference corpora), etc. We automatically linked the Arasaac pictographs associated with one or more synsets of PWN 3.1, WOLF and WoNeF through the PWN 3.0 identifiers and the Collaborative Interlingual Indexes (CILI) available on the GitHub repository of the Global WordNet Association. It would also be possible to have translations from the Open English WordNet (McCrae et al., 2020) into Arasaac pictographs. This WordNet and the PWN 3.1 have the same synset identifiers.

For example (see Figure 1), the Arasaac pictograph docteur or médecin (doctor) has the identifier 2467. It is associated with a PWN 3.1 synset and other information (e.g. one or several tags) that we separated in other tables for future work. By transferring the English synset automatically with CILI, we obtain the PWN 3.0 synset, POS, relation(s) and lemma(s) of French WordNets. In this case, {docteur/médecin/toubib} for WOLF and only {médecin} for WoNeF (coverage and fscore versions) in which the lemmas {docteur} and {toubib} are linked to another synset. Surprisingly, in the WoNeF (precision), there is no lemma {docteur} and {médecin} although they are frequent terms for doctor, but only the rare term {toubib}, linked to two other synsets.

![Figure 1: Mapping Arasaac pictographs with French WordNets.](image-url)

As a result of this process, our Text-to-Picto system is the first that uses synsets of the French WordNets. In contrast, Schwab et al. (2020) directly used the PWN 3.0 and automatically translated the text because they consider the original PWN as the most complete and reliable database. As mentioned before, the automatic translations of WOLF and WoNeF versions differ and are, indeed, less complete compared to PWN 3.0.

### 3.2 Description of the System

We describe the architecture of our system used to translate a textual input into a sequence of Sclera, Beta, or Arasaac pictographs (see Figure 2).

![Figure 2: Architecture of the Text-to-Picto system adapted from Vandeghinste et al. (2015).](image-url)

The source text first undergoes shallow linguistic analysis: on the one hand, sentence detection, tokenization, part-of-speech tagging and lemmatization,
tion are carried out by TreeTagger (Schmid, 1994); on the other hand, we added detection of Multi-Word Expressions (MWE), processing of specific French phenomena (e.g. elision, negation variants), and simple Named Entity Recognition (NER) based on rules and dictionaries. As in Vaschalde (2018), the named entities detected are substituted by generic placeholders such as character or city.

For example (see Figure 3), the sentence Max ira à Leuven l’été, au revoir (Max will go to Leuven the summer, goodbye) is translated by a sequence of seven pictographs perso, aller, à, ville, le, été, au revoir (character, go, to, city, the, summer, goodbye) after the shallow linguistic analysis. Without the rules of elision and MWE detection, the article le (the) would not be translated and the MWE au revoir (goodbye) would be incorrectly translated, i.e. by two pictographs: the preposition au (at) and the verb revoir or corriger (revise).

In the next step, two routes are possible depending on the word to translate: the semantic route and the direct route. In the semantic route, each word is looked up in the WordNet database. In case a word is not found, we leverage two WordNet relations – has_hyperonym and near_antonym – to get substitute translation. For example, there is no pictograph for saumon (salmon), the word is therefore translated by its hyperonym poisson (fish). The word infecter (infect) does not have a pictograph either and is translated by its antonym followed by the negative pictograph, i.e. désinfecter pas (desinfect no).

In their annotations for Sclera and Beta sets, Vandeghinste and Schuurman (2014) indicated whether the pictograph is complex or not, i.e. whether it represents several concepts (verb + noun, noun + noun, noun + adjective). For example, manger un sandwich (eat a sandwich) is translated by the single pictograph boterham-eten in Sclera. This filename is linked to the head synset {manger/alimenter/déjeuner} (eat/feed/lunch) and to the dependent synset {sandwich}. Information about pictographs corresponding to a MWE is missing for Arasaac. It is worth mentioning that inflection is taken into account for MWE annotated with two synsets, unlike the MWE detection used in the shallow linguistic analysis.

For the direct route, we build a dictionary for each of our three pictograph sets for the words not covered by WordNet, i.e. pronouns, prepositions, etc. In Sclera and Beta, the pictographs were linked to their Dutch filename by Vandeghinste et al. (2015). We have then manually translated these two Dutch dictionaries into French. For Arasaac, pictographs were manually linked to French lemmas through their identifiers. A part-of-speech tag were also used to distinguish certain homonyms, e.g. the negative adverb pas (not) and the noun pas (step). As a result, our dictionaries provide respectively 412, 298 and 420 direct links between pictographs and French tokens or lemmas.

To choose the optimal path while converting a sequence of lemmas to a sequence of pictographs, we use the search algorithm A* described in detail by Vandeghinste et al. (2015). It works with different parameters (i.e. penalties) related to WordNet relations, pictograph features and route preference.

### 3.3 Use Cases

We briefly describe our three corpora representing several use cases of AAC. They are used for the automated and manual evaluation of our system in which we use different metrics to compare the system’s output to a reference translation.
1. The **Email Corpus** (130 sentences), manually translated into Sclera and Beta pictographs by Sevens (2018). The emails, written by people with an ID, their teachers, or their parents, were extracted from the WAI-NOT Belgian website. We manually translated this Dutch corpus into French and Arasaac pictographs. We have slightly pre-edited the reference translations into Sclera and Beta to maintain French word order of our corpus. We did not reproduce the spelling mistakes of people with an ID because we do not evaluate the automated spelling correction.

2. The **Book Corpus** (254 sentences), consisting of six copyright-free children stories manually translated into Arasaac pictographs by Vaschalde (2018). We have slightly pre-edited this French corpus to make it compliant with our evaluation format: e.g., we did not translate plural words twice as is the case in Vaschalde (2018). For example, *les couvertures* (the covers) in its source corpus is manually translated by *le couverture couverture* (the cover cover) in its reference corpus. In our reference corpus, we replaced it by *les couverture* without repetition and keeping the plural for the article because we added the pictograph *les* in our dictionary. We also modified some filenames in their reference translations because we renamed the duplicates when we preprocessed the Arasaac data.

3. The **Medical Corpus** (260 sentences), is a subset from BabelDr, a medical translation system (Bouillon et al., 2017). These sentences are relatively simple compared to some variations offered by the system. There are mainly questions from doctors to patients, i.e. *pouvez-vous décrire la douleur ?* (can you describe the pain?) or *à combien était votre température la dernière fois que vous l’avez mesurée ?* (was what your temperature the last time you measured it?). There are also patient instructions such as *je vais m’occuper de vous aujourd’hui* (I will take care of you today). As for the Email Corpus, we manually translated the Medical Corpus into Arasaac pictographs. The Figure 4 shows an example of reference translation, the sequence of five filenames: *avoir, vous, des, carie, ?* (have, you, the, cavities, ?).

As regards manual translations, all the words in the source text are translated into pictograph filenames in our reference corpora. However, the process is not a literal translation. We have sometimes translated several words into a single pictograph: e.g. for MWE such as *bouteille de coca* (bottle of coca-cola) or *envoyer une lettre* (send a letter), which can be translated by the complex pictograph *Coca-Cola* or *envoyer*2 in Arasaac (see Figure 5). Some Arasaac pictographs can also have different filenames or meanings, e.g. the pictograph for *mal de tête* (headache) or *faire mal* (hurt).

![Figure 5: Example of complex pictographs for bouteille de coca (Sclera/Arasaac), envoyer une lettre (Sclera/Arasaac) and mal de tête or faire mal (Arasaac).](image)

4 Results

This section presents how we tuned the system (Section 4.1) and describes the results of the automated evaluation (Section 4.2), followed by the manual evaluation (Section 4.3).

4.1 Tuning the System

For tuning our system, we used 56 sentences sampled from the Email Corpus, that is our development set. We should also stressed that running several times the Text-to-Picto system on the same sentence may yield slightly different translations, even with the same parameters (cf. Section 5). Therefore, each BLEU score has been computed as the average over 10 runs (translations). We also report the standard deviation (SD) over the 10 runs.

We first experimented with the WordNets: the WOLF and the three versions of WoNeF – coverage (c), f-score (f), and precision (p). At this step, as we did not know the optimal parameters for Text-to-Picto yet, we used the best ones reported by Sevens (2018) for Sclera and Beta sets (for Arasaac, we
took Beta’s parameters). The standard BLEU score (Papineni et al., 2002), reported in Table 2, allowed us to choose WOLF as the best French WordNet, as it obtains the highest BLEU scores regardless of the pictograph set. Therefore, WOLF will be used for all our evaluations. These results can be explained because WOLF is often connected to more synsets than the WoNeF; therefore it is more likely that there is a link to the pictograph. For WOLF, the SD is always higher than for WoNeF (SD equals 0 for the high precision version, as its small size makes it less likely to refer to several lemmas).

</tbody>
</table>

Table 2: Results of the French Text-to-Picto for WOLF and WoNeF by pictograph set with BLEU metric.

In the next step, we tuned the parameters (cf. Section 3.2) through an automated procedure, using a local hill climbing algorithm (Vandeghinste et al., 2015) with BLEU as the evaluation metric. For each pictograph set – Sclera (S), Beta (B) and Arasaac (A) –, we run five trials of 50 iterations with different random initialisation of the parameters and using a granularity of one, in order to cover different areas of the search space. Finally, we took the best scoring parameter values (see Table 3).

4.2 Automated Evaluation

We automatically evaluated the performance of our French Text-to-Picto system on the Email Corpus, the Book Corpus and the Medical Corpus. Different experimental conditions were tested, progressively activating more features of the system: a) only with dictionary, b) with dictionary and synonyms of WOLF, c) with dictionary, synonyms and other relations of WOLF (i.e. hyperonyms, antonyms). In addition, we compared our results with those of the Dutch Text-to-Picto system (Sevens, 2018) and those of the French system of Vaschalde et al. (2018), when available. Such comparisons should be taken with caution, as the experiments are not strictly comparable.

For a better comparison with these studies, we reused the metrics of Sevens (2018) and Vandeghinste et al. (2015): the BLEU (Papineni et al., 2002),9 the Word Error Rate (WER) and the Position-independent word Error Rate (PER). BLEU is designed for machine translation, while WER and PER are used in speech recognition. All of these metrics compare the system output to one or more reference translations. In our case, we used sentences translated manually into pictograph filenames (cf. Section 3.3). As described in Section 4.1, each evaluation metric was estimated based on an average over 10 runs of the system. Standard deviations are reported in brackets in the tables.10

Table 4: Results of the French Text-to-Picto and Dutch Text-to-Picto on Email Corpus by pictograph set with BLEU, WER and PER metrics.

We compared our results with those of Sevens (2018) for Dutch on the same 84 sentences from the Email Corpus (see Table 4). As regards BLEU scores, we got very comparable results, especially

---

9The standard BLEU based on average of 1-grams, 2-grams, 3-grams, and 4-grams (mteval-v011b.pl on https://github.com/moses-smt/mosesdecoder).

10For the first condition (a), the SD is always 0 because, as without WordNet, there is no variation in the results.
for Sclera. For Beta, our scores are lower than those of Sevens (2018). Arasaac obtains the best BLEU scores, except for the first condition (a). This can be explained by the fact that dictionaries for Sclera and Beta are more suitable for this task. They were built from frequent untranslated words from the Email Corpus. For the conditions (b) and (c), differences does not seem meaningful.

For the Book Corpus, as proper names occur frequently, we added one condition: d) without the step of Named Entity Recognition (NER), based on the work of Vaschalde (2018). Results are reported at Table 5. Our BLEU scores for conditions (b) (28.0) and (c) (28.3) are in line with those of Vaschalde et al. (2018). Their translation system from French into Arasaac pictographs obtains a BLEU score of 25.45 when all the words are translated, without word sense disambiguation and without a specific treatment for plurals (26.65 with it). The rather decent score of the dictionary condition (a) on this corpus – in contrast with its performance on the two other use cases – can probably be explained by the effect of the NER module. Indeed, the test set includes 152 occurrences of proper names and we observe that, without NER module (d), scores drop a lot.

Table 7: Results of the French Text-to-Picto on Medical Corpus and Dutch/English/Spanish Text-to-Picto on Email Corpus by pictograph set with Precision, Recall and F-score metrics.

By comparison, Sevens (2018) obtained on its Email Corpus a F-score between 81-85% for English-to-Sclera/Beta system and 87-91% for Dutch/Spanish-to-Sclera/Beta (without counting proper names). Our French system obtains a higher recall than precision and recall of other linguistic versions. In our manual evaluation, we assume that all words must be translated.

5 Discussion

As regards the efficiency of the different pictograph sets, tested on the Email Corpus, we see that our results are better for the Beta set than for the Sclera set. Sevens (2018) explained that Beta contains less pictographs than Sclera. As a result, more paraphrasing translations are possible in Sclera, resulting in a less accurate measurement of translation quality by BLEU. However, our scores for Arasaac, the largest set of pictograph, are the best. Compared to others, this set includes more function words (articles, prepositions, etc.) that have been encoded in our dictionary. Therefore, they will always be well translated, which improves the results. It should also be mentioned that, despite
relatively good results, some pictographs generated by our system are not also easily comprehensible, depending on the context of the sentence. This is especially the case for function words and pain description on a specific body part. In addition, medical words are not always translated because there is no corresponding pictographs, e.g., symptôme (symptom), cancer (tumor), etc.

Our experiments also aimed at assessing the contribution of different components to our Text-to-Picto system for French. Using only the dictionary clearly yields unsatisfactory results. The system improves when we add the synonym or the relation component, regardless of the pictograph sets and corpora. However, the difference between both components appears marginal. In our reference corpora, a manual inspection of the data reveals that the relation of synonymy is much more frequent than those of hyperonymy and antonymy – which is very rare –, especially for the largest Arasaac pictograph set. Translating text into pictographs is a meticulous and time-intensive process (Sevens et al., 2016). This explains why the corpora are small. It is worth mentioning that the BLEU score is very dependent on the reference translation, which may be partially subjective.

Finally, as explained above, every time we run the French system with the same parameters, we get slightly different translations. This happens when the optimal path calculation step has to choose randomly between several pictographs that have an equal weight, using WordNet. For future work, it would be possible to associate the pictographs with frequency information to regulate this issue. Some studies (Imam et al., 2019; Sevens, 2018; Sevens et al., 2016) also showed that word sense disambiguation improves the results of text-to-picto systems. This would avoid translation errors related to homonyms identified in our manual evaluation, e.g., enceinte (to be pregnant or a speaker) and bleu (the colour or a bruise).

6 Conclusion

We presented the French version of the Text-to-Picto system, which automatically translates a textual input into pictographs for people with an ID. Our experiments show that this system is easily extensible to other natural or pictograph languages.\textsuperscript{11}

Compared to the Dutch version, we adapted the shallow linguistic analysis by adding new steps (detection of MWE, preprocessing of specific phenomena, and simple NER). Data cleaning was performed to link the Arasaac pictographs to French semantic resources. The evaluations on the Email and the Book Corpus with WOLF show that our results are indeed in line with those of previous studies. However, there is room for further improvement, for instance adding a word sense disambiguation step to select the right pictograph for a given meaning. We also carry out automated and manual evaluations on a new use case: medical data, which raised new challenges related to the translation of technical terms. We have seen above that our system currently tends to poorly handle technical terms, often missing from WOLF. We plan to investigate solutions to this limitation, for example by applying automatic text simplification for the medical domain (Cardon and Grabar, 2020) on the original sentences.

We also plan to run tests with target users to tune this Text-to-Picto system for medical communication between doctors and patients in the hospital setting. The Dutch version of the presented system has already been tested in real situations with a focus group of five adults with an ID and two coaches in a day centre in Belgium (Sevens, 2018).

Acknowledgments

This research was funded by the UCL-FSR mandate N°13936.2020. This work is also part of the PROPICTO project, funded by the Fonds National Suisse (N°197864) and the Agence Nationale de la Recherche (ANR-20-CE93-0005). The pictographs used are property of the Aragon Government and have been created by Sergio Palao to Arasaac (http://arasaac.org). Aragon Government distributes them under Creative Commons License (BY-NC-SA). The other pictographs used are property of Sclera vzw (https://www.sclera.be/) which distributes them under Creative Commons License.

Abstract

In this paper, we present a major update to the first Hungarian named entity dataset, the Szeged NER corpus. We used zero-shot cross-lingual transfer to initialize the enrichment of entity types annotated in the corpus using three neural NER models: two of them based on the English OntoNotes corpus and one based on the Czech Named Entity Corpus fine-tuned from multilingual neural language models. The output of the models was automatically merged with the original NER annotation, and automatically and manually corrected and further enriched with additional annotation, like qualifiers for various entity types. We present the evaluation of the zero-shot performance of the two OntoNotes-based models and a transformer-based new NER model trained on the training part of the final corpus. We release the corpus and the trained model.

1 Introduction

1.1 Resources

Named entity recognition is a fundamental NLP task that has played an important role in tasks like information extraction, document deidentification, conversational models, etc. Following the annotation scheme used in the CoNLL 2002/2003 NER annotation tasks, legacy named entity corpora usually contain annotation of four entity types: organizations (ORG), persons (PER), locations (LOC) and general entity category covering all the rest (MISC). This is the case for all named entity corpora available for Hungarian, the Szeged NER corpus (Szarvas et al., 2006), the silver-standard Hungarian hunNERwiki corpus (Simon and Nemeskey, 2012) automatically derived from Wikipedia, and the recently published NerKor corpus.\footnote{https://github.com/nytud/NYTK-NerKor} The English OntoNotes 5 corpus (Weischedel et al., 2013), on the other hand, contains a richer set of entities. Geopolitical entities (GPE: countries, settlements, etc.) and facilities (FAC: buildings, roads, airports etc.) are differentiated from geographical locations like continents or bodies of waters. Within the MISC category, products (PROD), laws and other norms (LAW), events (EVENT) and titles of works of art (WORK_OF_ART) are differentiated. In addition, the OntoNotes NER tagset also encompasses time and numerical expressions distinguishing dates and times, cardinal and ordinal numbers, quantities, percentages and amounts of money. In addition, other categories covering non-entities like languages (LANGUAGE) and nationalities, religions and political affiliations (NORP ‘nationality/other/religion/political’) are covered, presumably just because English orthography happens to prescribe capitalization for words (adjectives in the case of NORP) belonging to this category.

Some resources in languages other than English also use NER tagsets richer than the basic four-class tagset. Although the NoSta-D resource used in the GermEval2014 shared task targeting German NER (Benikova et al., 2014) maintains a four-class distinction, words (especially adjectives) derived from names as well as compounds containing them are marked as such. This corpus, similarly to other resources like the GENIA corpus (Kim et al., 2003) containing biomedical entities and the Spanish and Catalan newspaper text corpus AnCora (Taulé et al., 2008), also features nested named entities. One of the most richly annotated NER corpora is the Czech Named Entity Corpus (Ševčíková et al., 2007). It contains both a rather rich set of entity types and nested entities.

1.2 Architectures for Sequence Tagging and Cross-lingual Transfer

Legacy data-driven statistical machine learning algorithms based on Hidden Markov Models (Baum
and Petrie, 1966), Maximum Entropy models (Ratnaparkhi, 1996) and CRF (Lafferty et al., 2001) provided then state-of-the-art performance for sequence tagging, however they relied on data and features pertaining strictly to the target language. This meant that a significant amount of annotated training data in the target language was required to attain acceptable performance using these models.

The paradigm shift to neural models offered the possibility of changing this situation. Already the simplest non-contextual distributional word embedding models like word2vec (Mikolov et al., 2013a,c) were discovered to have some kind of inherent language-independent property. It was found that models trained on different languages independently can be mapped to each other with high accuracy using a rather limited bilingual vocabulary (Luong et al., 2015) or even in an unsupervised manner (Mikolov et al., 2013b).

It was also discovered that, with neural machine translation models, it is possible to improve performance in specific lower-resource languages simply by training the encoder and the decoder of the model in a shared manner on multiple languages. This resource-sharing also made direct translation between all of the represented languages possible, and resulted in savings in resources concerning both training, storage and inference, i.e. using the model in production. The models offering state-of-the-art performance in machine translation performed similarly well in other NLP tasks. Pre-training the encoder of models used in NMT (especially the now-ubiquitous transformer architecture (Vaswani et al., 2017)) for simple mask-filling tasks on high amounts of (monolingual) plain text resulted in contextual language models that could be fine-tuned for specific tasks in a much more efficient manner than training similar models from scratch (Devlin et al., 2019). These models significantly improved the state-of-the-art for nearly all NLP-related tasks even for high-resource languages like English. The improvement is even more significant in the case of lower-resource languages.

Multilingual training turned out to be fruitful not only in the domain of machine translation. The publication of multilingual contextual language models like multilingual BERT (Devlin et al., 2019) and XLM-RoBERTa (Conneau et al., 2019) made cross-lingual knowledge transfer efficient for other NLP tasks as well. It is possible to fine-tune the language model for e.g a token classification task, like named entity recognition in one language and apply it to another language. Even in a zero-shot scenario, where the token classification model has not seen any training data in the target language, it can provide a reasonable performance, especially if the target language is included among the languages covered by the underlying language model.

On the other hand, models trained on multiple languages were found not to provide state-of-the-art performance if a significant amount of training data is available for the given task in the target language. Fine-tuning a monolingual language model for a specific task usually results in better performance than using a heavily multilingual model like multilingual BERT, because the target language is usually relatively underrepresented in the underlying multilingual model (Martin et al., 2020). In this paper, we present a data annotation scenario in which we used zero-shot transfer to preannotate a language resource, which was then manually corrected and enriched to create a resource that can then be used to train a monolingual model to optimize performance.

2 Method

In the project presented in this paper, we significantly enriched the annotation in the first Hungarian named entity dataset, the Szeged NER corpus (Szarvas et al., 2006).

2.1 Zero-shot Preannotation

When preannotating the corpus, we fed the tokens to two models trained on the English OntoNotes 5 NER corpus. The first model was created by the DeepPavlov team fine-tuning multilingual BERT (Burtsev et al., 2018). The other model is based on XLM-RoBERTa, a multilingual contextual language model trained on a significantly bigger multilingual corpus than multi-BERT. The latter model is part of the FLAIR tool set (Akbik et al., 2019).

The two models use different tokenization following the tokenization scheme of the underlying contextual language model. The token sequence in the output of the models was thus different from the original input token sequence. This had to be taken into account when merging the annotation from the models with the original annotation. The merging procedure was automatic. While merging the annotations, in the case of overlapping entity spans, we considered the spans in the input anno-
tations gold standard, and if the zero shot model suggested a compatible entity subtype, we updated the entity type. E.g. an entity of type location (LOC) in the original annotation is compatible with any of geographical location (LOC), facility (FAC) and geopolitical entity (GPE). Annotation of non-entities, like dates, quantities and nationalities not present in the original annotation were introduced based on the output of the models.

2.2 Error Analysis and Automatic Error Correction

We identified typical errors of the zero-shot models that could be corrected automatically using regular-expression-based patterns. We have found that, in the case of transfer from English to Hungarian, a typical problem is that for many named entity types like names of organizations, bodies of waters, titles of works of art etc., a definite article is present in most but not all cases in Hungarian, while there is no article in English. This resulted in the model including definite articles for these types of entities in the annotation, an error that could be easily eliminated from the output.

While cross-lingual mapping resulted in some anomalies like inclusion of definite articles, it had other side-effects that we found to be useful. The output of the models also included annotation for adjectives derived from named entities like londoni ‘of London’. In contrast to the German NoSta-D corpus, words like this remained unannotated in all legacy Hungarian named entity corpora in spite of the fact that the identification of these words as references to named entities would be desirable in practical applications like information retrieval. We thus decided to keep this kind of annotation as part of our annotation enrichment effort.

After automatic correction of entity spans and types, we manually merged the outputs of the two models by checking the differences of the two annotations.

2.3 Considering a Third Model

We also applied a third model to the corpus. We used the Czech model of the NameTag 2 neural named entity tagger (Straková et al., 2019) trained on the Czech Named Entity Corpus CNEC 2 (Ševčíková et al., 2007). The underlying corpus and thus also the model contains a very fine-grained set of entity classes offering many subclasses within the broader categories like a distinction of companies vs. governmental/political institutions vs. academic/educational/cultural institutions and conferences/contests (the latter are also considered a subclass of organizations). NameTag 2 is capable of returning nested annotations (with a maximal depth of two overlapping entities). The model can be accessed via a web service. However, at least in the zero-shot cross-lingual setting, the annotation generated by this model seemed to be less accurate than those generated by OntoNotes-based models. Since there are no definite articles in Czech, this model had a similar problem including definite articles for the types of entities (e.g. organizations) that often appear with a definite article in Hungarian. It often generated two overlapping annotations for these types of entities differing only in whether the article is included. More importantly, the different occurrences of the same entity were often assigned different classes (usually this was an error rather than real ambiguity due to metonymic use). Also the extent of the span of the entities was less accurate than in the annotation generated by the English-based models. The subclassification itself also introduces problems of its own. It is not clear where sports clubs or central banks like the Bank of England should belong in this taxonomy.

2.4 Introduction of New Entity Types

Nevertheless, we found good use of the annotation generated by NameTag 2. As Hungarian is an agglutinating language and thus words appear in many different suffixed forms in the corpus, we applied lemmatization to the entity annotations generated by all models and aggregated the results listing the frequency of alternative annotations for the same entity. Tags generated by the FLAIR OntoNotes model and NameTag2 for the most frequent organizations in the corpus are shown in Table 1. Tags containing a hyphen in columns 3 to 8 were assigned by NameTag2, the rest by the FLAIR OntoNotes model. The list features the Budapest Stock Exchange (Budapesti Értéktőzsde = BÉT), the Budapest Commodity Exchange (Budapesti Árutőzsde), Nasdaq, Wall Street, the Hungarian Central Bank (Magyar Nemzeti Bank) and news agencies (MTI, MTI-ECO, Reuters). It is obvious that NameTag 2 struggles trying to assign them the right category. We thus refrained from adopting the taxonomy in CNEC 2.

On the other hand, the automatically generated gazetteer helped us identify entities really belonging to certain well-distinguishable entity classes
Table 1: Most frequent organizations in the corpus with several different annotations generated by the NameTag 2 tagger (labels containing a hyphen).

We generated regular-expression-based automatic correction patterns using manually marked entries from this automatically generated gazetteer (covering also suffixed forms), and mass-corrected annotations using these patterns.

We also discovered that certain types of expressions are mistagged by the zero-shot models due to lack of distinction in the original underlying OntoNotes annotation. One such example was expressions referring to time durations like ‘for five minutes’ or ‘six-day-long’. While other types of quantities are annotated in the OntoNotes NER resource as quantities resulting in sensible annotation also for the Hungarian input, the model mistagged duration expressions as time or date, which should only refer to expressions anchored to the timeline. We thus introduced a new entity type DUR to annotate unanchored duration expressions, and the annotation of many occurrences of this type of expressions could also be automatically introduced/corrected. We also annotated relative date expressions like days of week.

The Szeged NER corpus consists of business news, and due to its genre, it contains many occurrences of certain entity types not covered by the OntoNotes NER tagset: e.g. names of securities and stock exchange indexes. We introduced new tags for these entity types. They were also easy to identify in the generated gazetteer. We also introduced a tag for media like newspapers, broadcasting services and online news portals but refrained from distinguishing subtypes. This type of entities are somewhat similar to but can easily be distinguished from books (covered by the work of art category). On the other hand, they also involve an entity of the organization type (the publisher/redaction).

2.4.1 Metonymic Use of Names

Metonymic use of entities like referring to countries or other geopolitical entities as actors is usually annotated according to the actual metonymic sense. In the recently published NerKor corpus annotated with the coarse-grained ORG-PER-LOC-MISC tagset, references to countries as actors like Germany invaded France are annotated as ORG rather than LOC. This kind of metonymy is completely productive for all types of geopolitical entities, and annotating them as such solves the problem in a more elegant way than what the coarse-grained tagset makes possible. Incidentally, this
specific sort of metonymy is less prevalent in the business news genre than in certain other genres. On the other hand, Wall Street, one of the top entries on the organizations list in Table 1, is an example of an expression typically used in a metonymic sense referring to the New York Stock Exchange (and related financial institutions).

2.4.2 Qualifiers and Relations

In addition to the annotation mentioned above, we introduced two more tags that could be used to annotate qualifiers of named entities: QUAL and REL. These were used in situations where the named entity had a nominal modifier like in Ante Vulin\textsubscript{PER} építész\textsubscript{QUAL} ‘architect Ante Vulin’ or it was part of an appositive structure like in Jurij Lvov\textsubscript{PER} pénzügyminiszter-helyettes\textsubscript{QUAL} Világimír Putyn\textsubscript{PER} elnök\textsubscript{QUAL} bizalmasa\textsubscript{REL} ‘Yuri Lvov\textsubscript{PER}, Deputy Minister of Finance\textsubscript{QUAL}, confidant\textsubscript{REL} of President\textsubscript{QUAL} Vladimir Putin\textsubscript{PER}’. REL was used in situations where the phrase expresses a relation between named entities (if both are part of the same noun phrase), QUAL for other modifiers. We used this type of annotation to mark nominal phrases that are not named entities but as qualifiers of named entities have the same type of reference as the related named entity. We pregenerated and later refined this annotation using syntactic dependency parses of the sentences. The dependency structure could be used to identify the modified entities and thus their type, e.g. that elnök ‘president’ is a qualifier of persons and being a confidant is a relation between persons.

2.5 Filtering and Manual Annotation

We also filtered the corpus for repetitive boilerplate-like content: we removed identical sentences and ones differing only in numerical/date expressions. After creating the preannotation using the zero-shot models, automatically merging them with the original annotation and applying pattern-based corrections, we used the INCEpTION annotation framework (Klie et al., 2018) to correct and augment the annotations. Two researchers and five MA students of theoretical linguistics participated in the manual annotation process. Each document was revised by at least two annotators. Curation and final processing of the results was performed by a single researcher. In the current version, we refrained from generating nested annotation although currently the development of nested entity classifiers gained momentum, and some open-source neural nested entity taggers are available e.g. (Shibuya and Hovy, 2020) or (Wang et al., 2020). Although these models have sub-SOTA performance on flat NER datasets (we also found Nametag 2 to generate much less accurate annotation than the OntoNotes 5-based models), we will consider updating the dataset to have nested entities in a possible future release of the corpus. On the other hand, this resulted in ambiguities concerning the extent of entity spans and types, especially with the introduction of tags that mark non-names like qualifiers, nationalities etc.

![Table 2: The distribution of entity types in the original corpus](image)

</tr>
</tbody>
</table>

2.6 Properties of the Corpus

The size of the corpus is 206722 tokens, smaller than the original corpus due to the removal of repeated boilerplate content. On the other hand, it contains 40158 annotated spans, almost 2.8 times as much as in the original version. The distribution of entity types in the original Szeged NER corpus and the final version is shown in Tables 2 and 3. We conflated relational qualifiers with non-relational qualifiers of the same entity type. The MISC category in the final corpus covers only abbreviations annotated in the original corpus as MISC not referring to named entities. ORG-inf denotes entity mentions that refer to unique entities like names but use some informal reference instead of a name. This includes e.g. references to US departments, the FED and other governmental organizations which are referred to in Hungarian as ministries, offices etc., to central banks, stock exchanges etc. Note that there are more GPE entities than there were LOC entities in the original version due to adjectival forms also annotated and EU annotated as GPE rather than ORG. Many MEDIA entities were also ORG in the original corpus.

Entity types have an obviously skewed distribution with organizations, dates, money, nationalities and percentages (including ratios) dominating due to the genre of the corpus, while some tags are rather underrepresented. We plan to address this issue by adding text in other genres to balance the
3 Models and Performance

We tested the zero-shot performance of the original OntoNotes-based models on the final corpus disregarding entity types not covered by the OntoNotes annotation. The FLAIR model achieves $F_1 = 75.20$ with a great proportion of the errors coming from erroneously included definite articles. Considering all tag types, the performance is $F_1 = 67.46$. A simple fix of the definite article problem boosts performance on common tags to $F_1 = 87.91$, and $F_1 = 80.63$ on the full tagset.

The DeepPavlov model trained on the same dataset fared much worse achieving only $F_1 = 58.26$ on common tags and $F_1 = 53$ on the full tagset.

We trained a vanilla neural sequence tagger using the HuggingFace Transformers library (Wolf et al., 2020) fine-tuning the monolingual Hungarian huBERT language model (Nemeskey, 2021) using a 9:1 train:test split of the corpus. It achieved $F_1 = 92.69$, performing significantly better than the zero-shot models.

4 Conclusion

In this paper, we presented the procedure we followed to enrich the annotation in a legacy Hungarian NER resource by applying NER models based on multilingual language models and fine-tuned on NER corpora in other languages. We then made a significant effort identifying errors and correcting the annotation using automatic and semi-automatic methods, providing a solid base for the final manual annotation correction. We trained a neural sequence tagger on the final corpus achieving a solid $F_1 = 92.69$ performance.

Abstract
Unsupervised representation learning of words from large multilingual corpora is useful for downstream tasks such as word sense disambiguation, semantic text similarity, and information retrieval. The representation precision of log-bilinear fastText models is mostly due to their use of subword information.

In previous work, the optimization of fastText’s subword sizes has not been fully explored, and non-English fastText models were trained using subword sizes optimized for English and German word analogy tasks.

In our work, we find the optimal subword sizes on the English, German, Czech, Italian, Spanish, French, Hindi, Turkish, and Russian word analogy tasks. We then propose a simple n-gram coverage model and show that it predicts better-than-default subword sizes on the Spanish, French, Hindi, Turkish, and Russian word analogy tasks.

We show that the optimization of fastText’s subword sizes matters and results in a 14% improvement on the Czech word analogy task. We also show that expensive parameter optimization can be replaced by a simple n-gram coverage model that consistently improves the accuracy of fastText models on the word analogy tasks by up to 3% compared to the default subword sizes, and that it is within 1% accuracy of the optimal subword sizes.

1 Introduction

Bojanowski et al. (2017) have shown that taking word morphology into account is important for accurate continuous representations of words. However, they only show the optimal $n$-gram sizes on the German and English word analogy tasks (Bojanowski et al., 2017, Section 5.5). We continue their experiment by finding the optimal parameters on the Czech, Italian, Spanish, French, Hindi, Turkish, and Russian word analogy tasks and we show an up to 14% improvement in accuracy compared to the default subword sizes.

Furthermore, we propose a cheap and simple $n$-gram coverage model that can suggest near-optimal subword sizes for under-resourced languages, where the optimal subword sizes are unknown. We train our $n$-gram coverage model on the English, German, Czech, and Italian word analogy tasks, and we show that it suggests subword sizes that improve the accuracy by up to 3% on the Spanish, French, Hindi, Turkish, and Russian word analogy tasks and are within 1% accuracy of the optimal subword sizes on average. To make it easy for others to reproduce and build upon our work, we have publicly released a reference implementation of our $n$-gram coverage model.1

The rest of the paper is structured as follows: In Section 2, we discuss the related work. In Section 3, we discuss our methods and we propose our $n$-gram coverage model. In Section 4, we show and discuss our results. We conclude in Section 5 by summarizing our contribution. We outline the future work in Section 6.

2 Related work

Mikolov et al. (2013) described the Word2vec language model, which uses a shallow neural network to learn continuous representations of words: word embeddings. They also produced the English word analogy task, which tests how well word embeddings represent language regularities such as analogical relations (man is to woman what a king is to a queen), and evaluated Word2vec on their task.

https://doi.org/10.26615/978-954-452-072-4_121
Berardi et al. (2015); Köper et al. (2015); Sloboda and Brychcín (2016); Cardellino (2019); Güngör and Yıldız (2017); Korogodina et al. (2020) produced the Italian, German, Czech, Spanish, Turkish, and Russian word analogy tasks for evaluating the performance of non-English word embeddings. Their findings revealed that, despite the morphological complexity of the languages, Word2vec language models can generate semantically and syntactically meaningful word embeddings.

In order to take word morphology into account, Bojanowski et al. (2017) developed the fastText language model based on Word2vec. Their improvements consisted of representing each word as a sequence of subwords with their own embeddings. They evaluated their models on the English, German, Czech, and Italian word analogy tasks. They also showed the optimal subword sizes of fastText on the English and German word analogy tasks. However, they did not optimize the subword sizes of fastText on the Czech and Italian word analogy tasks and used subwords of size 3–6\(^2\), which they described as “an arbitrary choice” (Bojanowski et al., 2017, Section 5.5).

Grave et al. (2018) produced the French and Hindi word analogy tasks. Furthermore, they also trained and publicly released fastText language models for 157 languages. Like Bojanowski et al., they also neglected to optimize the subword sizes. Unlike Bojanowski et al., they used subwords of size 5–5 for all languages, noting that “using character n-grams of size 5, instead of using the default range of 3–6, does not significantly decrease the accuracy (except for Czech).” (Grave et al., 2018, Section 4.3)

\[^2\]For subword sizes, we adopt the notation of Bojanowski et al. (2017) and Grave et al., 2018. For example, subwords of size 3–6 are all subwords whose size is 3, 4, 5, or 6.

### 3 Methods

In this section, we describe our methods and propose our n-gram coverage model, which can be used to suggest subword sizes for a fastText model without expensive parameter optimization.

#### 3.1 Optimal subword sizes

In the first part of our experiment, we train fastText language models on the English (22 GiB), German (8.3 GiB), Czech (1.2 GiB), Italian (4.2 GiB), Spanish (5.2 GiB), French (7.4 GiB), Hindi (0.57 GiB), Turkish (0.72 GiB), and Russian (9.9 GiB) Wikipedia corpora. We use subword sizes \(i–j\) for all \(i, j\), where \(1 \leq i \leq j \leq 10\), and we report the accuracies and the optimal subword sizes \(i–j\) on the English (Mikolov et al., 2013), German (Köper et al., 2015), Czech (Sloboda and Brychcín, 2016), Italian (Berardi et al., 2015), Spanish (Cardellino, 2019), French and Hindi (Grave et al., 2018), Turkish (Güngör and Yıldız, 2017), and Russian\(^3\) word analogy tasks.

#### 3.2 N-gram coverage

In the second part of our experiment, we compute and report the ratio between the frequencies of unique subwords of size \(i–j\) and the frequencies of all unique subwords of size less than 10 on the English, German, Czech, Italian, Spanish, French, Hindi, Turkish, and Russian Wikipedia corpora. In the following text, we call this ratio the n-gram coverage. Table 1 shows how the n-gram coverage is computed by example.

#### 3.3 Suggested subword sizes

In the third part of our experiment, we show that the n-gram coverage can be used to suggest subword sizes that are close to the optimal subword sizes on word analogy tasks.

\[^3\]See https://rusvectores.org/static/testsets/ru_analogy.txt.
For training, we compute the mean $n$-gram coverage for the optimal subword sizes on the English, German, Czech, and Italian word analogy tasks. For testing, we suggest subword sizes for the Spanish, French, Hindi, Turkish, and Russian word analogy tasks, so that the $n$-gram coverages for the suggested subword sizes on the testing word analogy tasks are the closest to the mean $n$-gram coverage for the optimal subword sizes on the training word analogy tasks. Notice that the suggested subword sizes are not based on the optimal subword sizes for the testing word analogy tasks.

After the performance estimation, we fold the training and testing word analogy tasks and we compute the mean $n$-gram coverage for the optimal subword sizes on all word analogy tasks (English, German, Czech, Italian, Spanish, French, Hindi, Turkish, and Russian). This means $n$-gram coverage can be used in applications of fastText to suggest the optimal subword sizes without expensive parameter optimization.

### 3.4 Language distances

In the final part of our experiment, we interpret suggested subword sizes as two-dimensional vectors and use the Euclidean distance to measure distances between languages. To see if our language distance measure represents interpretable linguistic phenomena, we compare it to the typological, geographical, and phylogenetic language distance measures of Littell et al. (2017):

#### Typological

Littell et al. define three typological language distance measures: syntactic, phonological, and inventory. Each distance measure is defined as the cosine distances between different feature vectors:

- The **syntactic** features describe the sentence structure of a language and have been adapted from the World Atlas of Language Structures (WALS), Syntactic Structures of World Languages, and Ethnologue databases.

- The **phonological** features describe the structure of the sound and sign systems of a language and have been adapted from the WALS and Ethnologue databases.

- The **inventory** features describe the presence or absence of distinctive speech sounds in the sound system of a language and have been adapted from the PHOIBLE database.

#### Geographical

The **geographical** language distance measure is defined as the cosine distance between feature vectors, where the features have been adapted from declarations of language location in the Glottolog, WALS, and SSWL databases.

#### Phylogenetic

The **phylogenetic** language distance measure is defined as the cosine distance between feature vectors, where the features correspond to the shared membership in language families, according to the world language family tree in the Glottolog database.

To compare our language distance measure with the language distance measures of Littell et al., we compute and report the Pearson’s correlation coefficient ($r$) between the distance measures.

### 3.5 Implementation details

We reproduce the experimental setup of Bojanowski et al. (2017, Section 4): skip-gram architecture, hash table bucket size $2 \cdot 10^6$, 300 vector dimensions, negative sampling loss with 5 negative samples, initial learning rate 0.05 with a linear decay to zero, sampling threshold $10^{-4}$, window size 5, and 5 epochs.

Like Bojanowski et al. (2017), we use a reduced vocabulary of the $2 \cdot 10^5$ most frequent words to solve word analogies. We use the implementation of word analogies in Gensim (Rehurek and Sojka, 2010), which uses Unicode upper-casing in the en_US.UTF-8 locale for caseless matching.

To compute Pearson’s $r$ between two language distance measures, we use the Representational Similarity Analysis (RSA) framework of Kriegeskorte et al. (2008); Chrupała and Alishahi (2019): we produce two matrices of all pairwise distances between 282 Wikipedia languages and we compute Pearson’s $r$ between the upper-triangulars, excluding the diagonals.

To make it easy for others to reproduce and build upon our work, we have published a reference implementation of our $n$-gram coverage model, which suggests subword sizes for fastText models. The reference implementation contains pre-computed subword frequencies for 288 Wikipedia languages, which makes the suggestions instantaneous.

---

*For six out of the 288 Wikipedia languages, Littell et al. did not provide feature vectors: Bhojpuri (bh), Emilian-Romagnol (eml), Western Armenian (hyw), Nahuatl (nah), Simple English (simple), and Sakizaya (szy).*

*See [https://github.com/MIR-MU/fasttext-optimizer](https://github.com/MIR-MU/fasttext-optimizer).*

Table 4: Accuracies on the Spanish, French, Hindi, Turkish, and Russian word analogy tasks using the default subword sizes of Bojanowski et al. (3–6) and Grave et al. (5–5), the subword sizes suggested by n-gram coverage, and the optimal subword sizes. Best accuracies for each language are **bold**, second best are in *italics.*

4 Results

In this section, we show and discuss the optimal subword sizes, accuracies, and n-gram coverages on the English, German, Czech, Italian, Spanish, French, Hindi, Turkish, and Russian word analogy tasks. We also show that the n-gram coverage can be used to suggest subword sizes that are close to the optimal subword sizes.

4.1 Optimal subword sizes

In Table 2 on the previous page, we show the accuracies and the optimal subword sizes on the English, German, Czech, Italian, Spanish, French, Hindi, Turkish, and Russian word analogy tasks. The optimal subword sizes 4–5 for English and 6–6 for German reproduce and confirm the results of Bojanowski et al. (2017, Section 5.2).

The optimal subword sizes for English (4–5), Italian (2–5), Spanish (5–5), French (6–6), and Russian (5–6) word analogy tasks are equal or within 1% accuracy of the default subword sizes suggested by Bojanowski et al. (3–6) and Grave et al. (5–5). In contrast, we see an improvement of up to 14% for Czech (1–4), 5% for Hindi (2–2), 4% for Turkish (3–3), and 3% for German (6–6).

To understand these differences, we look to the linguistic typology of languages: Czech, Hindi, and Turkish are synthetic languages and benefit from short subwords that represent morphemes. German and Russian are also synthetic, but the long compound nouns in German and the use of separate characters for yers (ъ and ь) in Russian make both languages benefit from longer subwords.

4.2 N-gram coverage

In Table 3 on the preceding page, we show the n-gram coverages for English, German, Czech, Italian, Spanish, French, Hindi, Turkish, and Russian. The mean n-gram coverage for the optimal subword sizes on the training word analogy tasks (English, German, Czech, and Italian), which we use to suggest subword sizes for the testing word analogy tasks (Spanish, French, Hindi, Turkish, and Russian), is 3.76%. The mean n-gram coverage for the optimal subword sizes on all word analogy tasks, which can be used in applications of fastText to suggest the optimal subword sizes, is 4.91%.

4.3 Suggested subword sizes

In Table 4, we compare the accuracies on the testing word analogy tasks (Spanish, French, Hindi, Turkish, and Russian) using the default subword sizes of Bojanowski et al. (3–6) and Grave et al. (5–5), the subword sizes suggested by the n-gram coverage, and the optimal subword sizes.

Using the suggested subword sizes is never worse than using the default subword sizes. For Hindi and Turkish, the suggested subword sizes always improve the accuracy: by 2.58% on average compared to the weaker default subword sizes and by 1.23% on average compared to the stronger default subword sizes. For Spanish, French, and Russian, the suggested subword sizes equal the default subword sizes of Grave et al. and they improve the accuracy by 0.72% on average compared to the suggested subword sizes.

For Spanish, the optimal subword sizes equal the suggested subword sizes. For French, Hindi, Turkish, and Russian, the optimal subword sizes improve the accuracy by only 0.90% on average compared to the suggested subword sizes, whereas they improve the accuracy by 2.59% on average compared to the weaker default subword sizes and by 1.52% on average compared to the stronger default subword sizes.
Subword sizes have a profound impact on the accuracy of fastText language models and their word embeddings. However, they are expensive to optimize on large corpora. In this work, we showed the optimal subword sizes for Czech, Italian, Spanish, French, Hindi, Turkish, and Russian fastText language models, we confirmed prior optimal subword sizes reported for English and German, and we showed that the optimization of subword sizes improves the accuracy of fastText on word analogy tasks by up to 14% compared to the default subword sizes. Our optimal subword sizes can be used in applications of fastText as the new default.

Furthermore, we proposed a cheap and simple n-gram coverage model that consistently improves the accuracy of fastText models on the word analogy tasks by up to 3% compared to the default subword sizes, and that it is within 1% accuracy of the optimal subword sizes on average. Subword sizes suggested by our n-gram coverage model can be used in applications of fastText as the new default for under-resourced languages, where the optimal subword sizes are unknown.

## 6 Future work

Although the word analogy intrinsic task is a convenient proxy for the usefulness of fastText word embeddings, Ghannay et al. (2016); Chiu et al. (2016); Rogers et al. (2018) show that it is no substitute for actual extrinsic end tasks. In future work, we will evaluate our n-gram coverage model on extrinsic tasks.

In recent machine translation models (Vaswani et al., 2017), text is tokenized into words and subwords using word-piece (Wu et al., 2016) and byte-pair (Sennrich et al., 2016) models. Our experiments suggest that we can remove the subword size parameter from fastText models and draw subwords from byte-pair models with little adverse effect on the word analogy accuracy. In future work, we will evaluate the use of word-piece and byte-pair models for subword selection in fastText models both on the intrinsic word analogy task and on other extrinsic tasks.

Abstract

Reading is a complex process not only because of the words or sections that are difficult for the reader to understand. Complex word identification (CWI) is the task of detecting in the content of documents the words that are difficult or complex to understand by the people of a certain group. Annotated corpora for English learners are widely available, while they are less common for the Spanish language. In this article, we present CLexIS², a new corpus in Spanish to contribute to the advancement of research in the area of Lexical Simplification, specifically in the identification and prediction of complex words in computing studies. Several metrics used to evaluate the complexity of texts in Spanish were applied, such as LC, LDI, ILFW, SSR, SCI, ASL, CS. Furthermore, as a baseline of the primer, two experiments have been performed to predict the complexity of words: one using a supervised learning approach and the other using an unsupervised solution based on the frequency of words on a general corpus.

1 Introduction

Reading is a complex process not only because of the words or sections that are difficult for the reader to understand. Therefore, an adequate understanding of the content of the texts is required to be able to create coherent mental representations and this way to be able to capture their content (van den Broek, 2010).

Information technologies make it possible for people to access abundant information in different areas such as education, news, social, health, or government, among others. However, this information is not accessible to many, since some people face great reading barriers such as long sentences, unusual words, or complex linguistic structures that do not allow them to understand the content of the texts, with people with intellectual disabilities and people being directly affected in learning; including university students, who are people with a high educational level and specialized knowledge in different subjects of study but, still, could be part of groups of people with reading disabilities (Alarcón et al., 2020).

Complex Word Identification (CWI) is the task of detecting words in the contents of texts that are difficult or complex for people in a certain group to understand (Rico-Sulayes, 2020). CWI and the substitution of words identified as complex may significantly improve readability and understandability of a given text (Zotova et al., 2020).

In recent years, CWI has become an area of great interest for the scientific community and researchers in computational linguistics proposing development of computational semantic analysis systems as evidenced by the shared tasks of CWI by (Paetzold and Specia, 2016) in SemEval 2016, and NAACL-HTL 2018 by (Yimam et al., 2018), the task of the CWI of the ALexS 2020 contest, headquarters of IberLEF 2020 by (Ortiz-Zambranoa and Montejo-Ráezb, 2020), and 15th edition of SemEval but the first Lexical Complexity Prediction task. (Shardlow et al., 2021).

Annotated English Learner Corpus are widely available, Spanish Large Learner Corpus are far less common (Davidson et al., 2020). Although there are corpus for Natural Language Processing (NLP) research in Spanish, they do not contain the necessary annotations to develop reading comprehension tools for students in computing science.

Our aim is to begin to address the lack of data recorded in the corpora of written learner Spanish. This article introduces the creation of a new corpus in Spanish to contribute to the advances of research in the area of Lexical Simplification, specifically in the identification and prediction of complex words in computing studies.

The corpus is named CLexIS², and it is made
up of a collection of academic texts from the degrees in Computer Systems Engineering and the Software degree of the Faculty of Mathematical Sciences of the University of Guayaquil (Ecuador), a public institution, and one of the largest and oldest in the country, with around 67,000 students (according to the census in 2019).

2 Related work

2.1 Corpora for CWI in Spanish.
(Pitkowski and Gamarra, 2009) insure that a corpus is a large collection of different types of texts, oral or written, in electronic format, made up of tens of thousands of words, and in some cases made up of several million words. The processing of these large amounts of electronic texts contributes significantly to its application in numerous areas of study in the field of linguistics such as learning a second language (L2), lexical and syntactic simplification, predictions, automatic translations, retrieval and information extraction, speech synthesis, language analysis, among others. (Davidson et al., 2020) state that few corpus written in Spanish are available to NLP researchers. Some corpus for Spanish do not usually include annotations that facilitate the development of NLP models.

(Ortiz-Zambranoa and Montejo-Rázeb, 2020) recently created a resource that can be used to test complex difficult word identification systems, built to adapt to the educational environment. It is a new annotated corpus of transcripts of teaching classes, called VYTEDU-CW. This resource was provided for the ALeXs workshop (Task on Lexical Analysis at SEPLN 2020) as part of the second edition of IberLEF 2020 (Iberian Languages Evaluation Forum) that joined the efforts of the IberEval and TASS workshops where participants applied interesting approaches to address the CWI problem in an unsupervised or semi-supervised way.

(Davidson et al., 2020) generated the data corpus of Spanish students Corpus of Written Spanish of L2 and Heritage Speakers, or COWS-L2H built to help researchers better understand L2 development, examine practices teaching empirically and develop NLP tools and thus provide a better service for the community of Spanish teachers. This resource consists of 3.498 short essays written by students at an American university.

(Miaschi et al., 2020) presented an NLP-based approach to track the evolution of written language proficiency in L2 Spanish students using a wide range of linguistic characteristics automatically drawn from students’ written productions. To carry out their purpose, they analyzed the development of students’ writing from the COWS-L2H (Davidson et al., 2020).

The Complex Word Identification (CWI) Shared Task organized as part of the 13th Workshop on Innovative Use of NLP for Creating Educational Applications (BEA), hosted in conjunction with NAACL-HLT’2018, focused on multilingualism and provided data sets containing four languages: English, German, French, and Spanish. According to (Yimam et al., 2018) the goal of the CWI task was to predict which words challenge non-native speakers based on annotations collected from native and non-native speakers.

(Parodi, 2015) proposed the Corpus of Spanish Learners (CAES - acronym in Spanish) (Corpus of Spanish learners in English). (Segura-Bedmar and Martinez, 2017) used the EasyDPL (Easy Drug Package Leaflets) corpus, a collection of 306 booklets written in Spanish and manually annotated with 1400 adverse drug effects and their simplest synonyms. The objective of this work was to improve the readability of leaflets by replacing the terms that describe the effects of drugs with simpler synonyms. They used a vector from a previously trained word embedding model.

2.2 Lexical Complexity Measures.
A good indicator of writing quality is to use a measure of lexical complexity, referring to the size, variety, and quality of a student’s vocabulary (Crossley et al., 2012). The task of detecting in the content of the documents the words that are difficult or complex to the people of a certain group is known as complex word identification (CWI) (Rico-Sulayes, 2020). Replacing these words with their simplest synonym can improve the understandability and readability of a given text (Zotova et al., 2020). This process may be adapted for college students by making texts more readable (Alarcón et al., 2020).

(Schnur and Rubio, 2021) conducted a study that focused on the application of lexical complexity operationalized by three measures: lexical diversity, lexical density, and lexical sophistication using the 2.4 million-word written Spanish subsection of the Corpus of Utah Dual Language Immersion. The study investigated the effect of the three measures of lexical complexity where it was shown that a broad and deep lexical repertoire is a key charac-
teristic of the most advanced levels of proficiency.

In the research carried out by (Saggion et al., 2015) in the Implementation and Evaluation of a Text Simplification System for Spanish, they applied the Lexical Readability Measures based on the definitions of (Rebollo, 2008) for the calculation of low frequency words.

(Kajiwara and Komachi, 2018) introduced systems named TMU for the identification of complex words. TMU systems applied random forest classifiers and regressors whose characteristics were the number of characters and words and the frequency of target words in various corpus.

To characterize the corpus we applied in this work several metrics used to evaluate the complexity of texts in Spanish were applied, such as LC, LDI, ILFW, SSR, SCI, ASL, CS considered as an approach to validate the coherence of the manually annotated terms regarding their complexity.

3 A New Dataset

The creation of $CLexIS^2$ gave rise to a new data set in the scope of academic courses at a higher education level. The process of preparing the texts is detailed below:

As a first step, the subjects that make up each semester of study were identified. The first four semesters correspond to the Software career and the following four semesters to the Computer Systems Engineering career, giving a total of eight study semesters, where each semester consists of five subjects.

Next, the recordings of the classes (academic videos) taught by teachers in virtual classes in the last two semesters of study were selected, which were stored in each teacher’s work cloud.

Using the Dictation application, the transcription process of each of the academic videos was carried out. The automatic transcriber did not have precision in the accentuation of the words as well as in the punctuation of the sentences, therefore, a process of grammar revision was carried out manually in each text to achieve its correct accentuation; it was also considered vitally important to separate the text into sentences for better understanding.

Finally, the number of texts per subject corresponds to an average of 100 texts, and in turn, each text contains an average of 77.29 words. Table 1 shows the descriptive statistics of $CLexIS^2$, with a total of 3,887 texts. In Table 2 the definition of the variables is detailed.

3.1 Manual Annotation.

The students who participated in the labeling $CLexIS^2$ are ecuadorian university students with enrollment in the Computer Systems Engineering career, and the Software career in the regular academic period 2020-CII. Five annotators were chosen for each semester of study to carry out the corpus labeling work.

The average score of the academic performance of the participants according to their university expedient was 8.72 / 10 points. It should be noted that no distinctions were made in the selection of students who would carry out the process of labeling the complex words of the corpus texts. The students came from different levels of secondary education (private school, national - government), economic and geographical locations including vulnerable sectors such as suburban neighborhoods, rural parishes and several housing cooperatives located on the outskirts of the city.

3.2 Labeling Process.

An application was developed with free software tools Python, Fire-base, and Cloud Firestore for the creation and management of the database, and the texts were loaded into the system. The taggers had to begin to read the texts that corresponded to their study semester and then identify and write down the words that were difficult for them to understand.

The annotated data was collected for later management. The data set consisted of the following fields: the token (the difficult word), the annotator identification, the position of the token in the text, the name of the text, the length of the token and its frequency.

As can be seen in table 4, the columns in the table represent the number of scorers. Each row contains the semester of study and the total number of words rated as difficult in that semester. It is evident that the highest number of words labeled as complex is at the level of complexity of 0.2, they correspond to the total number of complex words identified by one annotator, which means that there are no coincidences that these words have been annotated by the other taggers.

A similar behavior occurs in the Computer Systems Engineering career, the total number of words annotated by a single tagger is much higher than when the words are annotated by more than one

4 Lexical Complexity of the Corpus

The evaluation of the complexity of the CLexIS² corpus texts was carried out by applying the seven measures of lexical complexity for the Spanish language as in (Saggion et al., 2015). These formulas were proposed by (Rebollo, 2008), with the exception of the SSR whose measurement was provided by (Spaulding, 1956). The detail is as follows:

The Lexical Complexity Index - LC.
Lexical Distribution Index - LDI.
Index of Low Frequency Words - ILFW.
Spaulding’s Spanish Readability Index - SSR.
The Sentence Complex Index - SCI.
The Average Sentences Length - ASL.
The Percentage of Complex Sentence - CS.

This evaluation was realized based on two factors, the first, at the lexical complexity of reading texts for which the readability indices LC, LDI, ILFW, and SSR were applied; and the second, the syntactic complexity of the texts where the measures applied were SCI, ASL, SC. For data processing, the open source statistical software Jasp version 0.14.1 was used, obtaining the descriptive statistics of the subjects that make up the Systems Engineering and Software degrees - 40 subjects in total. The table 3 shows the values that correspond to the lexical complexity metrics detailed in the previous paragraph.

The analysis of the results shows that the indices obtained determine that the texts corresponding to the first four semesters of the Software career and the remaining four to the Computer Systems Engineering career show an increase in terms of complexity at each semester, which represents that students who enter their university studies begin from the beginning to face the use and application of a new lexicon. As students are promoted to other semesters, the subjects to learn are new, and others correspond to the continuity of what was learned in the previous semester, which implies that students are constantly learning and using the technical vocabulary present in their studies.

The lexical complexity of the words per semester according to the results, determine that, in the case of the Systems Engineering career, the semesters of study correspond from the fifth semester to the eighth. The calculated index indicates a high complexity, with a value of 12,264.92, since in that semester the student learns subjects whose content involves a combination of programming languages and data that lead to the development of more complex solutions. These involved courses are: Database II, Organizational Behavior and Talent Human, Object Oriented Software Engineering, Artificial Intelligence, and Computational Organization and Architecture.

The LC has a slight decrease in the sixth semester down to 10,129.64; in that semester the course exhibits more theoretical subjects than practical, being these Elective III, Legislation in Computing, Financial Mathematics, Microprocessors,

Table 4: Results by semester of the careers of Software and Engineering in Computer Systems about the total number of complex words annotated by the taggers.

**Simulation.**

In the seventh semester, the LC shows an increasing order and reaches the value of 11,751.32; this is because the student has subjects whose LC is between 22301.81 and 26,971.89. The subjects are: Computer Center Administration, Compilers, Economics, Information Security and Distributed Operating Systems.

In the case of the eighth semester, the LC has a quite evident decrease, it decreases to 9,975.89, it is the last semester of studies for the student, it has subjects what has been learned is applied throughout their university stay, they are subjects that are more oriented to the administrative part and its approach is directed to the development of the student’s degree project, these subjects are: Systems Auditing, Elective IV, Finance, MIS (Information Systems Administration) and Management Information Systems.

### 5 The Experiments in CWI on the New Corpus

We carried out two experiments following two major approaches in CWI:

1. Detection of complex words based on the CREA resource. This is an unsupervised, lexicon based approach.

2. Prediction of complex words using a machine learning approach over different lexical features.

---

**Figure 1:** Lexical Complexity metrics in Computer Systems and Software Engineering careers by Semester of study.
detect if a word is complex or not based on CREA. Next, the confusion matrix was performed to determine the effectiveness of the classification system used.

We evaluated the effectiveness of this simple approach in terms of precision, recall, F1-score and accuracy. The results show that, the proportion of predictions that the model classified correctly corresponds to an accuracy of 0.4394, a precision of 0.5165 that belong to the really correct positive identifications, the hit rate allowed us to obtain a recall of 0.4709, and the proportion of real negatives correctly identified whose measure is the specificity with a value of 0.3963, finally, an $F1$ of 0.4927 was obtained that indicates the precision and robustness of the applied model.

The analysis of the data determines that the Software career has a higher Lexical Complexity than the Computer Systems career. Once again, first-semester students find it difficult to move from high school to undergraduate education. The subjects that first semester students have are: Programming Algorithms and Logic, Differential Calculus, Democracy, Introduction to Software Engineering, and Language and Communication.

5.2 Complex Word Identification using a Machine Learning Approach.

A supervised learning approach was applied using the Random Forest algorithm. The annotated data identifying the simple or multi-word complex word was necessary. Therefore, our system was developed following the process detailed below.

5.2.1 Training/Test Data.

Data from the annotated corpus CLexIS2-CW were used. We follow the example of the corpus data model provided by Lexical Complexity Prediction (LCP) shared task, organized by the International Workshop on Semantic Evaluation - SemEval-2021 (Shardlow et al., 2021) for Task 1: Lexical Complexity Prediction on the Lexical semantics track.

The data set consisted of the fields: Id of the text from which the complex word comes, the sentence, the word labeled as complex, and a level of complexity (computed as the division between the number of taggers who scored the word as complex and the total number of taggers). See Table 5.

5.2.2 Features.

To feed the learning algorithm, a total number of 15 characteristics were generated per sample, as in the works of (Gooding and Kochmar, 2018) y (Finnimore et al., 2019) for the detection of complex words:

- Absolute frequency (abs-frequency): the absolute frequency.
- Relative frequency (rel-frequency): the relative frequency of the target word.
- Word length (length): the number of characters of the token.
- Number of syllables (number-syllables): the number of syllables.
- Target word position (token-position): the position of the target word in the sentence.
- Number of words in the sentence (n-words-sentences): number of words in sentence.
- Relative frequency of the previous the token (freq-rel-word-before): the relative frequency of the word before the token.
- Relative frequency of the word after the token (freq-rel-word-after): the relative frequency of the word after the token.
- Length of previous word (len-word-before): the number of characters in the word before the token.
- Length of the after word (len-word-after): the number of characters in the word after the token.
- Measure of Textual Lexical Diversity (MTLD-diversity): the lexical diversity of the target word in the sentence using the metric proposed by (McCarthy and Jarvis, 2010), computed using this Python library.
- Number of synonyms (number-synonyms).
- Number of hyponyms (number-hyponyms).
- Number of hypernyms (number-hypernyms).
5.2.3 Applying Supervised Learning.

These numerical features were scaled to a standard range, because it has been proven that many machine learning algorithms when normalized are when they achieve the best results. Besides, a polynomial transformation with a degree value of 2 was applied to the characteristics which produced the creation of new characteristics. The Random Forest algorithm was selected as learning approach. To build the Random Forest regression model, the data set was divided into: the training set and the test set, where 10% of the data set was used as the test set and the remaining 90% was used as training set.

Several runs were performed with different configuration values to observe the performance of the algorithm and fine-tune the hyper-parameters of the model. The results on the test set lead the configuration with best scores, which consisted in 241 nodes and all the 15 features considered. The best results reported a MAE of 0.060970, MSE of 0.005889 and RMSE of 0.076739. See Table 6.

6 Conclusions

A new corpus was created and made available. We believe that it becomes a fundamental resource for the identification of complex words in computer science studies, which means a very useful resource for the development of effective NLP tools for university students. The texts used as a central source of linguistic information reveal the difficulties faced by students of computer science studies.

The application of the lexical complexity metrics allowed evaluating the complexity of the content of the corpus texts, determining that in a large number of subjects, the lexicon that teachers use when teaching their classes contains complex sentences, a technical language and sophisticated causing difficulty in the understanding of students.

Future works could propose solutions that involve the creation of tools applying lexical simplification that greatly contribute to the contribution of students with low reading comprehension or intellectual disabilities to better understand the content of texts in the area of computer science. A possible solution will be the creation of a system that transforms complex texts into accessible ones, benefiting mainly university students in computer science who have disabilities and those who have reading comprehension difficulties.

The best result obtained for the predictive value of the words for the data set was: MAE of 0.060970, MSE of 0.005889 and RMSE of 0.09687 in the configuration with 240 nodes and 15 selected characteristics. The resource is available and can be shared by contacting the authors.

7 Acknowledgments

We appreciate Darwin Fabricio Borbor Merejildo, Kevin Francisco Labre Hidalgo, graduates of the Computer Systems Engineering degree from the University of Guayaquil, for their valuable contribution to the development of our work.

This study is partially funded by the Spanish Government under the LIVING-LANG project (RTI2018-094653-B-C21).

Abstract

Terminological consistency is an essential requirement for industrial translation. High-quality, hand-crafted terminologies contain entries in their nominal forms. Integrating such a terminology into machine translation is not a trivial task. The MT system must be able to disambiguate homographs on the source side and choose the correct wordform on the target side. In this work, we propose a simple but effective method for homograph disambiguation and a method of wordform selection by introducing multi-choice lexical constraints. We also propose a metric to measure the terminological consistency of the translation. Our results have a significant improvement over the current SOTA in terms of terminological consistency without any loss of the BLEU score. All the code used in this work will be published as open-source.

1 Motivation

The importance of consistent terminology has long been discussed by translation experts (Dagan and Church, 1994; Merkel, 1998; Itagaki et al., 2007; Saraireh, 2001; Byrne, 2006). Terminological standardisation is a critical task for technical and non-technical industrial translation. Patents, technical manuals, and medical instructions rely on consistent usage of technical terminology. But also non-technical news releases, marketing texts, promotion materials, legal and financial documents need to adhere to the same terminology. Byrne (2006) correctly points out that many large companies have their own terminologies that should be used in all texts. Such terminologies prescribe the correct usage of terms and provide not only a list of words that are to be used but also a list of their synonyms that should not be used by writers and translators (so-called negative terms). Sukhareva et al. (2020) describe such terminology for an automotive company and its usage in detail. Not adhering to these rules can be not only confusing for a reader but can also lead to serious legal and financial consequences if it is proven that damage was caused by the ambiguity of the instructions.

Morphologically rich languages also pose a very practical problem for terminology integration: terminological entries are provided in their nominative singular form (Susanto et al., 2020). The SOTA approaches rely on the assumption that the terminological entry can be found as is in the translated text. This is not the case for Slavic languages (e.g. Russian), for which finding the correct wordform on the target side is a key challenge for the terminology integration.

Morphologically poor languages (e.g. English), on the contrary, pose a very different challenge. Homographs appear in such languages not only due to polysemy and homonymy but also due to poor derivational morphology (e.g. a report vs. to report), thus, becoming a very common phenomenon. Liu et al. (2018) show that SOTA neural machine translation (NMT) fails to resolve homography efficiently. Despite being a known issue, the problem has received very little attention from the research community, and we are currently not aware of any prior work that would explicitly address the problem of homographs in the context of terminology integration into machine translation. This paper focuses on the following issues: resolving homographs when the source language is morphologically poor, choosing the right wordform in the morphologically rich target language, and evaluating terminological consistency in the resulting translation. We show that our approach for homograph disambiguation and morphologically flexible lexical constraints significantly improves terminological consistency as compared to the current SOTA.
2 Related Work

Previous work can be roughly divided into two groups: approaches that integrate lexicon during inference and approaches that integrate lexicon during training. A constrained decoding approach that has established itself as the SOTA in the past two years is Post and Vilar (2018). They proposed the Dynamic Beam Allocation (DBA) strategy, which decreased the decoding time complexity to constant time in respect to the number of lexical constraints. The proposed algorithm aims to allocate banks dynamically, prioritising the beams that satisfy the most constraints. This algorithm only allows incorporating a single wordform of a constraint, as Dinu et al. (2019) discussed in their work. This is a notable disadvantage of this approach as it assumes an unrealistic precondition that the provided lexical constraints will be correctly inflected. This condition cannot be satisfied when translating into a morphologically rich language.

On the contrary, training time approaches are more flexible in selecting the inflected forms. The SOTA in-training approaches tune a transformer model (Vaswani et al., 2017) towards producing translations that are biased towards an external lexicon. Song et al. (2019) proposed a simple way to copy target side terms into source sentences. Likewise, Dinu et al. (2019) suggested a source sentence modification method by replacing/appending target side terms using additional source factors. Nevertheless, these methods are only encouraging the model to use predefined target terms, whereas constrained decoding methods are enforcing terms’ usage. Thus, it can be argued that in-training approaches are inferior to the constrained decoding methods in terms of straightforward terminology integration and, indeed, Dinu et al. (2019) report the terminology usage rate 6-9% less than the constrained decoding method. To ensure the appearance of terms in the output, Michon et al. (2020) use placeholders with the help of morphosyntactic annotations. Even though the approach is effective for choosing a correctly inflected form, it depends on the availability and performance of morphological analysers both in source and target languages.

While all the aforementioned approaches have succeeded in improving the terminological consistency of translations, they essentially rely on a supervised selection of terminological entries. In other words, they assume that the homographs have already been resolved and a correct wordform is provided. Once the discussed approaches are set on a trial under realistic conditions, translation quality deteriorates. Word sense disambiguation is meanwhile a well-researched NLP task, and current state-of-the-art approaches can efficiently resolve homographs (Bohnet et al., 2018; Huang et al., 2019) but due to being time-consuming, are not applicable during translation inference.

3 Data

3.1 Parallel Corpus

For the training of the baseline NMT model, we used preprocessed bilingual WMT18 data\(^1\). We filtered out sentence pairs that have a length ratio of less than 1/3 or more than 3. We also applied language detection (\texttt{langid}) filtering (Lui and Baldwin, 2011) in a tolerant way: The sentence pairs for which \texttt{langid} could not predict the expected language in the first 10 predictions are filtered out. Finally, we removed 75,000 sentences with the worst alignment scores (Dyer et al., 2013). All the reported models utilize WordPiece (Wu et al., 2016) for tokenisation. To fine-tune the hyperparameters of the model, we used newstest2014, newstest2018, and newstest2019 as development sets. Newstest2017 is reserved for reporting the results. Since EN $\rightarrow$ RU newstest2020 was not available during the time of our experiments, we used RU $\rightarrow$ EN test set including an additional test set (test-ts\(^2\)), as a second set to report the results.

3.2 Terminology Extraction

Despite dictionaries of negative and positive synonyms being standard resources used by industrial translators, they usually cannot be openly shared. Thus, in order to ensure the reproducibility and comparability with previous work, we decided to use openly available resources: WMT Corpus and Russian Wordnet. We believe that such an approximation does not diminish the fairness of the evaluation as we are not focusing on domain adaptation but solely on improving lexical consistency of translation, which is just as applicable to and observable on news translations.

Tab.1 describes the process of generating our pseudo-dictionary of positive and negative terms. The Russian side of the training set is lemmatised

and matched against the Russian Wordnet (Chernobay, 2018). We use fast_align (Dyer et al., 2013) to extract word alignments of Russian and English sides of the training set. We proceed with finding the English word that is most frequently aligned to all the synonyms in a synset (e.g. "engine" is the most frequent match to "двигатель" dvigatel’ and "мотор" motor). This leaves us with a lexical entry for the English word "engine" and its Russian translations, which are the WordNet synonyms. Finally, we labelled the most frequently aligned Russian synonym in this list as a positive term, and all other Russian synonyms as negative terms (e.g. "двигатель" dvigatel’ is labelled as a positive synonym). Thus, from now on, if an English sentence has a word that occurs in our dictionary, the translator should resort to using the positive term in the translation and avoid negative terms. An example of a terminology entry can be found in Tab. 2.

3.3 Extraction of Wordforms

We further matched the terminology entries in the bilingual training data and kept track of the co-occurrence counts of inflected words to obtain a one-to-many list of wordform candidates per entry. Only the first candidate could be used as a lexical constraint for the related source phrase, whereas all the most frequent k options can be incorporated by our multi-choice lexical constraint approach. In order to extract Russian wordform candidates, we created a list of Russian wordforms most frequently aligned to a single inflected English wordform. As English is a morphologically poor language, we would end up with a list of Russian wordforms that would frequently contain five or more entries. Tab. 3 shows three distinct wordform lists of a terminology entry aligned to an inflected form of the English entry.

4 Approach

The approach consists of two major steps. On the source side of the morphologically poor language, it solves the problem of frequent homographs by applying a homograph disambiguator. On the target side of the morphologically rich language, it ensures that the translated term is correctly inflected.

4.1 Homograph Disambiguation for the Morphological Poor Language

Tab. 2 shows an entry in our terminology. All three Russian words are interchangeable synonyms in a certain context. But a straightforward string matching of word engine (Tab. 2) with an aim to force the translator to use a certain synonym in the target language would fail: the English word engine can also be used in the sense of a search engine (Fig. 1) which would have a Russian literal translation as "search system". In this case, the lexical constraint enforced by our terminology would not be correct

and would cause poor translation quality.

To mitigate this problem, we propose a homograph disambiguation method. Our homograph disambiguation task is simpler than standard word-sense disambiguation (WSD) tasks (e.g. GlossBERT (Huang et al., 2019)) as it suffices to predict whether or not a certain word in the source sentence is used in the same sense as a terminology entry that has the same spelling and, unlike traditional WSD, there is no need to label all the possible senses of this word. We propose a word labelling model, similar to named entity recognition (NER) models, fine-tuned on BERT\footnote{BERT-Base, Cased (12-layer, 768-hidden)} (Devlin et al., 2019) having only two classes (\(T\) for Term and \(O\) for Non-Term). The model tags all the words in a sentence in one forward pass.

In order to create the training data for the homograph disambiguation, we used the same parallel corpus that we used for training the machine translation models. All the training data were processed with a word aligner \texttt{fast_align} (Dyer et al., 2013). All the sentences were lemmatised. Every lemma in the Russian sentence was compared against the extracted terminology (Sec. 3.2). If it is found in the terminology as a positive or negative term, we check whether the aligned English lemma is also listed as its translation (Tab. 2). If this is the case, the English word is labelled as "Term", otherwise as "Non-Term" (Fig. 1).

The BERT homograph tagger is fine-tuned for 4 epochs on this data.

### 4.2 Morphology Integration for the Morphologically Rich Language

As described in the Sec. 2, the Dynamic Beam Allocation (DBA)\footnote{For a detailed description of the DBA, refer to Post and Vilar (2018)} runs in constant time with respect to the number of constraints. The DBA accepts a list of constraint pairs (i.e. a term and its translation). During decoding, the candidates are grouped into banks with the number of banks equal to the number of constraints. If a term is found in the source sentence, then the translation candidates in which term’s translation occurs are propagated to a higher bank. The best translation is chosen from the bank with the highest rank (i.e. the ones that have the most satisfied constraints). The drawbacks of this approach is that it matches words without their context and can neither discriminate between homographs (addressed in the previous section) nor choose the correct inflection. As it forces a higher score on the translations that are compliant with the constraint list, the approach is not applicable to translating from a morphologically poor to a morphologically rich language as on one hand there are plenty of homographs on the source side and on the other hand there is a multitude of inflected wordforms on a target side. Constraining a translation on a wrong wordform (e.g., a nominative noun form instead of a dative form) would result in a translator giving a top score to a poor translation.

We propose multi-choice lexical constraints approach that overcomes DBA’s limitations and enables the translator to deal with morphologically rich languages by choosing a correct wordform. Similarly to (Post and Vilar, 2018), during inference we allocate candidates to banks. We find the longest possible (in terms of the number of tokens) candidate for every constraint to make sure there will be enough banks for all the possible constraints. Then to prioritise the entirely satisfied constraint phrases regardless of their token count, we rewarded them with the token count of the longest candidate. Without this change, the allocation strategy would be biased towards longer candidates.

**Number of constraints** The algorithm requires multiple banks to allocate candidate hypotheses. In the worst case, all the longest candidates would need a seat in the bank. For this reason, the number of constraints is the sum of the byte pair encoding (BPE) token counts of the longest constraint options. The size is calculated once since the constraint list remains unchanged during decoding. The number of constraints is calculated as follows:

\[
\text{size} = \sum_{c \in C} \max_o |c_o|
\]

where \(C\) is the constraint list, and \(o\) is a constraint \(c\) candidate in multi-choice lexical constraints (MLC) algorithm.

**Number of satisfied constraints** The satisfied constraint count of hypotheses decides in which bank they should be allocated. The number of banks equals to the maximum possible count if all the longest constraint variants are to be satisfied. However, as the algorithm is biased towards prioritising sentences with the most satisfied constraints, such sentences are longer and have higher overall cross-entropy loss. It causes a significant drop in the general quality of translations, especially if BPE tokenisation is used as more frequent
Figure 1: Labelling of the training data for homograph disambiguation: English words that are aligned to a synonym in Russian Wordnet synset are labelled as terms, otherwise they are considered to be homographs. “Двигатель” “dvigatel’” and “мотор” “motor” are found in the dictionary, while “система” “sistema” and “моторный” “motornyi” are not.

tokens are usually represented with fewer BPE tokens. To overcome this problem, we calculated the size of the satisfied constraints as follows: given $f(c)$ is the list of the advanced token indices of the constraint $c$’s variant, the number of satisfied constraints in a hypothesis is calculated as:

$$m(c) = \begin{cases} \max_{c_o} |c_o|, & \text{if } c \text{ is entirely met.} \\ \max_{c_o} f(c_o), & \text{if } c \text{ is advanced.} \\ 0, & \text{otherwise.} \end{cases}$$

$$\text{num\_met} = \sum_{c \in C} m(c)$$  \hspace{1cm} (2)

**Set of allowed constraints** We keep track of the advanced constraint to make sure we will advance on started but not entirely met constraints. However, when we have multiple variants for a constraint, even if the advanced constraint is known, we might have multiple variants of that constraint as advanced but not fulfilled yet. Therefore, we track the number of advanced tokens for all variants of the constraints. Finally, the set of allowed constraints is defined as the next tokens of all the advanced variants of the advanced constraint. If there is no advanced constraint, the set is simply the initial tokens of all the constraint options. The set $A(C)$ of all the allowed token indices is defined as:

$$A(C) = \begin{cases} f(c_o) + 1, & \exists c \text{ with advanced } o. \\ 0 \text{ for all } c, & \text{otherwise.} \end{cases}$$

(3)

**Advancing on constraints** The major difference to the DBA approach is that the advanced constraints have a list of variants on which the algorithm can advance in one step. Therefore, when there is an advanced constraint, all variants are considered as a possible advancement step. For instance, if the initial tokens of the constraint in example (1) are already advanced (поп, ##аж, ##ений ##ении) in decoding time step $i$, the algorithm advances on that constraint. The following tokens of both candidates are advanced together for the same hypothesis, which is a usual case when the choices have the same stem, and the only difference is the inflections. Its benefit is not only improving decoding run-time but also distributing the hypotheses more efficiently in the beams.

(1) поп, ##аж, ##ений ##ении

Fig. 2 shows that the run time of the MLC algorithm is comparable with the DBA (Post and Vilar, 2018) in different beam size settings and with different number of wordform choices.

Figure 2: Runtime comparison of (Post and Vilar, 2018) and multi-choice lexical constraints (MLC) as a function of wordform choices per constraints (average runtime per sentences with 2 constraint groups and similar sentence length) where $k$ is beam size.

5 Evaluation

All the models in our experiments were trained in the SOCKEYE toolkit (Hieber et al., 2017). The models that incorporate 6-layer, 8-head transformer architecture are trained 50 epochs on the training corpus (10,402,336 bilingual sentences after preprocessing). We modified the SOCKEYE toolkit to add the multi-choice lexical constraints algorithm and are going to publish the extension as an open-source.

For translation quality evaluation, we report BLEU score (Papineni et al., 2002) using SACREBLEU (Post, 2018), after detokenising the translations. Following Post and Vilar (2018), Dinu et al. (2019), and Susanto et al. (2020), we also report the terminology usage rate to evaluate terminological consistency.

5.1 Terminological F-score

Both BLEU score and terminological usage rate (Post and Vilar, 2018) are not sufficient to evaluate terminological consistency. The usage rate has proven to be seriously flawed as this metric does not account for homographs. Tab. 4 shows an example of a sentence translation that includes a homograph rest in its source sentence. Our terminology prescribes translating rest as a Russian adjective meaning “remaining” and does not contain an entry that would have the same meaning as its homograph verb to rest. The terminology usage rate used in the previous research was calculated in a rather straightforward manner by mere string matching. In our example, it would mean that the metric would only give a perfect score if the verb rest was incorrectly translated as its homograph adjective. If this were the case, despite the perfect score, the resulting translation would be of a very poor quality.

As Dougal and Lonsdale (2020) discuss, it is necessary to report an f-score metric when evaluating lexicon injected systems. Their suggested metric TREU intends to mitigate the negative effect of unmatched terminology tokens on BLEU metric assuming the reference sentences do not usually contain terminology promoted tokens. However, to assess the general quality of MT systems clearly, we find it more suitable to use the standard BLEU score. Thus, we require a separate metric based on the precision and recall of the terminology usage.

We propose a terminological f-score to account for precision and recall of the terminology usage in the hypotheses as compared to the reference translations. A similar metric was suggested to evaluate the performance of NMT models for the handling of homographs (Liu et al., 2018). The major difference between our metric and theirs is that we focus on the sense of the word rather than the string by consider all the aligned WordNet synonyms in the reference sentences. The precision and recall per sentence are calculated as follows:

$$
P = \sum_{l \in L_s} \min \left| l_s \right|, \left| l_f \right|, \left| l_r \right| \left| l_f \right|
$$

$$
R = \sum_{l \in L_s} \min \left| l_s \right|, \left| l_f \right|, \left| l_r \right| \min \left| l_s \right|, \left| l_r \right|
$$

where $L_s$ is the list of the terminological entries that occurred in the source sentence, $|l_s|$ is the occurrence number of terminology entry $l$ in the source sentence, $|l_f|$ is the occurrence number of the positive usage of that entry in the translation sentence, and $|l_r|$ is the occurrence number of both the positive and negative synonyms of the entry $l$ in the reference sentence. Thus, we calculate the precision and recall as 1/1 for the example in Tab. 4, whereas the terminology usage rate is 1/2.

5.2 Quantitative Results

Tab. 5 shows the results of the evaluation in terms of terminology usage rate, terminological f-scores, and BLEU scores for the newstest2017 and newstest2020 testsets. The baseline is a vanilla transformer model trained with the same parameters as all the other models without integrating the terminological dictionary. For the in-training baselines, we reproduce on our data the source-factoring (SF) model with append strategy that was described by Dinu et al. (2019). The inference time baseline is the lexical constraints (LC) approach by Post and Vilar (2018).

(b) newstest2020 (extracted from ru-en wmt20/test-ts)

Table 5: Terminology usage and BLEU scores of baseline, source factoring by append (SF), lexical constraints (LC) and multi-choice lexical constraints (MLC) (ours) models.

Vilar (2018). We compare the baselines with the following proposed contributions:

1. Introducing homograph disambiguation (+BERT) as described in Sec. 4.1
2. Introducing multi-choice lexical constraints (MLC) for the inference approach as described in Sec. 4.2
3. Combining multi-choice lexical constraints and homograph disambiguation (MLC+BERT)

The evaluation shows that previously proposed SOTA methods for lexica integration by Dinu et al. (2019) and Post and Vilar (2018) suffer from a large decrease in the BLEU score. It also shows that the term usage rate used in the previous research is essentially meaningless for measuring translation quality as even though it has a nearly perfect score for Post and Vilar (2018), the BLEU score greatly dropped. Our approach, on the contrary, showed a significant improvement over all the baselines in terms of terminological f-score without decreasing translation quality. The reasons for the slight decrease of the BLEU score for MLC+BERT are discussed in detail in Sec. 5.3.

5.3 Qualitative Analysis

For a better insight into the results, we manually inspected the Russian translations. One of the primary reasons why MLC+BERT had a slight drop in the BLEU score as compared to the vanilla baseline was that the WMT testset was not tailored to have consistent terminology. We are also not aware of any open-source MT evaluation dataset with terminological consistency in mind. The evaluation showed that this was the reason for the drop in BLEU. Tab. 6 shows translations for which the BLEU score is lower for the MLC+BERT model. This hypothesis was tested by calculating the BLEU score for a subset of test sentences that contain the positive term in the Russian reference translation (80% of newstest2017 and 85% of newstest2017). The results in showed that the difference in the BLEU score between the baseline and our model decreases by more than double if all the test sentences with negative terms are eliminated (see Appendix A).

As compared to other baselines, our method greatly improves the quality of the translation for Post and Vilar (2018) and Dinu et al. (2019). Post and Vilar (2018) baseline is particularly prone to hallucinate Lee et al. (2018) if a lexical constraint
Table 6: An example from the newstest2020 evaluation set. The Russian gold sentence and the baseline contain a negative term. The MLC+BERT translation uses a positive interchangeable syllable. Even though the translation is perfectly fine, the BLEU score is lower for MLC+BERT.

<table>

</tr>
</tbody>
</table>

is a homograph or is not correctly inflected (see Appendix B). In this case, the model generates an output till it reaches the maximum length. For example, the output of the LC baseline has 8% more characters than the reference translations. In comparison, the vanilla baseline has only 0.5% more characters and the MLC+BERT has exactly the same amount of characters. The manual evaluation showed that reducing hallucinations is the reason for the large increase of the BLEU as compared to the SF and LC baselines.

We also examined the effect of automatically generated lexicon on the translation quality. While we found cases in which positive terms were not perfect synonyms and were not interchangeable with negative terms, the homograph disambiguation seemed to show certain robustness by labelling the English term only if they occurred in the context that was common for negative and positive Russian translations. While we still believe that better results could be achieved in real-life settings where a high-quality dictionary would be used, our examination showed that there was no unreasonable error propagation from the usage of an automatically extracted dictionary.

The greatest weakness that we found during qualitative examination lies in how the top inflected candidates are scored in MLC. The MLC model takes a list of top \(n\) Russian wordforms that are most frequently aligned to a given English wordform of a term. In rare cases, an acceptable wordform does not appear to be in the top \(n\) list. In this case, the translation ends up being grammatically incorrect or hallucinates in a similar sense as the LC baseline.

A possible solution for this would be generating the top \(n\) choices for MLC in a more elaborated manner e.g. by considering the position in the sentence or even using syntactic information. For now, we leave exploring those options for future work.

### 5.4 Evaluation of Homograph Disambiguation

The homograph disambiguator was trained on artificially created labels, and we are not in possession of any gold standard data for the direct evaluation. We assume that evaluating the approach on the artificially labelled data will not ensure the objectivity of such an evaluation and both train and testset will contain the same errors. For transparency, we still provide the scores in Appendix (Tab. 8).

Thus, measuring the effect of homograph disambiguator on the downstream translation task is more sound. To make sure that the improvement of the terminological f-score is caused by the homograph disambiguation and not by the reduction of the number of lexical constraints, we introduce the MLC\textsubscript{random} baseline (see Tab. 5). We have calculated the total amount of constrained terms after applying the homograph disambiguation (+BERT) and randomly labelled the same amount of terms to be constrained in the original testsets. The evaluation results showed that the f-score dropped by 7% for the randomly labelled dataset, thus, proving that our homograph disambiguation is the actual cause of the f-score’s improvement.

### 5.5 Runtime Analysis

In order to ensure that MLC is also feasible for real-life usage, we compared the inference speed between the Post and Vilar (2018) and our MLC input (Fig. 2). As well as the DBA algorithm, MLC makes sure that the number of hypotheses is limited by the beam size. Thus, the runtime complexity of our approach is constant in the number of constraints. We have made an interesting observation that MLC is actually faster than LC for the beam size of 5 and slightly slows down for the beam size of 10. We have found the following explanation for such behaviour: Lexical constraints expect a large beam size in order to be able to generate enough hypotheses with the provided lexical constraints. The DBA does not allow a beam to generate the end of sentence symbol unless the constraints are met. Once a translation is incorrectly constrained on a homograph or on a wordform that cannot occur in translation, the beam cannot terminate unless it reaches the maximum length, and, thus, it negatively influences the inference time. On the con-
trary, the MLC allows a beam to terminate which makes it more time efficient.

6 Conclusion

We have presented an approach for terminology integration into a neural machine translation from a morphologically poor into a morphologically rich language. Our work makes the following contributions:

1. Disambiguation of the homographs in the morphologically poor language.

2. Multi-choice lexical constraints to ensure the correct choice of an inflected target wordform in the morphologically rich language.

3. A metric that takes into account precision and recall of terminology usage.

We propose a solution to the problem of rich morphology in the target language by presenting multi-choice lexical constraints and show that our combined approach (MLC+BERT) has a significantly\(^8\) better f-score than all the other models.

References

\(^8\)We used McNemar’s significance test (McNemar, 1947). The significant difference is defined as \(p < 0.05\).

Table 8: Evaluation table for homograph disambiguation task. Since there is no gold labels, predicted labels are compared against the artificially created labels.

B Qualitative Comparison of Translation Systems

| Type of error | Hallucination after correct translation  
|---------------|----------------------------------------|
| EN            | It was earlier reported that capital CSKA player Konstantin Kuchaev spoke out against the introduction of VAR (Video Assistant Referee).  
| RU            | Ранее сообщалось, что футболист столичного ЦСКА Константин Кучаев высказался против внедрения VAR.  
| baseline      | Ранее сообщалось, что столичный игрок ЦСКА Константин Кучаев выступил против введения ВАР (видео помощника судьи).  
| LC            | Ранее сообщалось, что столичный игрок ЦСКА Константин Кучаев выступил против введения ВАР (видео помощника судьи, который говорил о том, что арбитру докладе не удалось выступить с рефери).  
| MLC+BERT      | Ранее сообщалось, что столичный игрок ЦСКА Константин Кучаев выступил против введения ВАР (видео помощника судьи).  
| Comment       | The LC model generates a string after comma (marked in italics) that does not occur in the source text nor meaningful in the context. It happens because the lexicon prescribes to translate "report" as a noun meaning "an account given of a particular matter" доклад, while the source actually has a homograph verb "to report". The LC model generates a correct translation and proceeds to hallucinate till it finally produces a sentence with "a report". It leads to not only longer nonsensical output but also to longer inference time. The homograph disambiguation (MLC + BERT) correctly marks "report" as a non-term, thus, preventing the model to force a constraint on this sentence  

Type of error | Hallucination with a grammatically correct sentence  
|---------------|--------------------------------------------------|
| EN            | As reported by Chempionat, the 41-year-old specialist flew into Moscow to weigh up the possibility of working at one of Russia’s clubs.  
| RU            | Как сообщает “Чемпионат”, 41-летний специалист прилетел в Москву, чтобы изучить возможность найти работу в каком-нибудь российском клубе.  
| LC            | Как сообщает Chempionat, 41-старый специалист вылетел в Москву, чтобы в докладе проанализировать возможность работы в одном из российских клубов.  
| MLC+BERT      | Как сообщает Chempionat, 41-летний специалист вылетел в Москву, чтобы изучить возможность работы в одном из российских клубов.  
| Comment       | As in the previous example, the LC model forces to use the homograph noun "a report" to be a translation of the verb "to report". Unlike the example above, the model does not produce a correct translation at any point and generates a sentence with an entirely different meaning: “As reported by Chempionat, the 41-year old specialist got on a flight to Moscow to analyse in his report possibilities of working at one of Russia's clubs.” This kind of translations are particularly dangerous, as it would be extremely difficult for a native speaker without looking at the source to detect that the translation completely fails to convey the meaning. The homograph disambiguation solves this problem and the translation is correct.  

Type of error | Hallucination with an ungrammatical sentence  
|---------------|--------------------------------------------------|
| EN            | Documents obtained by the publication, reveal that the owners of TikTok (ByteDance company) with the help of their app are promoting Chinese foreign policy goals overseas.  

1098
В документах, оказавшихся у издания, рассказывается, что владелец TikTok (компания ByteDance) с помощью приложения продвигает цели внешней политики Китая за рубежом. Документы, полученные публикацией, показывают, что владельцы TikTok (компании ByteDance) с помощью своего приложения продвигают китайские внешнеполитические цели за рубежом. Документы, полученные изданием, показывают, что владельцы TikTok (компании ByteDance) с помощью своего приложения продвигают китайские цели внешней политики за рубежом. Документы, полученные изданием, показывают, что владельцы TikTok (компании ByteDance) с помощью своего приложения продвигают китайские цели внешней политики за рубежом. Документы, полученные изданием, показывают, что владельцы TikTok (компании ByteDance) с помощью своего приложения продвигают китайские цели внешней политики за рубежом. Роман Зарипов, основатель нашего цифрового агентства, согласился с Богдановым: “Основные правила для пользователей TikTok перечислены в пользовательском соглашении: нельзя выкладывать шокирующий контент, дискриминационные высказывания и так далее”.

Abstract

Offensive language detection and analysis has become a major area of research in Natural Language Processing. The freedom of participation in social media has exposed online users to posts designed to denigrate, insult or hurt them according to gender, race, religion, ideology, or other personal characteristics. Focusing on young influencers from the well-known social platforms of Twitter, Instagram, and YouTube, we have collected a corpus composed of 47,128 Spanish comments manually labeled on offensive pre-defined categories. A subset of the corpus attaches a degree of confidence to each label, so both multi-class classification and multi-output regression studies are possible. In this paper, we introduce the corpus, discuss its building process, novelties, and some preliminary experiments with it to serve as a baseline for the research community.

1 Introduction

Offensive language is defined as the text which uses hurtful, derogatory, or obscene terms made by one person to another person (Wiegand et al., 2019). Related terms in the literature are hate speech (Waseem and Hovy, 2016), cyberbullying (Rosa et al., 2019), toxic language (van Aken et al., 2018), aggression language (Kumar et al., 2018), or abusive language (Nobata et al., 2016). Although there are subtle differences in meaning, they are all compatible with the above general definition.

Due to the well-acknowledged rise in digital social interactions, in particular on social media platforms, the amount of offensive language is also steadily growing. Unfortunately, this type of prejudiced communication can be extremely harmful and could lead to negative psychological effects among online users, especially among young people, causing anxiety, harassment, and even suicide in extreme cases (Hinduja and Patchin, 2010).

At the same time, this issue also implicates governments, online communities, and social media platforms. In order to help fight this problem, these stakeholders are continuously taking appropriate actions to implement laws and policies combating hate speech. For instance, since 2013 the Council of Europe has sponsored the "No Hate Speech" movement1 seeking to mobilize young people to combat hate speech and promote human rights online. In May 2016, the European Commission reached an agreement with Facebook, Microsoft, Twitter, and YouTube to create a “Code of conduct on countering illegal hate speech online”2. From 2018 to 2020, platforms such as Instagram, Snapchat, and TikTok adopted the Code. According to a Spanish report in 2019 on the evolution of hate crimes in Spain3, threats, insults, and discrimination are counted as the most repeated criminal acts, with the Internet (54.9%) and social media (17.2%) as the most widely used media to commit these actions.

To help achieve this goal, automatic systems based on Natural Language Processing (NLP) techniques are required. To train these systems, corpora labeled on offensive language are essential. In recent years, the NLP community has invested considerable effort into resource generation. However, most of them have been directed towards English, even though it is a global concern and there are important cultural differences depending on the language examined. In addition, most of them have been focused on Twitter data, despite the presence of offensive language on other platforms such as YouTube or Instagram, which more widely used by young people.

To contribute to filling this gap, in this paper4

3. https://cutt.ly/ej5EgU7
4. NOTE: This paper contains examples of potentially ex-
we present OffendES, a Spanish collection of comments manually labeled for offensive content using a fine-grained annotation scheme. We collect our data from young influencers from well-known social platforms including Twitter, Instagram, and YouTube. Therefore, a comparative study of offensive behavior in social media and its relationship with the influencers is conducted. Finally, we propose preliminary experiments to serve as a baseline for the NLP community in which we show the validity of the corpus.

The remaining of the paper is organized as follows. Section 2 describes the related work on offensive language including some available datasets. Section 3 introduces our OffendES dataset and some descriptive statistics. Section 4 depicts our baseline evaluation of the novel dataset. A discussion is provided in Section 5. Finally, we conclude with our future studies in Section 6.

2 Related Work

2.1 Offensive Language Detection

In recent years, while offensive language continues to spread on the Internet, the importance of identifying this type of content in textual information has become increasingly significant in the NLP field, with several studies applying different machine learning systems. Most of these studies focus on the detection of offensiveness in social media, usually including a binary classification task to detect the presence of offensive language in the text.

Early studies explored traditional machine learning algorithms including Support Vector Machines, Logistic Regression, Random Forest, or Decision Trees, as well as the combination of different types of syntactic, lexical, semantic, and sentiment features (Chen et al., 2012; Nobata et al., 2016; Oråsan, 2018; Plaza-del-Arco et al., 2019).

As neural network architectures have shown promising results, extensive studies have recently explored a variety of deep learning architectures including Recurrent and Convolutional Neural Networks (Ransinghe et al., 2019; Sharifirad and Matwin, 2019; Georgakopoulos et al., 2018). More recently, Transformer-based models have made significant progress and represent the state-of-the-art of multiple tasks, including offensive language detection (Plaza-del-Arco, Flor Miriam and Molina-González, M. Dolores and Ureña-López, L. Alpícit or offensive content which may be offensive to some readers. They do not represent the views of the authors.

2.2 Data Available

Several labeled datasets are publicly available and usually include a binary annotation, indicating whether the content is offensive or not. Most of them have been generated in the context of different shared tasks for different languages.

For instance, the well-known offensive language task OffensEval has held two editions in the International Workshop on Semantic Evaluation (SemEval). In the first edition, Zampieri et al. (2019b) released the OLID dataset which contains over 14,000 English tweets. It was annotated using a three-level hierarchical annotation model by two people using a crowd-sourcing platform (Zampieri et al., 2019a). In order to retrieve tweets, they selected specific keywords and constructions often included in offensive posts related to Twitter accounts. Following the same annotation scheme, in the second edition Zampieri et al. (2020) introduced multilingual datasets comprising five different languages.

The Germeval shared task focused on offensive language identification in German tweets (Wiegand and Siegel, 2018). A dataset of over 8,500 annotated tweets was provided following also a hierarchical annotation. To collect the data, the authors explored the timeline of users that regularly post offensive content. Tweets were manually annotated by one of the three organizers of the task, and to measure inter-annotation agreement, 300 tweets were annotated by the three annotators in parallel. The annotation scheme is similar to the previously shared task, but differs in the following aspects: the number of levels in the hierarchy, the labels in the second level, and the language.

Related to Spanish, most of the datasets within the context of offensive language target hate speech, including AMI (Fersini et al., 2018), HateEval (Basile et al., 2019), and the HaterNet (Pereira-Kohatsu et al., 2019) collections. However, there is a lack of resources regarding the Spanish offensive language. To the best of our knowledge, the first corpus appeared at the 3rd SEPLN Workshop on Evaluation of Human Language Technologies for Iberian Languages (IberEval) (Carmona et al., 2018). This corpus was also used in the next edition of this workshop in 2019 (Aragón et al., 2019). The dataset focuses on the Mexican variant of Spanish
and contains around 10,475 tweets binary labeled as offensive or non-offensive. This collection has been recently revised (Díaz-Torres et al., 2020). EmoEvent (Plaza-del-Arco, Flor Miriam and Strapparava, Carlo and Ureña López, L. Alfonso and Martín-Valdivia, María-Teresa, 2020) is a multilingual emotion corpus based on different events, it also includes a small proportion of tweets labeled as offensive. Finally, the DETOXIS task recently introduced the first dataset of comments in response to news articles labeled at different toxicity levels. To the best of our knowledge, there is no other Spanish corpus available with fine-grained categories for offensive language focused on young people. As the authors point out in (Aragón et al., 2019), the characterization of the offensiveness level found in a text is complex; therefore, there is a need for a more detailed classification of the tweets.

Our dataset, OffendES, differs from existing Spanish offensive language datasets because (i) apart from Twitter, we study the problem of offensive language detection on YouTube and Instagram, platforms that young people are more used to, (ii) we collect the data with a focus on young influencers, and (iii) we propose an annotation scheme with fine-grained classification.

3 OffendES Dataset

In this section, we describe the context of the dataset, the methodology followed to collect it and the annotation scheme proposed to label offensive content. Besides, we give some descriptive statistics and a detailed analysis of the collected data. OffendES is available upon request to the authors.

3.1 Scope of the Dataset

To understand the rationale behind the design and generation of the corpus, certain contextual information may be useful. As stated in the introduction, dealing with offensive posts in social networks is a growing concern. Several platforms are clear on this issue, as can be read in rules and policies of Twitter⁶, Instagram⁷ or YouTube⁸. Indeed, YouTube has disabled comments on videos and channels featuring children (The YouTube Team, 2019). But this is a major concern not only for platform providers but for public administrations, in order to limit the possible side effects of harmful messaging to more vulnerable communities, like children or teenagers. With this in mind, the creation of this resource aims to achieve the following long-term goals:

1. Early detection of offensive language use in social media on the Internet, with a special focus on young people.
2. Identifying improvements in protection systems for young people in social networks.
4. Creating a reference corpus for the study of language technologies applied to the classification of sexist language.

3.2 Data Collection

Instagram, YouTube, and Twitter are among the social media platforms most used by people ages from 18 to 24 (Jenn Chen, 2020). These three have been selected as the main data sources. A total of 12 controversial influencers with a significant number of followers have been identified and their respective accounts in the three selected media. Table 2 (Appendix) shows the accounts used by the selected influencers in the three selected media. They are Spanish influencers from 24 to 35 years old and, six are men and six are women. The process for collecting comments consisted of two main steps. To collect the data, first, the last 50 posts by each influencer were obtained using the platform API. Then, an ad hoc web scraper was launched to extract user comments to each of the posts obtained (limited to 2,000 replies). This script uses scrolling through JavaScript code commands to retrieve further comments. In the case of YouTube, instead of the scraper, its API⁹ has been used to retrieve comments.

During two months (from February to March 2020), a total number of 283,622 comments were collected (see Table 1 for detailed information). The comments were then filtered according to two main constraints: the presence of potentially offensive language and lexical diversity.

⁶https://cutt.ly/RkrVTQn
⁷https://cutt.ly/1j5Eut0
⁸https://cutt.ly/yj5Eijc
⁹https://cutt.ly/JkrVSYv
To avoid the creation of a corpus with few or no offensive comments set, we labeled all the comments with flags determining whether the comment contained any of the words found in five different controlled lexicons (Plaza-del-Arco, Flor-Miriam and Molina-González, M Dolores and Ureña-López, L Alfonso and Martín-Valdivia, M. Teresa, 2020). All comments with potentially offensive language were selected (23,788 comments). We selected 60,000 comments to be labeled in the manual annotation phase. Therefore, we selected 36,212 comments without offensive terms. Applying lexical diversity measures proved to be an interesting approach to ensure a diverse set of comments. Therefore, we first attempted to include those comments that added the highest lexical diversity value to the growing set of collected comments. To that end, we applied the Measure of Lexical Textual Diversity MTLD (McCarthy and Jarvis, 2010), but the expected time to build the corpus with our implementation was unacceptable. Thus, we simply added those comments that produced the highest increase in the vocabulary size to the collection by iterating through all the comments and checking the amount of increase in vocabulary size comment by comment. At each iteration, that comment with the highest contribution of new vocabulary to the final collection was selected. This process was repeated until 60,000 comments were reached.

3.3 Labeling Process

In order to establish the annotation schema, we followed those defined in (Wiegand and Siegel, 2018; Zampieri et al., 2019a), while introducing some additional details that we consider important. Namely, we created a new category to include those posts with inappropriate language but no offense intended. For instance, the comment “eres la puta ama” (you’re the fucking boss) contains inappropriate but non-offensive language and has a positive polarity. Then, we reformulated the definition of offensiveness to not include such posts.

The previous analysis led us to propose a definition of an offensive comment: one where language is used to commit an explicit or implicitly directed offense that may include insults, threats, profanity or swearing. Based on this definition, we established the following categories:

- **Offensive, the target is a person (OFP).** Offensive text targeting a specific individual.
- **Offensive, the target is a group of people or collective (OFG).** Offensive text targeting a group of people belonging to the same ethnic group, gender or sexual orientation, political ideology, religious belief, or other common characteristics.
- **Offensive, the target is different from a person or a group (OFO).** Offensive text where the target does not belong to any of the previous categories, e.g., an organization, an event, a place, an issue.
- **Non-offensive, but with expletive language (NOE).** A text that contains rude words, blasphemes, or swearwords but without the aim of offending, and usually with a positive connotation.
- **Non-offensive (NO).** Text that is neither offensive nor contains expletive language.

The annotation of the collected data was performed via Amazon Mechanical Turk (MTurk)\(^\text{10}\), which is a popular crowdsourcing platform. It provides the option of specifying some requirements that human annotators must meet to work on the task, and the time allotted per assignment. In our case, we selected the location as Spain and the time to five minutes due to the presence of some long comments from YouTube. Apart from releasing the annotation scheme with four examples of instances

\(^{10}\)https://www.mturk.com/
for each class, in the purpose of ensuring clear and concise documentation, we also provided a list of instructions about rules, tips, and FAQs to try to solve any potential problems that could arise during the labeling process. Finally, to ensure the quality of the annotations, we used tracking comments.

We first conducted a round of trial annotation for both types of labeling, 4,500 and 1,500 instances with three and ten annotators, respectively. The goal of the trial annotation was (i) to identify any confusion in understanding the annotation schema, (ii) to estimate the average time to label the dataset, and (iii) to learn about the platform. The launch of these datasets was on September 24th, 2020, and it took two weeks to complete the annotation process on both sets. After analyzing the annotations, we observed through the comments of the annotators that the NOE and OFO classes were the most difficult to identify in the comments by the annotators. For this reason, we improved the definition of each class, providing examples as clear as possible to the annotators. The average agreement (kappa coefficient) grew from 36.85% for trial annotations up to 39.37% for final released comments. Yet, this level of agreement is lower than expected, which reflects the difficulty to discriminate among proposed classes.

Once the trial round was completed, the next step was to release the final dataset. A total of 54,023 instances were released in two subsets: 40,513 labeled by three annotators, and 13,510 labeled by ten annotators. The annotation took place from 17 November 2020 to 2 January 2021. As result, the three annotators subset covered 44,951 comments and the ten annotators subset 14,989 comments.

### 3.4 Post-processing

In order to check the reliability of the annotators, we analyzed their annotations in the tracking comments, i.e., those comments given as examples in the annotation guide. We observed that one of the annotators had over 60% of error rate in the tracking comments of both types of labeling, so we decided to remove their annotations since they could negatively affect the quality of the dataset. Sadly, this annotator was one of the most prolific, so the removal of his/her annotations resulted in a reduction of the three annotators subset to a number of 44,951 comments. A sample of the collected data is given in Tables 3 and 4 (Appendix).

### 3.5 Corpus Analysis

Thus, the final dataset is released divided into two subsets: the three annotators subset (3-Ann), with 44,951 comments, and the ten annotators subset (10-Ann), with 14,989 comments. The former is intended for multi-class classification research and the latter for tackling multi-output regression problems. Only 38 comments belong to both subsets. Comments are compiled without processing, therefore, case, punctuation, and emojis are preserved. Every comment is associated with a social network platform (Instagram, Twitter, or YouTube) and directed to one of the 12 selected influencers as the target. In Table 2, the amount of comments associated with each platform and influencer is depicted. Comments on dalas’ posts are more frequent (over 26% in both subsets). YouTube is the platform where most of the comments were collected (about 75% for both subsets), followed by Instagram (over 18%). Comments from Twitter only represent just over 6% of the collection.

For both subsets, the label is the majority class according to human annotators. For the subset labeled by ten annotators, the majority vote was set to five annotators. An additional None label was used when no agreement was reached between annotators. Table 3 shows the number of comments for each label on both subsets. Noticeably, the 10-Ann subset has a much lower percentage of None labels than the 3-Ann subset. The more annotators that were involved, the easier it was to decide the final label for a comment.

Table 4 shows statistics on comments length (i.e., the number of characters in the text). As expected, YouTube is the platform with the highest average length (about 190 for both subsets), with high variance; Twitter comments average length is lower (149 characters), with very small variance, and Instagram is the platform where comments tend to be the shortest (with an averaged length of 114).

Figure 1 shows the distribution of comments among influencers and social media platforms in the 3-Ann subset. YouTube is the most frequent platform, followed by Instagram. The influencer dalas is the target of more than a quarter of the total amount of comments. A similar distribution of comments is found in the 10-Ann subset.

An interesting analysis is to measure label frequency according to each influencer. Figure 2 shows the proportion of influencer-level labels and reflects the differences among these users as tar-

get of offensive comments. In terms of gender, it is can be seen that female influencers are subject to a greater number of offensive comments than male accounts. In particular, soyunapringada, miare_love, and WindyGirk are the accounts ranked with the most offensive comments. Regarding male influencers, accounts like JaviOliveira and NauterPlay contain more offense comments than accounts like WildHater and JPelirrojo. The profile of the influencer may define more controversy compared to others, or raise more negative emotions to their followers. Therefore, it could be interesting to consider the target profile as a source of information in offensive detection systems.

Inter-annotator agreement using the three annotators subset was measured with Cohen’s kappa coefficient. The k value is 0.3579 (fair agreement), which is quite low and reflects how difficult it is for humans to agree between the proposed categories. By analyzing annotations on tracking comments, we found that it was a common mistake to label a comment NOE or OFG when it should have been labeled OFO. Figure 3 shows the percentage of consensus per label in the subset of 3-Ann taking as consensus the majority vote (2-annotators agreement and 3-annotators agreement). As can be noticed, the label OFO exhibits the lowest consensus rate, with all three annotators only agreeing on 33.72% of the time. We found that many OFO comments were wrongly annotated with the NOE label and, actually, this could be reasonable since these offenses are not directly targeted to persons or groups, and they often consist in expletive ex-
pressions. Thus, we decided to merge them. After merging the OFO label into the NOE label, the kappa value increases slightly up to 0.3837. Figure 4 shows the final percentage of consensus per label after the merge of NOE and OFO labels.

Another feature we analyzed is the lexical diversity of comments. To this end, we use the MTLD metric already introduced, which allows us to get an insight into lexical variation and avoiding biases due to different text lengths. Table 5 shows the average values for MTLD for comments over labels and platforms, respectively.

As can be noticed, offensive comments targeted to a person (OFP) have low lexical diversity, as well as for those with expletive language (NOE). When the comment is not offensive at all, the lexical diversity is clearly higher. Regarding social networks, we would expect the lowest value of diversity in Twitter, as it limits comment length. On the contrary, Twitter is the platform with the highest lexical diversity, followed by YouTube. Instagram is clearly much poorer in terms of the diversity of vocabulary used. These findings are worth exploring, as they could provide more understanding of how language is used across platforms and how it relates to harmful language use, or on the average profile of their communities. To understand MTLD values, we have to consider that a value of 50 is the average lexical diversity of texts for an average adult text (being 80 for academic writings).

4 Baseline System

In order to establish a baseline for the OffendES corpus, we conducted experiments based on three different approaches:

Simple majority class model. Our simplest classifier assigns the majority class of the training set, i.e., the NO class, to each instance in the test set. This results in accuracy values of 58.78% and 64.85% respectively for 3-Ann and 10-Ann subsets.

Lexicon-based model. We also developed a lexicon-based approach using the lexical resources described in Section 3.2. In this approach, we only consider a binary classification scenario: whether the comment is offensive or not. For the 3-Ann subset, we obtained 67.13% of accuracy, 21.27% precision, 83.78% recall, and 33.93% F1. For the 10-Ann subset, the values of accuracy, precision, recall and F1 were, respectively, 71.45%, 35.59%, and 81.60%, 49.56%.

Transformer-based model. Finally, we experimented with a Spanish pre-trained BERT model called BETO (Canete et al., 2020) which has shown

promising results in offensive language detection tasks (Plaza-del-Arco et al., 2020). Details about different configurations of the BETO model and the training process are given in the Appendix. In order to evaluate the model, we sampled from the collection two different sets, for training and evaluation. Measures used to report performance are Precision (P), Recall (R), and F1-score (F1) at class level, and macro and weighted average of these metrics. For the multi-output regression task, since we are not dealing with a multi-class scenario, we used one of the most preferred metrics for regression tasks, the mean squared error (MSE), a risk metric corresponding to the expected value of the squared (quadratic) error or loss.

### 4.1 Multi-class classification

This experiment is performed on the 3-Ann subset. All entries labeled as *None* were discarded (as no final label was assigned to these comments). The set was split into training (95%) and evaluation (5%) partitions, resulting in 30,079 comments in the training set and 3,343 in the evaluation set. Transformers (Wolf et al., 2020) library by Huggingface\(^\text{11}\) was used to build the BERT network and the tokenizer from available BETO models (uncased variant).

A sequence classifier was implemented for this multi-class task, with a final linear layer with four outputs (the logits for each possible label). Training the model took 2 hours and 26 minutes.

After seven training epochs, the model was evaluated against the evaluation partition. The results obtained are depicted in Table 6.

### 4.2 Binary classification with BETO

Same configuration as the previous model, but using non-weighted cross-entropy as loss function during training. Classes have been merged into two classes as follows: *Non-offensive*, which comprises labels NO and NOE, and *Offensive*, combining OFP and OFG labels. This results in 28,895 non-offensive comments and 4,527 offensive comments. Training the model took 2 hours and 16 minutes. The results obtained are depicted in Table 7.

<td>89.06</td>
<td>89.59</td>
<td>89.26</td>
</tr>
</tbody>
</table>

Table 7: Binary classification experiment results.

### 4.3 Multi-output regression with BETO

For every sample, a vector of probabilities is computed by counting the number of annotators that selected each label and dividing by the number of annotators. This provides an estimate of the confidence of each label to be assigned to the comment. Training the model took 48 minutes.

The 10-Ann dataset was split into training and validation partitions. After training for seven epochs over a partition of 13,020 samples, the model was evaluated against a partition of 685 test samples, obtaining an MSE of 0.0241.

### 5 Discussion

One of the main characteristics of the corpus is its imbalance at all levels: comments are not uniformly distributed across labels, influencers, or social platforms. The corpus size allows for stratified random sampling over those dimensions, but we considered that releasing the full set of comments is the best choice to allow researchers to decide on how to prepare their experiments. That is also the reason why comments with *None* class have been kept in the corpus, so different studies on the use of language within groups of young users of social networks can be conducted. Also, the *None* label is of interest by itself, as it reflects the absence of consensus in determining the nature of the comment.

Results show that deep learning models, like BERT, are good estimators of the presence of different kinds of offensive language, but that it is still a challenging task to decide whether a comment is directed to a person or not (so cyber-bullying risk could be measured). Despite the fusion of NOE

\(^{11}\)https://huggingface.co
and OFO categories, precision values for all labels different from NO are low.

6 Conclusion and Future Work

In this paper, we described OffendES: the first large-scale Spanish dataset of user comments on influencer posts from Instagram, YouTube and Twitter. It consists of 47,128 comments manually labeled for offensive content using a fine-grained annotation scheme. A subset of the corpus (10-Ann) assigns a confidence degree allowing both multi-class classification and multi-output regression studies. Additionally, a preliminary analysis of offensive behavior in social media and its relationship with the selected influencers is presented. Finally, baselines experiments have been performed, showing the validity of the corpus as well as the difficulty of the task.

A number of challenges remain open. On the one hand, we plan to explore systems trained on OffendES to monitor offensive messages in online channels participated by young people. On the other hand, the gender of the commenters and the subject of the comments have been left out for deeper analysis, so further research could be shed light on these matters. Finally, we believe that this dataset enables future work in the NLP community to tackle these interesting issues regarding Spanish language.

Hyper-parameters. In the experiments with Transformer the hyper-parameters used for fine-tuning BETO are specified in Table 1. In the multioutput regression task the hyper-parameters are the same, except for the loss function, which is replaced by mean squared error loss, as it is a regression problem.

All experiments (training and evaluation) were performed on a node equipped with two Intel Xeon Silver 4208 CPU at 2.10GHz, 192GB RAM, as main processors, and six GPUs NVIDIA GeForce RTX 2080Ti (with 11GB each).

Abstract

This work investigates neural machine translation (NMT) systems for translating English user reviews into Croatian and Serbian, two similar morphologically complex languages. Two types of reviews are used for testing the systems: IMDb movie reviews and Amazon product reviews.

Two types of training data are explored: large out-of-domain bilingual parallel corpora, as well as small synthetic in-domain parallel corpus obtained by machine translation of monolingual English Amazon reviews into the target languages. Both automatic scores and human evaluation show that using the synthetic in-domain corpus together with a selected subset of out-of-domain data is the best option.

Separated results on IMDb and Amazon reviews indicate that MT systems perform differently on different review types so that user reviews generally should not be considered as a homogeneous genre. Nevertheless, more detailed research on larger amount of different reviews covering different domains/topics is needed to fully understand these differences.

1 Introduction

Machine translation (MT) has evolved very rapidly since the emergence of neural approaches in 2015, and it is being used for different genres and domains. Every year, evaluation campaigns which include both human and automatic evaluation are carried out with the goal of advancing the state of the art. The most well-known is the WMT shared task\(^1\) which focuses on news articles and (since 2016) on biomedical texts, and both can be considered as instances of “formal written text”. The IWSLT evaluation campaign\(^2\), on the other hand, focuses on the translation of TED talks, and some European projects (TraMOOC, transLectures) investigated the translation of online lectures. In both cases, the text can be considered to be “formal speech”, with the challenges of dealing with characteristics of spoken language and speech recognition output.

Recently, interest in the translation of user-generated content in the form of “informal written text” has been increasing. For example, JSALT 2019 workshop\(^3\) focused on translation of very noisy text content originating from sources like WhatsApp, Twitter and Reddit.

In this work, we focus on a different type of written user-generated content, namely user reviews. While the style is not as colloquial and noisy as that of Twitter or of other similar sources, it certainly is much less formal than news texts or other sources that have been investigated traditionally in the MT community. There are also important applications for focusing on this kind of data, both from commercial and from user perspective. More and more companies are expanding into multinational markets, and user reviews of products have become an important asset for online transactions and a feature that many customers expect to find. And in the era of always-available internet connectivity, many individuals rely on experiences of other people not only for guiding purchasing decisions, but also for entertainment options like choosing movies, books, restaurants, etc. In this work, we focus on both kinds of user reviews, namely product reviews from Amazon and movie reviews from IMDb.

Translating user reviews can increase and improve its reach and utility. The main issue for human translation is the fact that there is way too

---

\(^1\)http://www.statmt.org/wmt20/
\(^2\)http://workshop2019.iwslt.org/index.php
\(^3\)https://www.clsp.jhu.edu/workshops/19-workshop/improving-translation-of-informal-language/
much content to be translated. Therefore, MT is very helpful for this kind of content. However, the genre introduces several important challenges, such as informal language, spelling errors, a large number of domains/topics, and lack of in-domain parallel (bilingual) data.

In this work, we compare two approaches for building MT systems for translating user reviews: training on large parallel out-of-domain data and training on small synthetic in-domain data. We also compare MT performance on two types of user reviews: IMDb movies and Amazon products.

We investigate Croatian and Serbian as target languages, as a case involving mid-size less-resourced morphologically rich European languages. For these languages, a reasonable amount of out-of-domain parallel data is publicly available to train an NMT system, however still much lower than for “major” European languages (such as German, French, Spanish).

All our experiments were carried out on publicly available data sets. We used OPUS parallel data for out-of-domain training and a selected set of Amazon reviews for in-domain training. For development, we used the publicly available texts consisting of a selected set of English IMDb reviews and their Croatian and Serbian human translations. For testing, we used another selected set of IMDb reviews as well as a selected set of Amazon reviews. Neither of the test reviews has been investigated yet, and they will also be made publicly available.

1.1 Related work

A considerable amount of work in the Computational Linguistics/Natural Language Processing community has been done on processing user-generated content, mostly on sentiment analysis, but also on different aspects of machine translation (MT). Some papers investigate translating social media texts in order to map widely available English sentiment labels to a less supported target language (Balahur and Turchi, 2012, 2014).

Several researchers attempted to build parallel corpora for user-generated content in different language pairs in order to facilitate MT (Jehl et al., 2012; Ling et al., 2013; San Vicente et al., 2016), while (Banerjee et al., 2012) explored methods for domain adaptation. A recent JSALT Workshop dealt with improving MT for messages (Messenger, WhatsApp), social media (Facebook, Instagram, Twitter), and discussion forums (Reddit). Evaluating MT outputs of user-generated content was the topic of several publications, too. Two important measures of overall quality, comprehensibility and fidelity, were investigated in (Roturier and Bensadoun, 2011) in order to compare different English-to-German and English-to-French MT systems for technical support forums, and automatic estimation of these two measures for English-to-French MT was investigated in (Rubino et al., 2013). Maintaining sentiment polarity in German-to-English MT of Twitter posts was explored in (Lohar et al., 2017, 2018). However, none of these publications explored translation of user reviews.

The first publication about MT for user reviews (Lohar et al., 2019) explored translating English IMDb reviews into Croatian and Serbian and reported results of both automatic and human evaluation. However, all the systems were trained on very small amounts of parallel data so that the reported performance was rather low. More experiments on the same IMDb reviews were carried out (Popović et al., 2020), however, still only small amounts of training data were used. Also, no results of any kind of human evaluation were reported.

In this work, different sizes of the training corpora were explored, including a large corpus consisting of all publicly available parallel data for the two language pairs. Two types of reviews are explored, IMDb and Amazon, and both automatic scores as well as results of human evaluation are reported. In addition, differences between the two types of reviews are examined in order to see whether all user reviews can be considered as a homogeneous genre.

2 Building NMT systems

All our systems are based on the Transformer architecture (Vaswani et al., 2017) and built using the Sockeye implementation (Hieber et al., 2018). Previous work on the given two target languages (Popović et al., 2020) reported that multilingual sys-
tem which translates into both languages performs better than two separated bilingual systems. Therefore, all our systems are multilingual, built using the same technique as (Johnson et al., 2017; Aharoni et al., 2019), namely adding a target language label “SR” or “HR” to each source sentence. The amount of Croatian and Serbian data is balanced in all set-ups in order to achieve optimal performance for both target languages.

The systems operate on sub-word units generated by byte-pair encoding (BPE) (Sennrich et al., 2016b) with 32000 BPE merge operations both for the source and for the target language texts. We do not use shared vocabularies between the source and the target languages because they are distinct. On the other hand, we built a joint vocabulary for the two target languages because they are very similar.

All the systems have Transformer architecture with 6 layers for both the encoder and decoder, model size of 512, feed forward size of 2048, and 8 attention heads. For training, we use Adam optimiser (Kingma and Ba, 2015), initial learning rate of 0.0002, and batch size of 4096 (sub)words. Validation perplexity is calculated after every 4000 batches (at so-called “checkpoints”), and if this perplexity does not improve after 20 checkpoints, the training stops.

“Teacher/student” model As a first step, we built a system trained on all publicly available parallel data consisting of about 55 million sentences. These data, however, do not contain any user reviews. On the other hand, there is a vast amount of monolingual English user reviews, and in order to get use of it, we created a synthetic in-domain parallel corpus which is a widely used practice in NMT (Sennrich et al., 2016a; Zhang and Zong, 2016; Burlot and Yvon, 2018; Poncelas et al., 2018). We selected a set of about four million sentences from Amazon reviews originating from 14 different topics, and translated them by the system trained on out-of-domain data. In this way, we applied so-called “teacher/student” model, or “knowledge distillation” (Saleh et al., 2020; Chen et al., 2017; Kim and Rush, 2016). Knowledge distillation is the training of a smaller network (student) who learns from an already trained network (teacher). The idea is that the student will be performing much faster and hopefully approximately well as the teacher. The method is often used for reducing the amount of training data, to speed up the process, as well as for domain adaptation.

In our set-up, knowledge distillation is used for domain adaptation: the teacher model is the system trained on a large amount of out-of-domain parallel data. This system is used to create a small synthetic in-domain corpus, which is then used to train the student model.

“Advanced student” model The best option for using synthetic training corpora for NMT is not to use them alone, but to enrich “natural” parallel corpora. However, we do not have any natural in-domain parallel corpora. Yet, some parts of the large out-of-domain corpora might be more useful for translating reviews than others, especially subtitles which are usually informal spoken language. To explore this potential, we ranked out-of-domain sentences according to their similarity to user reviews, and extracted the most similar ones to combine them with the synthetic parallel corpus and train an “advanced student” model.

The details about all data sets and data selection are presented in the next section.

3 Data sets

3.1 User reviews

IMDb movie reviews (Maas et al., 2011) consist of about 10 sentences and 230 words on average. Each review is labelled with a score: negative reviews have a score < 4 out of 10, positive reviews have a score > 7 out of 10, and the reviews with more neutral ratings are not included.

In our experiments, IMDb reviews were used for development and testing, but not for training.

Amazon product reviews (McAuley et al., 2015) are generally shorter, consisting of 5 sentences and 93 words on average. Each review is labelled with a rating from 1 (worst) to 5 (best). The reviews are divided into 24 categories/topics/domains, and we used the reviews from the following 14 topics: “Beauty”, “Books”, “CDs and Vinyl”, “Cell Phones and Accessories”, “Grocery and Gourmet Food”, “Health and Personal Care”, “Home and Kitchen”, “Movies and TV”, “Musical Instruments”, “Patio, Lawn and Garden”, “Pet Supplies”, “Sports and Outdoors”, “Toys and Games”, and “Video Games”.

For our systems, Amazon reviews were used both for training as well as for testing, however
not for development. In order to obtain a balanced multi-target training corpus, half of the selected reviews from each of the topics were translated into Serbian and another half into Croatian.

3.2 Out-of-domain data

We used the publicly available OPUS\footnote{http://opus.nlpl.eu/} parallel data (Tiedemann, 2012) as out-of-domain data. The vast majority of these resources for the desired language pairs consists of OpenSubtitles, and there are also SETIMES News, Bible, Tilde, EU-bookshop, QED, and Tatoeba corpora. In addition, we used GlobalVoices for Serbian, and hrenWac, TED and Wikimedia for Croatian. In total, the corpus is well balanced over the two target languages.

3.3 Selected out-of-domain data

As mentioned in Section 2, we extracted a set of sentences from the out-of-domain subtitles according to their similarity to Amazon reviews. The subtitles were ranked using the Feature Decay Algorithm (FDA) (Biçici and Yuret, 2011, 2015; Poncelas et al., 2018; Poncelas, 2019). FDA selects sentences from a set $S$ based on the number of n-grams which overlap with an in-domain text $Seed$ and adds these sentences to a selected set $Sel$. In addition, in order to promote diversity, the n-grams are penalised proportionally to the number of instances already present in $Sel$. During the execution of FDA, candidate sentences from the set $S$ are selected one by one according to the following score:

$$\text{score}(s, Seed, Sel) = \frac{\sum_{ngr \in s \cap Sel} 0.5 C_{Sel}(ngr)}{\text{length}(s)}$$

The sentence $s$ with the highest score is removed from $S$ and added to $Sel$. The count of occurrences of n-gram $ngr$ in the selected set $Sel$, $C_{Sel}(ngr)$, is updated so that in the following iterations this n-gram contributes less to the scoring of one sentence. The process is executed iteratively, adding a single sentence from the set $S$ to the selected set $Sel$ at each step, and stopping after enough sentences have been extracted.

For our experiment, the out-of-domain subtitles represent the set $S$, and the Amazon reviews are $Seed$. From the 4 million English review sentences selected for training, we selected 140,000 sentences as seed (about 10,000 from each of the topics). We then used this seed to extract the similar sentence pairs from English-Croatian and English-Serbian subtitles. For each target language, we selected the top 9 million sentence pairs, thus 18M balanced sentence pairs in total.

Table 1 shows number of sentences, running words and distinct words (vocabulary) in training, development and test sets, as well as contributions of each of the review types.

4 Experimental set-up

In order to systematically explore influence of different sizes and natures of training data, we built the following MT systems:

- GENERAL (teacher model): system trained on all publicly available out-of-domain parallel data.
- REVIEWS (student model): system trained on in-domain synthetic corpus consisting of original English Amazon reviews and their translations generated by the GENERAL system.
- REVIEWS+SELECTED (advanced student): system trained on combination of synthetic in-domain data and selected natural out-of-domain data. We investigated different amounts of selected data:
  - REVIEWS+6M: adding 6 million selected out-of-domain sentences (3M for each target language)
  - REVIEWS+12M: adding 12 million selected out-of-domain sentences (6M for each target language)
  - REVIEWS+18M: adding all 18 million selected out-of-domain sentences (9M for each target language)

5 Results

5.1 Comparing MT systems

In order to get a quick feedback about each of our systems, we first evaluated them using the following three automatic overall evaluation scores: sacREBLEU (Post, 2018), chrF (Popović, 2015) and characTER (Wang et al., 2016).

The two best systems according to automatic scores, the “teacher” system GENERAL and the “advanced student” system REVIEWS+18M, were also evaluated by human annotators. The evaluators marked all words considered as adequacy errors, as described in (Popović, 2020), on a sub-set of about 200 sentences per system.
The results are presented in Table 2, and the tendencies are same for both target languages. As expected, the small synthetic in-domain corpus alone (REVIEWS) cannot achieve the same performance as the large out-of-domain corpus (GENERAL), however the difference in scores is not so large as could be expected considering the difference in the sizes (55M vs 4M) as well as the fact that the target part of the in-domain corpus is machine translated. Adding 6M of selected parallel sentences (REVIEWS+6M) slightly improves the performance, while additional 6M selected sentences (REVIEWS+12M) yield (and even slightly improve) the performance of the GENERAL “teacher” system. Adding 18M selected sentences (REVIEWS+18M) only slightly improves over the REVIEWS+12M system, and definitely outperforms the GENERAL “teacher” system. Since the improvements from 12M to 18M are rather small, we did not experiment with larger selected corpora.

We also present the scores for two on-line MT systems, AMAZON and GOOGLE, and it can be seen that our best two systems outperform both of them. Although their automatic scores are notably lower than the two best systems, they were also evaluated by human annotators in order to gather more annotations for comparing two different types of reviews which will be described in the next section.

Before moving to that, we will present a set of translation examples for the two best systems in Table 3. The first four sentences represent examples where the review-oriented “advanced student” system REVIEWS+18M performs better. In the sentence (1), the GENERAL system completely mistranslated the noun phrase “reddish brown hair”, and in the sentences (2) and (3) it choose incorrect variant of ambiguous source words “characters” and “care”. In the sentence (4), the word order is not optimal.

In sentences (5) and (6), REVIEWS+18M performed better on the first part of the sentence while GENERAL performed better on the second part. GENERAL failed to properly rephrase the first part of the sentence (5) and generated overly literal translation. In sentence (6), it choose incorrect variant of the ambiguous source word “great”. On the other hand, REVIEWS+18M failed to properly

Table 1: Data statistics: number of sentences, running words and distinct words (vocabulary) in training (a), development and test sets (b), and contribution (% of segments) of IMDb and Amazon reviews in training, development and test sets (c).
Table 2: Comparison of English→Croatian (a) and English→Serbian (b) systems trained on different texts by automatic evaluation scores: BLEU, chrF and characTER as well as by percentage of words marked as adequacy errors by human evaluators (“human”).

### 5.2 Comparing Amazon and IMDb reviews

In order to compare the MT performance of two types of reviews, separated scores for joint target languages are presented in Table 4. The reviews+18M system shows the best results for both types of reviews, which means that the “knowledge distillation” in form of forward translation of Amazon reviews by the general system was helpful for both review types.

Furthermore, for all systems, automatic scores are notably better for Amazon product reviews than for IMDb movie reviews, indicating that IMDb is more difficult for machine translation. However, the tendencies of human scores are different, except for Google. For other systems (our two and Amazon), the evaluators found less errors in IMDb than in Amazon reviews. Also, it has to be taken into account that IMDb reviewers were not used for training, only Amazon reviews, which can influence the results. More experiments with equal distributions in training and test sets should be carried out in future work.

After looking into errors marked by human evaluators in order to identify the most prominent error types (Popović, 2021), we found out that there are some differences in frequencies of certain error types, presented in Table 5. The largest difference can be seen for named entities, which are generally more frequent in IMDb than in Amazon reviews. Also, it has to be taken into account that IMDb reviewers were not used for training, only Amazon reviews, which can influence the results. More experiments with equal distributions in training and test sets should be carried out in future work.

<td>0.7</td>
<td>1.6</td>
</tr>
</tbody>
</table>

Table 5: Different error types in IMDb and Amazon user reviews; the largest difference can be noted for named entity errors, which are especially frequent in IMDb.

Among errors, untranslated words (English words copied into translation) as well as non-existing words (which do not exist either in the source or in the target language).

All these results indicate that there are differences between different types of reviews so that user reviews generally do not represent a homogeneous genre. However, the analysis is carried out on relatively small amount of data, especially human evaluation, so that it is not yet possible to draw any conclusions about the nature of these differences. Further analysis on more data as well as detailed analysis of different review topics including more review types (such as hotel reviews from TripAdvisor) should be carried out in future work.

6 Summary and outlook

This work investigates machine translation of two types of user reviews, IMDb movie reviews and Amazon product reviews, from English into Serbian and Croatian.

Since one of the main challenges for MT of user reviews is lack of parallel in-domain training data, we explored a possibility to make use of large out-of-domain bilingual parallel corpora as well as monolingual in-domain English corpora. We trained a general “teacher” system on all out-of-domain data and then used this system to create a small synthetic in-domain parallel corpus by translating English Amazon reviews into the target languages. Both automatic scores and human evaluation show that using this synthetic in-domain corpus together with a selected sub-set of out-of-domain data is the best option.

The results on separated IMDb and Amazon reviews indicate that MT systems perform differently on different review types so that user reviews generally should not be considered as a homogeneous genre. However, evaluating and training on larger amount of different reviews covering different domains/topics is needed to identify the nature of differences between different types of reviews, and also influence of different topics. Another direction of future work should include using more in-domain data, as well as other techniques for domain adaptation.

Abstract

In this paper, we present coreference resolution experiments with a newly created multilingual corpus CorefUD (Nedoluzhko et al., 2021). We focus on the following languages: Czech, Russian, Polish, German, Spanish, and Catalan. In addition to monolingual experiments, we combine the training data in multilingual experiments and train two joined models – for Slavic languages and for all the languages together. We rely on an end-to-end deep learning model that we slightly adapted for the CorefUD corpus. Our results show that we can profit from harmonized annotations, and using joined models helps significantly for the languages with smaller training data.

1 Introduction

Coreference resolution is the task of finding language expressions that refer to the same real-world entity (antecedent) of a given text. Sometimes the corefering expressions can come from a single sentence. However, the expressions can be one or more sentences apart as well. It is necessary to see the whole document in some hard cases to judge whether two expressions are corefering adequately. This task can be divided into two subtasks. Identifying entity mentions, and grouping the mentions together according to the real-world entity they refer to. The task of coreference resolution is closely related to anaphora resolution – see (Sukthanker et al., 2020) to compare these two tasks.

One of the challenging difficulties of coreference resolution lay in linguistically complicated annotations. Some examples of linguistic complications are split antecedents (a mention refer to more than one real-word entities), near identity relations, anaphoric and cataphoric relations, etc (Nedoluzhko et al., 2021).

In this paper, we rely on a CorefUD corpus (Nedoluzhko et al., 2021) of harmonized annotations. This corpus enables us to battle linguistic complications since it simply presents corefering mentions in clusters. Since the corpus is compiled from 11 different corpora in 8 different languages, we can conduct multilingual experiments in this work. Our research goal is to evaluate whether the harmonized annotations open the possibility to obtain some performance gain by joint learning on multiple languages. We aim to compare the harmonized annotations with the original corpora as well.

2 Related Work

In agreement with many other NLP tasks, deep learning models prevail in the coreference resolution task. Lee et al. (2017) were first to introduce the end-to-end approach that many following papers adopted (they obtained an average of 67.2 of F1 score). The task experienced a big leap in performance with the introduction of large pre-trained models. BERT based models deliver the best results; Kantor and Globerson (2019) F1 76.6, and Joshi et al. (2019) F1 76.9. Joshi et al. (2020) came up with a new pretraining task focused on better span representations. Their model called SpanBERT brings additional improvements in the coreference resolution task (F1 79.6). Xu and Choi (2020) question the importance of modeling higher-order inference (HOI). They show that with advanced encoders, HOI has only a minor effect on the performance of models.

Research is significantly less evolved for other languages than English. However, some notable experiments were published in recent years. Recasens et al. (2010) describe multilingual experiments (for English, Catalan and Spanish, Dutch, German and Italian) similarly to our paper. However, the annotations were not harmonized as in our case. Therefore, they provide no experiments with
joint training.

Other cross-lingual experiments include Portuguese by learning from Spanish (Cruz et al., 2018); Spanish and Chinese relying on an English corpus (Kundu et al., 2018); and Basque based on an English corpus as well (Urbizu et al., 2019). All these approaches employ neural networks, and they transfer the model via cross-lingual word embeddings.

Treex CR (Novák, 2017) is a coreference resolution module in the Treex NLP framework. It produces an advanced syntactic analysis with semantic features that the tool uses to find coreference relations – offers models for Czech and English. Other non-English experiments include Polish (Nitòn et al., 2018), Russian (Sboev et al., 2020), and German (Srivastava et al., 2018).

3 Dataset

For our experiments, we use the harmonized multilingual coreference dataset CorefUD (Nedoluzhko et al., 2021). The dataset was created by converting 17 existing datasets for 11 different languages into a common format on the top of universal syntactic annotations – Universal Dependencies. For coreference representation, a cluster-based approach was selected instead of the link-based approach. It is simpler and moreover the most frequently used dataset for English – OntoNotes adopt this approach too. In a cluster-based approach, every mention belongs to one cluster, represented by a unique ID. In a link-based approach, coreferences are expressed by the links between corefering mentions. In the link-based approach, coreference structures form a chain, but there are more complex coreference structures in some cases (Nedoluzhko et al., 2021). Datasets that use the link-based approach were converted to cluster-based at the cost of some information loss.

There are some notable differences between the datasets. One of the most prominent ones is the presence of singletons. Singletons are clusters that contain only one mention. Singletons are not present in any coreference relation. However, they are annotated as mentions in all datasets. Discontin-ued mentions represent another notable difference. A discontinuous mention consists of a sequence of words that is interrupted at least once with some words that do not belong to the mention. Such mentions can cause problems to models that assume mentions to be continuous (such as our model).

Table 1 shows the statistics of the datasets including the above-mentioned differences. More detailed analysis can be found in Nedoluzhko et al. (2021).

4 Model

We use the basic end-to-end model from Xu and Choi (2020) with no higher-order inference (HOI), so it is the same model as it was proposed by Lee et al. (2017).

In the model, we start by modeling the probability \( P(y_i|D) \) of a mention \( i \) corefering with the antecedent \( y_i \) in a document \( D \). Since the model adopts the end-to-end approach, the mentions are identified together with the coreference links. We consider every continuous sequence of words as a mention \( i \). Therefore, we work with \( N = \frac{T(T+1)}{2} \) possible mentions, where \( T \) is the number of words in a document \( D \).

We model the score of a mention \( i \) corefering with an antecedent \( y_i \) as a combination of two types scores \( s_m(i) \) and \( s_a(i, y_i) \). The \( s_m \) is a score of a sequence of words (spans) \( i \) being a mention. The \( s_a(i, y_i) \) score is the score of a span \( y_i \) being an antecedent of span \( i \). The scores are combined as a sum of \( s_m(i) \), \( s_m(y_i) \) and \( s_a(i, y_i) \) as follows:

\[
    s(i, y_i) = \begin{cases} 
    0 & y_i = \epsilon \\
    s_m(i) + s_m(y_i) + s_a(i, y_i) & y_i \neq \epsilon 
    \end{cases}
\]

(1)

where \( \epsilon \) is an empty antecedent. Both scores \( s_m(i) \) and \( s_a(i, y_i) \) are estimated with a feed-forward neural network over the BERT-based encoder. In our experiments we use two encoders – multilingual BERT (Devlin et al., 2018) and Slavic BERT (Arkhipov et al., 2019).

The probability of an antecedent \( y_i \) can be expressed as the \( \text{softmax} \) normalization over all possible antecedents \( y' \in Y(i) \) for a mention \( i \):

\[
    P(y_i|D) = \frac{\exp(s(i, y_i))}{\sum_{y' \in Y(i)} \exp(s(i, y'))} \tag{2}
\]

The formula for all antecedents uses a product of multinomials of all individual antecedents:

\[
    P(y_1, \ldots, y_N|D) = \prod_{i=1}^{N} P(y_i|D) \tag{3}
\]
In the training phase, we maximize the marginal log-likelihood of all correct antecedents:

\[
J(D) = \log \prod_{i=1}^{N} \sum_{\hat{y} \in Y(i) \cap \text{GOLD}(i)} P(\hat{y})
\]

where \text{GOLD}(i) is the set of spans in the training data that are antecedents.

5 Experiments

First, we perform monolingual experiments with the model described in Section 4 on several largest datasets from CorefUD. Namely Czech, Russian, Polish, Spanish, Catalan, and German-PotsdamCC. The employed datasets are summarized in Table 1 along with some basic statistics. The datasets are split to train, dev, and test, but the test datasets are not publicly available. Therefore, we use the original dev datasets as test datasets, and we create new dev datasets by taking 10% of the training parts. We tune the hyperparameters and perform early stopping on the development parts.

As the next step, we perform multilingual experiments, where we train one model for all the Slavic languages (Czech, Russian, and Polish) and another model for all the languages (Czech, Russian, Polish, German, Spanish, and Catalan). Multilingual results in comparison with the monolingual ones are shown in Table 2.

The results in Table 2 are influenced by the presence of singletons in the datasets. Particularly, Polish, German, Spanish, and Catalan contain a large portion of singletons, which negatively impacts the results. Since our employed model cannot model singletons, we have removed them from the test datasets. We show the results on filtered datasets in Table 4. Singletons are not important for coreference resolution since they form no coreference relation. However, they can be important in the training phase, if the model can use them for mention recognition.

We report the average F1 measure from the official scoring script for the coreference resolution task in CoNLL. The metric is computed as the average of MUC, B3 and CLEAF1. Definition of these metric can be found in Pradhan et al. (2014). The F1 scores are reported with 95% confidence intervals measured from 5 runs. We use the same set of hyperparameters for all the languages and for all models. We train the models for approximately 100k steps. We employ the Adam optimizer with the learning rate of 0.00001 for BERT layers and 0.0002 for other layers.

6 Discussion

From the result (See Table 3), we can see that joined multilingual models helps all the languages except for Czech – which does make sense because the Czech dataset is the largest one in the CorefUD corpus.

For the smallest datasets (Russian and German), multilingual models outperform the monolingual ones by a large margin (cca 2 – 6 % F1). We can see that at least in small training datasets, using joined models definitely helps, and we can profit from the harmonized coreference annotations. It is also worth noticing that the confidence intervals for these datasets are significantly wider than for other datasets.

After the singleton filtering the employed model achieves good results for all languages tested.

For German, there are 6.3% of discontinuous entity mentions. The model iterates over all possible continuous spans. Therefore, it is not able to identify discontinuous mentions at all. For German, the effect of singletons and discontinuous mentions

---

7 Future Work

Currently, we experimented only on a subset of languages available in CorefUD. This was caused mainly by the resource-exhaustive training. We need 32GB graphic cards to capture long-enough contexts. We plan to experiment with the rest of the languages in the future.

Additionally, it would be interesting to explore the possibilities of zero-shot cross-lingual transfer in CorefUD, where we will not use the training data for the target language at all.

8 Conclusion

We performed pilot experiments to evaluate inter-language transferability of the models based on the CorefUD dataset. To do so, we used an end-to-end coreference resolution model based on BERT-like models. Our experiments show that learning from multiple languages in CorefUD annotation scheme helps significantly especially for languages with smaller training data (like Russian and German data in CorefUD).

Predicting Informativeness Of Semantic Triples

Judita Preiss

Abstract

Many automatic semantic relation extraction tools extract subject-predicate-object triples from unstructured text. However, a large quantity of these triples merely represent background knowledge. We explore using full texts of biomedical publications to create a training corpus of informative and important semantic triples based on the notion that the main contributions of an article are summarized in its abstract. This corpus is used to train a deep learning classifier to identify important triples, and we suggest that an importance ranking for semantic triples could also be generated.

1 Introduction

Subject-predicate-object triples are used in numerous natural language processing areas, including question answering (e.g. Hristovski et al. (2015)), ontology building (e.g. Du and Li (2020)) and literature based discovery (e.g. Hristovski et al. (2006)). While they can be thought of as representing the minimum unit of semantic expression, there is a large degree of variability in the amount of new (not commonly known) content they convey. On the one hand, they sometimes represent what can be termed background knowledge, for example “New Zealand - ISA - country” or “pharmaceutical services - TREATS - health personnel”, while on the other, they may describe very specific findings such as pimobendan TREATS hypertrophic cardiomyopathy or LCN2 protein, human - ASSOCIATED_WITH - chronic kidney disease. We use biomedical publications to test the hypothesis that training data consisting of such, important, triples can be created from abstracts, and train a deep learning algorithm to identify these high importance triples from a list of all triples appearing in a paper. The system could also be adjusted to output a weight instead of a binary decision, allowing for an importance ranking of semantic triples within an article.

The paper begins with an overview of related work in Section 2, the experimental set-up follows in Section 3, with the results and discussion in Section 4 and conclusions drawn in Section 5.

2 Background

A number of tools for automatically extracting semantic relations – (subject, relation, object) triples – from unstructured text exist (Yuan and Yu, 2018). However, as Papadopoulos et al. (2020) point out, the majority of works incorporating these do not perform much pre- or post-processing and therefore include many potentially uninformative triples, and works proposing to extend currently existing collections of semantic relations often speak of extending the set of relations, not refining the relations present (e.g. Koroleva et al. (2020)).

Evaluations of semantic relation extraction systems are often very comprehensive, e.g. Kilicoglu et al. (2020) present a detailed independent evaluation of SemRep – a biomedical domain tuned triple extraction tool – and discover common sources of error for this tool, but such evaluations do not quantify the quality of the triple that is retrieved by the system. It is unclear whether the incorrectly extracted triples are uninformative, or the opposite.

While not phrased as focusing on informative / important triples, existing works often restrict to particular types of relations: Yuan and Yu (2018) evaluate the extraction of health claims, defined as a relation between something that is being manipulated and something that is being measured (e.g. the relation between a substance and a disease). Yadav et al. (2020) restrict to drug-drug interaction, protein-protein interaction, and medical concept relation extraction, while Hope et al. (2021) focus on mechanisms, i.e. activities, functions and...
causal relations. Such restrictions are likely to increase the overall quality of the remaining triples: removing the ISA relation alone eliminates a large quantity of background knowledge. The closest to our work is due to Zhang et al. (2021) who filter out uninformative triples computationally, based on the difference between triples’ expected and observed frequencies.

3 Experiment Design

Below, we discuss the two steps needed to explore the hypothesis that a dataset based on abstracts can be used to detect important triples using machine learning: 1) creation of a training corpus, and 2) selection of a deep learning architecture.

3.1 Training Corpus Creation

The CORD-19 dataset (Wang et al., 2020) was chosen for this work due to: 1) scale, the 2021-05-03 version contains 198,347 full articles, 2) availability of extracted text, the dataset contains the text extracted from available full article PDFs, 3) domain, the restricted nature of the dataset allows the application of existing biomedical tools.

3.1.1 Semantic Relation Extraction

Subject-relation-object triples are extracted from all article texts present in the dataset using SemRep (Rindflesch and Fiszman, 2003). Designed for the biomedical domain, the tool extracts triples such as “*imatinib* TREATS Gastrointestinal Stromal Tumors” but with concepts mapped to Unified Medical Language System metathesaurus (UMLS) (Bodenreider, 2004) concept unique identifiers, CUIs (i.e. yielding C0935989 - TREATS - C0238198 for the example). This addresses the problem of multi-word identification (recognizing gastrointestinal stromal tumours rather than merely tumours) and word sense disambiguation (distinguishing between occurrences of concepts with multiple meanings, such as COLD, which could - among other options - represent the common cold or chronic obstructive airway disease).

3.1.2 Identifying Important Triples

To train a machine learning classifier, a training set of important triples is needed. Since an abstract usually summarizes the main findings of an article, we hypothesize that important triples can be considered to be those that appear in both the body and an abstract. It is important to note that the training set of important triples does not need to be complete, i.e. not every important triple from the body needs to be identified. The dataset should be as noise free as possible, and therefore background knowledge triples (which may appear in both the abstract and the body of an article) should not be included. To reduce noise, the following filtering is performed:

- Previously published triples. The construction of positive examples in the training set hinges on the identification of important triple(s). If these triples are defined as those which describe the novel contribution(s) of an article, an identical triple (i.e. contribution) should not have appeared in abstracts prior to the current paper. Therefore triples appearing in SemRep processed Medline (V40, released October 2019, i.e. before the CORD-19 dataset), a vast collection of biomedical abstracts (Lozano-Kühne, 2013), are removed from the dataset.
- Frequent concepts. Some frequent concepts often appear in non important triples, such as: 
  - therapeutic procedure TREATS disease
  - malaise PROCESS_OF patients
  - lung PART_OF *homo sapiens*

Since the training set does not need include an annotation for every triple encountered and there is high probability of mis-annotation with triples involving these concepts, triples involving the top 1% of concepts appearing in V40 of SemRep processed Medline are removed. The top 1% includes patients, therapeutic procedure, homo sapiens and other very general terms. Note that this does not mean that the system will be unable to classify triples including these concepts.

In some cases, an identical triple is used both in the abstract and the body of an article, however, when repeated, novel contributions of a paper are sometimes rephrased using (near) synonyms. Therefore a measure of triple similarity needs to be defined. Since the triples are of the format *subject CUI* → *predicate word* → *object CUI*, this measure can be defined on each component (subject, predicate, object) separately. Word (CUI) embeddings represent each word (CUI) as a vector which captures information about the contexts it appears in, therefore yielding similar – close – vectors for synonyms. A triple similarity measure can therefore be implemented based on cui2vec (Beam et al.,
2019) (for subject and object similarity) and GloVe embeddings (for predicate similarity).

Similarity between two triples, \( \text{cui}_1 - \text{rel}_1 - \text{cui}_2 \) and \( \text{cui}_21 - \text{rel}_2 - \text{cui}_22 \), is then given by the formula:

\[
\text{cs}(\text{c}2\text{v}(\text{cui}_1), \text{c}2\text{v}(\text{cui}_21)) + \text{cs}(g(\text{rel}_1), g(\text{rel}_2)) + \text{cs}(\text{c}2\text{v}(\text{cui}_12), \text{c}2\text{v}(\text{cui}_22))
\]

where \( \text{cs} \) represents the cosine similarity, \( \text{c}2\text{v}(x) \) the cui2vec vector of \( x \) and \( g(x) \) \( x \)'s GloVe vector.

As the maximum value for cosine similarity is 1, the triple similarity is a decimal between 0 and 3 inclusive, 0 corresponding to complete lack of similarity between triples and 3 an exact match. For each body-triple, a similarity can be computed between it and each abstract-triple in the same article, with the highest becoming the body-triple’s similarity value. A threshold can be set on the similarity value to decide which triples are deemed important.

3.2 Deep Learning Algorithm

The machine learning component consists of three parts: 1) feature extraction, 2) architecture selection, and 3) experiment settings.

3.2.1 Feature Extraction

The ability to extract important triples (described in Section 3.1.2) makes it possible to use supervised machine learning approaches to train a classifier. To this end a number of features are extracted for each body-triple.

Frequency based features: 1) the number of times the triple appeared in the body of the article, and 2) the total number of relations within the body of the publication.

UMLS based features: 1) the frequency count of the CUIs in the body triple as extracted from SemRep processed Medline – while the top 1% of CUIs have been discarded, it is believed that CUIs with lower frequencies are more likely to be part of novel contributions, 2) the UMLS source vocabulary of the CUIs – the metathesaurus consists of many different types of biomedical vocabularies and the information pertaining to which one(s) a CUI belongs to can serve to give an overall idea of its category, and 3) the depth of the body triple CUIs within UMLS. For some source vocabularies, a hierarchy is present, allowing the computation of the concept’s distance to the root – assuming a concept further away from the root is more likely to be more fine-grained, this feature also investigates whether important triples are more likely to contain more specific CUIs (the shortest path to the root is taken if a concept appears in multiple hierarchies).

Semantics based features: 1) the relation used, 2) the title of the section the body triple appeared in – since the majority of articles in this collection have relatively rigid structure, this was restricted to the commonly prescribed sections such as introduction, background, methods etc, and is based on the hypothesis that a novel contribution of a work is likely to appear in the discussion and / or conclusion sections, and 3) the rank of the sentence the triple appeared in as ranked by TextRank (Mihalcea and Tarau, 2004). TextRank is a graph based algorithm, often used in summarization, which can be used to order the sentences in an article according to importance, and therefore we hypothesize that a sentence with a low TextRank (high importance) is more likely to yield an important triple.

After performing one hot encoding of the relation feature, this gives 129 features for the 55,745 triples in the dataset.

3.2.2 Architecture Selection

While the similarity value of a body-triple calculated as described in Section 3.1.2 can be predicted directly, initial experiments with regression showed that this is hard to do exactly. The problem was therefore framed as binary classification. In this case, a threshold is set on the similarity value and triples with a value above the threshold are used as positive, important, instances.

Deep learning model is chosen due to its ability to cope with feature dependencies. The model, implemented using Keras, was designed with fully connected (dense) layers of halving sizes with the final layer of size 1. ReLU was used for all layers except the last, where the sigmoid activation function was employed. The loss function was binary entropy and accuracy was used as the metric when classes weren’t extremely imbalanced, \( F_1 \) was used otherwise. A number of parameters were tuned: 1) the depth of the model (with halving sizes, thus depth one model has a single dense layer of size \( \text{int}(129/2) \), depth two model has two dense layers of sizes \( \text{int}(129/2) \), \( \text{int}(129/4) \), and so on), 2) the number of epochs, 3) dropout, and 4) whether class weights were used.

3.2.3 Experiments

As suggested above – by exploring the use of class weights within the model – the dataset is highly imbalanced with, as expected, the majority of triples
not appearing in the abstract. The following methods for addressing this bias were explored:

- Using class weights within the deep learning algorithm: this allows more emphasis to be given to the minority class.

- Under-sampling: randomly sampling the majority class such that the number of examples used in training corresponds to a pre-decided ratio. The minority and majority class can be made equal (1:1) but other ratios were explored, making the majority class more frequent but not overpowering.

While all the minority, important, class triples are included in the training set, this does not have to be the case for the majority class. As mentioned above, the triples to include in the minority class are selected by a threshold. However, this can lead to a triple with, say, similarity of 2.5 being included in important triples, while a triple with similarity of 2.499 appearing in the non important triples class. Such small difference may be detrimental to the performance of the machine learning algorithm and a buffer band of similarities between the two classes was also explored. I.e. two thresholds, \( t_1 \) and \( t_2 \) are set such that \( t_1 - t_2 > 0 \) and all triples with similarity \( \geq t_1 \) are assigned to the important class while triples with similarity \( \leq t_2 \) are deemed not important.

### 4 Results And Discussion

A 5-fold cross validation was performed, and each explored model was trained on (a possibly balance adjusted version of) the training portion giving rise to an accuracy or F-measure on the test portion. This allows an average to be computed and the best model to be determined. The results are presented in Table 1: the similarity value refers to the threshold from Section 3.1.2 used to determine which triples are considered important, the buffer band – when on – removes the cases close to the similarity value threshold from training as described in Section 3.2.3, and the majority column represents the percentage of the training dataset attributed to the majority class. The final columns present the hyperparameters of the best model for the specific combination and the average accuracy / F-measure.

With under-sampling, the accuracies for similarities \( \geq 2 \) were all within 2% of the best performance, supporting the hypothesis regarding frequent use of synonyms. To avoid a uniform assignment of the majority class, the F-measure metric (which rewards both precision and recall) is used in models without under-sampling. An F-measure of 1 represents perfect precision and recall, and the highest F-measure achieved is 0.975.

SHapley Additive exPlanations (SHAP) (Lundberg et al., 2018) uses ideas from game theory to explain feature contributions to machine learning decisions. Figure 1 depicts the feature contributions on a randomly selected sample of 100 triples for the best model without under-sampling. Each dot represents a single triple, with the intensity (blue \( \rightarrow \) pink) indicating whether the feature value was low or high. The horizontal position indicates whether the contribution caused the prediction to go up – towards being classified as an important triple – or down. The top three rows show expected results: that high values in the number of relations in the document, very frequently occurring CUIs or relations arising from sentences low in importance ranked by TextRank (giving a high rank) impact the prediction very negatively. Unsurprising positive contributors are: 1) the frequency of the triple in the document: a new contribution may be reiterated in the document, 2) the triple appearing in the conclusion: this often contains a summary of contributions, 3) the triple including the TREATS relation: the filtering ensures this is a new triple and being treatment specific, is likely the focus of the work, 4) the triple appearing in the intro-

Table 1: Performance of informative triple classifier
duction, where the novelties of the work are often highlighted. The contributions of a higher depth value is also, as expected, positive.

Contributions are also due to the CUIs’ UMLS source vocabulary (indicated by source_). In some cases, these categorize the CUI; for example, AOD (alcohol and other drug thesaurus) and PSY (psychological index terms) are not unexpected. Surprising may be the pair MSHNOR and MSHJPN, representing the Norwegian and Japanese translations of Medical Subject Headings, as they appear to have opposite effect. However, MSHJPN’s contribution is very limited, suggesting that its completeness may not match that of MSHNOR.

5 Conclusions And Future Work

We have demonstrated that a dataset of semantic triples created from full articles based on similarity between triples in the body of the text and triples in the abstract can be used to train a deep learning classifier to make predictions about a semantic triple’s importance. An analysis of feature contributions was also performed.

While a direct prediction of the similarity score appeared difficult with the quantity of data available, converting the similarity scores into categorical values may be trainable and would provide the basis of a ranking. Again with greater quantity of data, features based on medical subject headings of each CUI could be beneficial indicated by the success of the UMLS source vocabulary features.

The work undertaken was in the biomedical domain based on a tool tuned for biomedical domain grammatical relation extraction. Porting the approach to another domain, where subject-verb-object triples would need to be extracted using a generic grammatical relation extraction algorithm and some features would require re-engineering, would also form an interesting extension of the work.

Abstract

Modelling and understanding dialogues in a conversation depends on identifying the user intent from the given text. Unknown or new intent detection is a critical task, as in a realistic scenario a user intent may frequently change over time and divert even to an intent previously not encountered. This task of separating the unknown intent samples from known intents one is challenging as the unknown user intent can range from intents similar to the predefined intents to something completely different. Prior research on intent discovery often consider it as a classification task where an unknown intent can belong to a predefined set of known intent classes. In this paper we tackle the problem of detecting a completely unknown intent without any prior hints about the kind of classes belonging to unknown intents. We propose an effective post-processing method using multi-objective optimization to tune an existing neural network based intent classifier and make it capable of detecting unknown intents. We perform experiments using existing state-of-the-art intent classifiers and use our method on top of them for unknown intent detection. Our experiments across different domains and real-world datasets show that our method yields significant improvements compared with the state-of-the-art methods for unknown intent detection.

1 Introduction

Detecting whether an intent is unknown or new in a dialogue system has become an important task for improving customer satisfaction. Since user intent may frequently change over time in many realistic scenarios, unknown (new) intent detection has become a crucial problem in conversational artificial intelligence (CAI). This can ultimately help enhance system interaction with the customer. This task is challenging since there is no prior knowledge of the type or the exact numbers of unknown intents that would be encountered in the future.

We model unknown intent detection as an (m+1)-class classification task as suggested by (Shu et al., 2017; Lin and Xu, 2019; Zhang et al., 2020) and consider unknown classes as the (m+1)th class. We aim to identify the known intent samples accurately, while at the same time we focus on determining the unknown intent samples. This has to be done without any prior knowledge about the kind of unknown intents. In order to solve this problem, researchers have proposed deep neural networks like OpenMax (Bindale and Boult, 2016), which fits Weibull distribution to the outputs of the penultimate layer. Another system MSP (Hendrycks and Gimpel, 2016) calculates the softmax probability of known samples and discards the unknown samples with lower confidence. In our approach, we attempt to solve the problem of unknown intent detection with added constraints such as not having any prior knowledge of a finite set of intents.

The main contributions of this paper are:

1. We propose an efficient method for unknown intent detection that post-processes using multi-objective optimization (non-deterministic genetic algorithm-NSGA2) by optimising two objectives i.e. recall and precision in order to obtain the optimal thresholds for each intent class.

2. Our proposed weight fine-tuning approach is model-agnostic, i.e. it can be applied on top of any deep neural network model.

The rest of the paper is organized as follows. In Section 2, we present the literature survey of previous work done on this topic. In Section 3 we elaborate describe the proposed methodology. In Section 4, we discuss the experimental setup and the datasets used in our experiments. In Section
5. we analyse the results of detecting the unknown intents. Finally, Section 6 concludes the paper with future work that can be explored in this field.

2 Related Works

Intent detection is a much explored area in dialogue systems with a broad spectrum of literature available (Min et al., 2020; Qin et al., 2020; Zhang et al., 2018; Niu et al., 2019; Qin et al., 2019). Most of these works are based on closed world classification that does not consider any open intent. (Srivastava et al., 2018) proposed a zero-shot learning (ZSL) for intent detection. However, ZSL is different from our task as it only contains finite known set of classes during testing. (Kim and Kim, 2018) tried to optimise the intent classifier together with an out-of-domain detector, which was trained using out-of-domain samples. The generative method proposed by (Yu et al., 2017) used adversarial learning to generate positive and negative examples from known classes but the method did not work well in the discrete data space like text. (Ryu et al., 2018) proposed generative adversarial network (GAN) to train on the ID samples and use the discriminator to detect the out-of-domain samples. (Nalisnick et al., 2018; Mundt et al., 2019) showed that deep generative models fail to capture the high-level semantics on real world data. (Jain et al., 2014) fit the probability distributions to statistical Extreme Value Theory (EVT) using a Weibull-calibrated multi-class support vector machine (SVM) to detect the unnormalized posterior probability of inclusion for open set problems. ODIN (Liang et al., 2017) enlarged the differences between known and unknown samples by using temperature scaling and input pre-processing but all the above method need negative samples for selecting the decision boundary or probability threshold. DOC (Shu et al., 2017), instead of using Softmax as the final output layer, built a multi-class classifier with a 1-vs-rest final layer which contains a sigmoid function for each seen class to reduce the open space risk.

Zero-shot intent classification aims to generalize knowledge and concepts learned from the seen intents to recognize unseen intents. Early methods (Ferreira et al., 2015a,b) explored the relationship between seen and unseen intents by introducing external resources such as manually defined attributes or label ontologies, but they are usually expensive to obtain. To deal with this, some methods (Chen et al., 2016; Kumar et al., 2017) map the utterances and intent labels to an embedding space and then model their relations in the same space. IntentCapsNet-ZS (Xia et al., 2018) extends capsule networks (Sabour et al., 2017) for zero-shot intent classification by transferring the prediction vectors from seen classes to unseen classes. ReCapsNet (Liu et al., 2019) shows that IntentCapsNet-ZS hardly recognizes utterances from unseen intents in the generalized zero-shot classification scenario, and proposes to solve this issue by transferring the transformation matrices from the seen to unseen intents. These approaches also need unknown intent embedding for classifying these instances. Our work do not require the assumption of that classes belong to a closed word. We don’t need the unseen intent samples to get the deep learning classifier to detect unknown intents as well.

3 Methodology

We train two different deep learning model for intent classification and use our post-processing steps on top of these to obtain optimal results. The pipeline of the system processes is shown in Figure 1. We describe the models along with our novel post-processing steps in this section.

3.1 Models

3.1.1 Bi-LSTM

We train Bi-directional Long Short Term Memory (Bi-LSTM) to obtain the prediction scores and use these scores to obtain the optimal thresholds for each known intent class using different threshold tuning methods as discussed in 3.3. Given an utterance with maximum class-ID length l, we transform a sequence of input words \(w_{1:l}\) into m-dimensional word embedding \(v_{1:l}\), which is used by forward and backward LSTM to produce feature representations x:

\[
\begin{align*}
\bar{x}_{l} &= LST M(v_{l}, \bar{c}_{l-1}) \\
\bar{x}_{l} &= LST M(v_{l}, \bar{c}_{l-1}) \\
x &= [\bar{x}_{l} : \bar{x}_{l}]
\end{align*}
\]

where \(v_{l}\) denotes the word embedding of input at time step \(l\). \(\bar{x}_{l}\) and \(\bar{x}_{l}\) are the output vector of forward and backward LSTM, respectively. \(\bar{c}_{l}\) and \(\bar{c}_{l}\) are the cell state vectors of forward and backward LSTM, respectively. We concatenate the last output vector of forward LSTM \(\bar{x}_{l}\) and the first output vector of backward LSTM \(\bar{x}_{l}\) into x as the sentence...
representation. It captures high-level semantic concepts learned by the model. The representation $x$ is then fed to an $n$ neuron feed forward layer where $n$ is the number of known intent classes in the dataset. The $n$ dimensional representation obtained is converted to probability distribution by using a ‘Softmax’ function.

3.1.2 BERT

We fine tune the pre-trained Bi-directional Encoder Representation from Transformer (BERT) model to get the ‘softmax’ classification scores of the input samples. Given $i^{th}$ input sentence $s_i$ we append a $[CLS]$ token at the beginning of the sentence. We obtain the token embeddings of the sequence $[CLS, T1, \ldots, TN] \in \mathbb{R}^{(N+1)\times H}$ from the last hidden layer of BERT. Here the $[CLS]$ vector representation is used for text classification, $N$ is the sequence length and $H$ is the hidden layer size. We calculate the prediction scores by applying ‘Softmax’ function to the last layer output (logits($x_i$)) of the trained BERT model.

3.2 Pre-Training

After training the intent classification model, for each input we obtain the ‘Softmax’ scores w.r.t each class at the output layer. We need to set a thresholds for these scores, above which the input sample is classified to the respective class. Since we do not use have any separate class for unknown intent, we train our model on a subset of the classes in the dataset, holding out the rest to be classified as unknown during testing. In order to reflect the effectiveness of the learned optimal thresholds we use cross-entropy loss $L_s$ to train our both the base models.

$$L_s = -\frac{1}{N} \sum_{i=1}^{N} y_i \log(\hat{y}_i)$$

where $N$ is total number of training samples $y_i$ is true label and $\hat{y}_i$ is predicted label. Then, we use the pre-trained model to obtain the prediction scores of the input samples. These scores are used further for threshold tuning of each known intent class.

3.3 Finding Optimal Threshold for Each Known Intent Class

To obtain the prediction scores corresponding to each sample we pass the training data samples to the pre-trained classifiers. After getting the prediction scores we apply two different techniques to obtain the optimal threshold for each known intent class, viz. normal thresholding, and multi-objective optimization.

3.3.1 Normal Thresholding

In this method, first the input text containing the training data samples is fed to the deep learning classifier to get the prediction scores corresponding to each samples. These prediction scores ($PS$) and the list of thresholds ($T$) ranging from 0.1 to 0.9 increasing by 0.1 in each step is used to calculate the correct classification matrix ($CCM$) and the mis-classification matrix ($MCM$).

The set of prediction scores is a matrix of $N \times M$ where $N$ is the total number of training samples and $M$ is the number of known intent classes. This
set of prediction scores and the list of thresholds containing $K$ threshold values is used to calculate correct classification matrix ($CCM$) and the misclassification matrix ($MCM$).

Let $C(X)$ be the output class, $Y$ the ground truth class, and $\{,\}$ the enumeration function, the standard definition for correctly classified sample (or true positives) rate of an intent class $i$ is given in Equation 1:

$$\text{CC}_i = \frac{(C(X) = i \text{ AND } Y = i)}{Y = i} \quad (1)$$

We can also write the standard definition of misclassified sample rate (or false negatives) of an intent class $i$ as given by Equation 2:

$$\text{MC}_i = \frac{(C(X) \neq i \text{ AND } Y = i)}{Y = i} \quad (2)$$

The correct classification rate ($CC$) and misclassification (MC) rate of an intent $i$ can be extended by introducing the thresholds $\tau_i$ and by adding the unsure classification (UC) rate, for each intent as shown in Equation 3, 4 and 5.

$$\text{CC}_i(\tau_i) = \frac{(C(X) = i \text{ AND } S(X) > \tau_i) \text{ AND } (Y = i)}{Y = i} \quad (3)$$

$$\text{MC}_i(\tau_i) = \frac{(X) \neq i \text{ AND } S(X) > \tau_i) \text{ AND } (Y = i)}{Y = i} \quad (4)$$

$$\text{UC}_i(\tau_i) = \frac{((C(X) = i) \text{ or } (C(X) \neq i) \text{ AND } (S(X) < \tau_i) \text{ AND } (Y = i)}{Y = i} \quad (5)$$

For each intent we have:

$$\text{CC}_i(\tau) + \text{MC}_i(\tau) + \text{UC}_i(\tau) = 1$$

$CCM$ is a matrix of $K \times M$ dimension containing the correct classification rate of each intent class corresponding to each threshold in the threshold list i.e each entry $CC_{ij}$ is calculated using equation 6.

$$CC_{ij} = \frac{\sum_{i=1}^{N} (C(X) = i \text{ AND } S(X) > \tau_j) \text{ AND } (Y = i)}{Y = i} \quad (6)$$

$MCM$ is a matrix of $K \times M$ dimension containing the mis-classification rate of each intent class corresponding to each threshold in the threshold list i.e each entry $MC_{ij}$ is calculated using equation 7.

$$MC_{ij} = \frac{\sum_{i=1}^{N} (C(X) \neq i \text{ AND } S(X) > \tau_j) \text{ AND } (Y = i)}{Y = i} \quad (7)$$

After obtaining these two matrices, we obtain optimal $\tau_j$ for each known intent class by the following technique. We keep the best correct classification rate while reducing the mis-classification rate. For this, we use two steps. First, we determine the threshold(s) $\tau$ which maximizes $CC_i(\tau)$. Since several thresholds could reach this maximum, we obtain a set of threshold(s) $Seg_1$. Then, we selected the threshold with the lower $MC_i(\tau)$. This can be mathematically written as:

$$s = \argmax_{\tau} (CC_i(\tau))$$

$$\tau_i = \argmin_{\tau \in Seg_1} (MC_i(\tau))$$

3.3.2 Multi-Objective Optimization (NSGA2)

To get the optimal threshold we use Non-dominated Sorting Genetic Algorithm II (NSGA-II) which...
is a multi-objective genetic algorithm, proposed by (Deb et al., 2002). In the structure of NSGA-II, in addition to genetic operators, crossover and mutation, two specialized multi-objective operators and mechanisms are defined and utilized. These are as follows:

- **Non-Dominated Sorting**: The population is sorted and partitioned into fronts (F1, F2, etc.), where F1 (first front) indicates the approximated Pareto front.

- **Crowding Distance**: It is a mechanism of ranking among members of a front, which are dominating or dominated by each other.

We optimize for two objective (i). Correct classification rate \((CC)\), and (ii). Precision of the known intents. The NSGA2 takes threshold values of an intent as the input variable (values ranging from 0.1 to 0.99). It then uses prediction scores of samples from the pre-trained base model to perform optimization on the two objective functions, explained in details in Section 3.3.1 to get an optimal threshold for each known intent class. We initialize the population by randomly selecting the values from the range of the threshold variables and then we calculate the two objective values for each entry in the initial population.

Next we perform a non-dominated sorting in the combination of parent and offspring populations and classify them by fronts, i.e. these are sorted in an ascending level of non-domination. Next, we fill new population according to front ranking. If one front is taken partially, crowding-sort is performed. The less dense population are preferred. The offspring population (children) is then created from this new population using crowded tournament selection (It compares by front ranking, if equal then by crowding distance), crossover and mutation operators. The most important solutions (i.e. the best entries) of the population are kept in fronts.

We run the same procedure 1000 times to get a set of optimal thresholds for each known intent class. From this set of thresholds we choose the maximum threshold. This optimal threshold is used to decide upon known and unknown intent samples.

### 3.4 Testing

During testing, when a new sample (unseen class) is encountered it is first fed to the base model (BiLSTM or BERT) to get the corresponding prediction scores. After getting the prediction scores we compare each entries in the prediction scores with the corresponding optimal thresholds and if we find all the entries to be less than the corresponding optimal thresholds we classify that sample as unknown else we classify the sample to the one known intent class for which the prediction score is higher than the corresponding optimal threshold.

## 4 Datasets and Experiments

### 4.1 Dataset

We use three datasets to conduct our experiments. The detailed statistics of the datasets are shown in Table 1. Few example intents from each dataset are shown in Table 2.

#### 4.1.1 Banking

This dataset contains fine-grained intents in the banking domain (Casanueva et al., 2020). It contains 77 intents and 13,083 customer service queries.

#### 4.1.2 Bank-Catridge

This is a real-world banking domain chat dataset which contains manually updated samples, created through paraphrasing followed by manual verification. This dataset consists of 14 intents in total, consisting of almost 100 samples per intent.

#### 4.1.3 SNIPS-NLU

SNIPS-NLU is an English natural language corpus collected in a crowd-sourced fashion to benchmark the performance of voice assistants. It contains 7 intents and almost 2000 samples per intent.

### 4.2 Experimental Setups

We keep 25% of the overall intent classes in training and validation set as masked while keeping these masked intent samples in the test set as unmasked. To have a fair evaluation on the imbalanced dataset, we randomly select known classes by weighted random sampling without replacement in the training and validation sets. For BERT initialization, we use the weights of the ‘bert-base-uncased’ model containing 8-layers transformer units. We fine-tune the model on our training sets. We keep learning-rate to 5e-5, the training batch size is 64 and number of training epochs is set to 50. For Bi-LSTM, we set the output dimension as 128 upon which final linear layer is built (according to the number of classes in the dataset). The maximum number of epochs is set to 50 with early

5 Result and Analysis

We experiment with different variants of the proposed model as follows: (i). Bi-LSTM + normal-thresholding, (ii). Bi-LSTM + NSGA2 and (iii). BERT + normal-thresholding and (iv). BERT+NSGA2. We also re-implement the ADM model (Shu et al., 2017) and obtain the results on the datasets mentioned in Section 4. Table 4 shows the F1 score of detecting unknown intent class samples with 75% of total intent class being kept as known on Banking, Bank Catridge and SNIPS-NLU dataset. The best results are highlighted in bold. Comparing with the best score of baseline and different variants of our approach we can see that our final model BERT+NSGA2 gives better results than the baseline and the different variants of our proposed model. Comparing with ADB our approach yields 0.7% improvement on Banking dataset, 3% improvement on Bank catridge dataset, and 21% improvement on SNIPS dataset. It can be observed by the results that our BERT+NSGA2 based approach is able to learn tight thresholds to clearly distinguish between known and unknown intent samples. Using Normal thresholding technique where the objective functions are optimised sequentially does not work well as optimizing one objective function can counter the optimization of another objective. This problem is addressed by multi-objective optimization based technique which simultaneously satisfies all the objective functions, finds a set of optimal solutions instead of one optimal solution. Some examples that are correctly classified by the BERT+NSGA2 and not by BERT+NT are shown in Table 5. We can see that multi-objective optimization plays a vital role in predicting the unknown samples correctly as compared to normal optimization.

Some examples that are correctly classified by the BERT+NSGA2, but not by ADB are shown in Table 3. From the examples we observe that our BERT+NSGA2 gives importance to the words which are there in the unknown intent samples like “refund”, “visa”, “master_card” and “didn’t make” to make the decision between known and unknown intent class. On the other hand, Table 6 shows that there are some samples in the test data which can be miss-classified to one of the similar intent classes. For example the text “I transferred my funds, why did it not go through?” can be miss-classified to “declined_transfer” intent but it actually belongs...
What is the number of days I have to wait for my Europe transfer?
I need to find out why my transfer didn’t get there.
I have a pending cash withdrawal
I don’t find your services useful anymore, how do I delete my account?
Will it cost more money if my currency needs to be exchanged?

Abstract

In this paper, we aim at improving Czech sentiment with transformer-based models and their multilingual versions. More concretely, we study the task of polarity detection for the Czech language on three sentiment polarity datasets. We fine-tune and perform experiments with five multilingual and three monolingual models. We compare the monolingual and multilingual models’ performance, including comparison with the older approach based on recurrent neural networks. Furthermore, we test the multilingual models and their ability to transfer knowledge from English to Czech (and vice versa) with zero-shot cross-lingual classification. Our experiments show that the huge multilingual models can overcome the performance of the monolingual models. They are also able to detect polarity in another language without any training data, with performance not worse than 4.4% compared to state-of-the-art monolingual trained models. Moreover, we achieved new state-of-the-art results on all three datasets.

1 Introduction

In recent years, BERT-like models (Devlin et al., 2019) based on the Transformer architecture (Vaswani et al., 2017) and generalized language models brought a significant improvement in performance in almost any NLP task (Raffel et al., 2020a), especially in English. Despite this fact, not much work has been recently done in sentiment analysis for the Czech language with the latest Transformer models. We partly fill this gap by focusing on the Sentiment Classification task, also known as Polarity Detection.

Polarity detection is a classification task where the goal is to assign a sentiment polarity to a given text. The positive, negative and neutral classes are usually used as the polarity labels. The polarity can also be defined with a different number of labels, i.e., fine-grained sentiment analysis (Liu, 2012).

The models based on BERT were almost exclusively trained for English, limiting their usage to other languages. Recently, however, their cross-lingual adaptions like mBERT (Devlin et al., 2019), mT5 (Xue et al., 2020), XLM (Conneau and Lample, 2019) or XLM-R (Conneau et al., 2020) emerged along with other non-English monolingual versions, for example, Czech (Sido et al., 2021), French (Martin et al., 2020; Le et al., 2019), Arabic (Safaya et al., 2020), Romanian (Dumitrescu et al., 2020), Dutch (Vries et al., 2019) or Finnish (Virtanen et al., 2019).

Our motivation is to reveal the performance limits of the current SotA transformer-based models on the Czech polarity detection task, check the ability of the multilingual models to transfer knowledge between languages and unify the procedure and data that enable the correct future evaluation of this task.

In this paper, we focus on the task of polarity detection applied on Czech text by comparing the performance of seven pre-trained transformer-based models (both monolingual and multilingual) on three Czech datasets. We fine-tune each model on each dataset and we provide a comprehensive survey of their performance. Our experiments show the effectiveness of the Transformer models that significantly outperform the older approaches based on recurrent neural networks. We observe that the monolingual models can be notably outperformed by the multilingual models, but only by those with much more parameters. Moreover, we achieve new state-of-the-art results on all three evaluated datasets.

We are also interested in the ability of the multilingual models to transfer knowledge between languages and its usability for polarity detection. Thus, we perform zero-shot cross-lingual classification,
fine-tune four cross-lingual transformer-based models on the English dataset and then test the models on Czech data. We also perform the same experiment in the reverse direction, i.e., from Czech to English. The results reveal that the XLM-R-Large model (fine-tuned solely on English) can achieve very competitive results that are only about 4 % worse than the SotA model fine-tuned by us on Czech data. To the best of our knowledge, this is the first paper that performs zero-shot cross-lingual polarity detection for the Czech language.

We also noticed that the comparison with the previous works is rather problematic and thus, we provide a split for all Czech datasets that allows comparing future works much easier. Our code and pre-trained models are publicly available1.

Our main contributions are the following: 1) We provide the comprehensive performance comparison of the currently available transformer-based models for the Czech language on the polarity detection task along with the models’ optimal settings. 2) We test the ability of the multilingual models to transfer knowledge between Czech and English. 3) We release all the fine-tuned models and code freely for research purposes and we provide a data split that allows future comparison and evaluation. Furthermore, we achieved new state-of-the-art results for all three evaluated datasets.

2 Related Work

The previous approaches (Kim, 2014; Johnson and Zhang, 2016; Cliche, 2017; Baziotis et al., 2017; Gray et al., 2017; Conneau et al., 2017) for English polarity detection and other related tasks mainly relied on transfer learning and pre-trained word embeddings such as word2vec (Mikolov et al., 2013) and fastText (Bojanowski et al., 2017) in combinations with Convolutional Neural Networks (CNN) or Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), eventually in conjunction with the modified attention mechanism (Bahdanau et al., 2015; Rocktäschel et al., 2015; Raffel and Ellis, 2015). Furthermore, the new contextualized word representations such as CoVe (McCann et al., 2017) or ELMo (Peters et al., 2018) and pre-trained language model ULMFiT (Howard and Ruder, 2018) were successfully applied to the polarity detection. Finally, the latest transformer-based models like BERT (Devlin et al., 2019), GPT (Radford et al., 2018), RoBERTa (Liu et al., 2019) or T5 (Raffel et al., 2020b) that are all in general trained on language modeling tasks proved their performance superiority for English over all previous approaches, for example in (Sun et al., 2019). These models are pre-trained on a modified language modeling tasks with a huge amount of unlabeled data. In the end, they are fine-tuned for a specific downstream task.

The initial works on Czech polarity detection and sentiment analysis usually used lexical features (Steinberger et al., 2011; Veselovská et al., 2012) or Bag-of-Words text representations along with the Naive Bayes or logistic regression classifiers (Habernal et al., 2013) or a combination of supervised and unsupervised approach (Brychcin and Habernal, 2013). Lenc and Hercig (2016) applied CNN using the architecture from (Kim, 2014) and the LSTM neural network to all three datasets that we use in this paper. Another usage of LSTM neural network with the self-attention mechanism (Humphreys and Sui, 2016) can be found in (Libovický et al., 2018). Similarly, Sido and Konopič (2019) tried to use curriculum learning with CNN and LSTM.

Lehečka et al. (2020) pre-trained a BERT-based model for polarity detection with an improved pooling layer and distillation of knowledge technique. The most recent application of the Transformer model is in (Sido et al., 2021). The authors created a BERT model for Czech and, as one of the evaluation tasks, they performed polarity detection on the FB and CSFD datasets.

To the best of our knowledge, there are no previous works that focus on the zero-shot cross-lingual polarity detection task in the Czech language. The recent related work can be found in (Eriguchi et al., 2018), where the authors use the neural machine translation encoder-based model and English data to perform zero-shot cross-lingual sentiment classification on French. In (Eriguchi et al., 2018) the authors performed the zero-shot classification from Slovene to Croatian. Another related work can be found in (Wang and Banko, 2021; Qin et al., 2020).

3 Data

To the best of our knowledge, there are three Czech publicly available datasets for the polarity detection task: (1) movie review dataset (CSFD), (2) Facebook dataset (FB) and (3) product review dataset (Mallcz), all of them come from (Habernal et al.,

---

1https://github.com/pauli31/improving-czech-sentiment-transformers
and each text sample is annotated with one of three labels, i.e., positive, neutral and negative, see Table 1 for the class distribution. For the cross-lingual experiments we use the two-class English movie review dataset (IMDB) (Maas et al., 2011).

</table>

The FB dataset contains 10k random posts from nine different Facebook pages that were manually annotated by two annotators. The CSFD dataset is created from 90k Czech movie reviews from the Czech movie database\(^2\) that were downloaded and annotated according to their star rating (0–2 stars as negative, 3–4 stars as neutral, 5–6 stars as positive). The Mallcz dataset consists of 145k users’ reviews of products from Czech e-shop\(^3\), the labels are assigned according to the review star rating on the scale 0-5, where the reviews with 0-3 stars are labeled as negative, 4 stars as neutral and 5 stars as positive. The English IMDB dataset includes 50k movie reviews scraped from the Internet Movie Database\(^4\) with positive and negative classes split into training and testing parts of equal size.

Since there is no official partitioning for the Czech datasets, we split them into training, development and testing parts with the same class distribution for each part as it is in the original dataset, see Table 1. For the Mallcz and CSFD datasets, we use the following ratio: 80% for training data, 20% for testing data, for the FB dataset, it is 70% and 30%, respectively and 10% from the training data (for all datasets) is used as the development data. We used different split ratio for the FB dataset because it is approximately ten and sixteen times smaller than the CSFD and Mallcz datasets, respectively and we did not want to reduce the size of the testing data too much.

### 4 Models Description

We performed exhaustive experiments with transformed-based models and in order to compare them with the previous works, we also implemented the older models (baseline models) that include the logistic regression classifier and the BiLSTM neural network.

#### 4.1 Baseline Models

We re-implemented the best models from (Habernal et al., 2013), i.e., logistic regression classifier (lrc) with character n-grams (in a range from 3-grams to 6-grams), word uni-grams and bi-grams features. The second baseline model is the LSTM model partly inspired by (Baziotis et al., 2017). Its input is a sequence of \(t\) tokens represented as a matrix \(M \in \mathbb{R}^{t \times d}\), where \(d = 300\) is a dimension of the Czech pre-trained fastText word embeddings (Bojanowski et al., 2017)\(^5\). The maximal size of the input vocabulary is set to 300 000. The input is passed into the trainable embedding layer that is followed by two BiLSTM (Graves and Schmidhuber, 2005) layers and after each, the dropout (Srivastava et al., 2014) is applied. After the two BiLSTM layers, the self-attention mechanism is applied. The output is then passed to a fully-connected softmax layer. An output of the softmax layer is a probability distribution over the possible classes. We use the Adam (Kingma and Ba, 2014) optimizer with default parameters \((\beta_1 = 0.9, \beta_2 = 0.999)\) and with weight decay modification (Loshchilov and Hutter, 2017) and the cross-entropy loss function. We replace numbers, emails and links with generic tokens, we tokenize input text with the TokTok tokenizer\(^6\) and we use a customized stemmer\(^7\).

We use different hyper-parameters for each dataset, see Appendix A.1 for the complete settings.

---

\(^2\)The FB dataset also contains 248 samples with a fourth class called bipolar, but we ignore this one.

### 4.2 Transformer Models

In total, we use eight different transformer-based models (five of them are multilingual). All of them are based on the original BERT model. They use only the encoder part of the original Transformer (Vaswani et al., 2017), although their pre-training procedure may differ. There are also text-to-text models like T5 (Raffel et al., 2020b) and BART (Lewis et al., 2019) and their multilingual versions mT5 (Xue et al., 2020) and mBART (Liu et al., 2020; Tang et al., 2020). The main difference from BERT-like models is that they use the full encoder-decoder architecture of the Transformer. They are mainly intended for text generation tasks (e.g., abstractive summarization). We decided to use only the BERT-like models with the same architecture because they fit more for the classification task.

All the models are pre-trained on a modified language modeling task, for example, Masked Language Modeling (MLM) and eventually on some classification task like Next Sentence Prediction (NSP) or Sentence Ordering Prediction (SOP), see (Devlin et al., 2019; Lan et al., 2020) for details. The evaluated models differ in the number of parameters (see Table 2) and thus, their performance is also very different, see Section 5.

Table 2: Models statistics with a number of parameters, vocabulary size and a number of supported languages.

**Czert-B** is the Czech version of the of the original BERTBASE model (Devlin et al., 2019). The only difference is that during the pre-training, the authors increased the batch size to 2048 and they slightly modified the NSP prediction task (Sido et al., 2021).

**Czert-A** is the Czech version of the ALBERT model (Lan et al., 2020), also with the same modification as Czert-B, i.e., batch size was set to 2048 and the modified NSP prediction task is used instead of the SOP task (Sido et al., 2021).

**RandomALBERT** we follow the evaluation in (Sido et al., 2021) and we also test randomly initialized ALBERT model without any pre-training to show the importance of pre-training of such models and its performance influence on the polarity detection task.

**mBERT** (Devlin et al., 2019) is a multilingual version of the original BERTBASE, jointly trained on 104 languages.

**SlavicBERT** (Arkhipov et al., 2019) is initialized from the mBERT checkpoint and further pre-trained with a modified vocabulary only for four Slavic languages (Bulgarian, Czech, Polish and Russian).

**XLM** (Conneau and Lample, 2019) utilizes the training procedure of the original BERT model for multilingual settings mainly by using the Byte-Pair Encoding (BPE) and increasing the shared vocabulary between languages.

**XLM-R-Base** (Conneau et al., 2020) is a multilingual version of the RoBERTas (Liu et al., 2019) specifically optimized and pre-trained for 100 languages.

**XLM-R-Large** (Conneau et al., 2020) is the same model as the XLM-R-Base, but it is larger (it has more parameters).

### 4.3 Transformers Fine-Tuning

To utilize the models for text classification, we follow the default approaches mentioned in the corresponding models’ papers and we fine-tune all parameters of the models. In all models except XLM, we use the final hidden vector \( \mathbf{h} \in \mathbb{R}^H \) of the special classification token \([CLS]\) or \(<s>\) taken from the pooling layer\(^9\) of BERT or RoBERTa models, respectively. The vector \( \mathbf{h} \) represents the entire encoded sequence input, where \( H \) is the hidden size of the corresponding model. We add a task-specific linear layer (with a dropout set to 0.1) represented by a matrix \( \mathbf{W} \in \mathbb{R}^{C \times H} \), where \( C \) is a set of classes. We compute the classification output, i.e., the input sample being classified as class \( c \in C \) as \( c = \arg \max (\mathbf{hW}^T) \).

In the case of the XLM model, we take the last hidden state (without any pooling layer) of the first input token and we apply the same linear layer \( \mathbf{W} \) and approach to obtain the classification output. For learning, we use the Adam optimizer with default parameters and with weight decay (same as for the \textsc{LSTM} model), and the cross-
entropy loss function. See Section 5.1 and Appendix A.2 for the hyper-parameters we used.

5 Experiments & Results

We perform two types of experiments, i.e., monolingual and cross-lingual. In monolingual experiments, we fine-tune and evaluate the Transformer models for each dataset separately on three-class (positive, negative, and neutral) and two-class (positive and negative) sentiment analysis. We also implemented the logistic regression (lrc) and LSTM baseline models and we compare the results with the existing works.

In cross-lingual experiments, we test the ability of four multilingual transformer-based models to transfer knowledge between English and Czech. We run the multilingual models only on the two-class datasets (positive and negative). We fine-tune either on English (IMDB) or Czech (CSFD), and then we evaluate on the other language. Thus we perform the zero-shot cross-lingual classification. We decided to use the IMDB and CSFD dataset because they are from the same domain i.e., movie reviews.

Each experiment\(^\text{10}\) was performed at least five times and we report the results using the macro \(F_1\) score.

5.1 Monolingual Experiments

The goal of the monolingual experiments is to reveal the current state-of-the-art performance on the Czech polarity datasets, namely CSFD, FB and Malicz (see Section 3) and provide a comparison between the available models and their settings.

As we already mentioned, we split the datasets into training, development and testing parts. There is no official split for the datasets and we found out that all the available works usually use either 10-fold cross-validation or they split\(^\text{11}\) the datasets on their own, the † and * symbols in Table 3, respectively causing the comparison to be difficult.

We fine-tune all models on training data and we measure the results on the development data. We select the model with the best performance on the development data and we fine-tune the model on combined training and development data. We report the results in Table 3 on the testing data with 95% confidence intervals.

Firstly, we re-implemented the logistic regression classifier (lrc) with the best feature combination from (Habernal et al., 2013) and we report the results on our data split. We can see that we obtained very similar results to the ones stated in (Habernal et al., 2013). We also tried to improve this baseline with TF-idf weighting, but it did not lead to any significant improvements, so we decided to keep the settings the same as in (Habernal et al., 2013), so the results are comparable.

For the LSTM model, we tried different combinations of hyper-parameters (learning rate, optimizer, dropout, etc.). We report the used hyper-parameters for the results from Table 3 in Appendix A.2. Our implementation is only about 1 % worse than LSTM with the self-attention model from (Libovický et al., 2018), but they used a different data split. For the Mallcz dataset, we were not able to outperform the lrc baseline with the LSTM model.

We fine-tune all parameters of the seven pre-trained BERT-based models and one randomly initialized ALBERT model. In our experiments, we use constant learning rate and also linear learning rate decay (without learning rate warm-up) with the following initial learning rates: 2e-6, 2e-5 and 2.5e-5. We got inspired by the ones used in (Sun et al., 2019). Based on the average number of tokens for each dataset and models’ tokenizer (see Table 4 and Figures 1, 2, 3)\(^\text{12}\), we use a max sequence length of 64 and a batch size of 32 for the FB dataset. We restrict the max sequence length for the CSFD and Mallcz datasets to 512 and use a batch size of 32. All other hyper-parameters of the models are set to the pre-trained models’ defaults. See Table 7 in Appendix A.2 for the reported results’ hyper-parameters.

We repeated all the basic experiments with the polarity detection task from (Sido et al., 2021) with the new data split. Our results do not significantly differ, as shown in Table 8 and in Appendix A.2. If we compare the BERT model from (Lehečka et al., 2020) with the Czert-B, mBERT and SlavicBERT models\(^\text{13}\), we can see that on the binary task, they also perform very similarly, i.e., around 93 %, but again they used different test data (the entire CSFD dataset\(^\text{14}\)). The obvious observation is that the XLM-R-Large model is supe-

---

\(^{10}\) Except for the experiments with the lrc model.

\(^{11}\) The authors do not provide any recipe to reproduce the results.

\(^{12}\) The distributions of the other models were similar to those shown in the mentioned Figures.

\(^{13}\) All of them should have the same or almost the same architecture and a similar number of parameters.

5.2 Cross-lingual Experiments

The cross-lingual experiments were performed with the multilingual models that support English and Czech. For these experiments, we use linear learning rate decay with an initial learning rate of $2e^{-6}$.

Firstly, we fine-tuned the models on the English IMDB dataset and we evaluated them on the test part of the Czech binary CSFD dataset (i.e., zero-shot cross-lingual classification). We randomly selected 5k examples from the IMDB dataset as the development data. The rest of the 45k examples was used as training data. We select the models that perform best on the English development data\footnote{The model was trained for a maximum of 15 epochs and it would probably get better with a higher number of epochs, but the other models were trained for the same or lower number of epochs.} and we report the results in Table 5. The $\text{dev (en)}$ column refers to results obtained on the CSFD testing part. For easier comparison, we also include the Monoling. (cs) column that contains the results (same as in Table 3) for models trained on Czech data. The XLM-R-Large was able to achieve results only about 4.4% worse than the same model that was fine-tuned on Czech data. It is a great result if we consider that the model has never seen any labeled Czech data. The XLM and mBERT models perform much worse.

Table 5: Macro $F_1$ score for cross-lingual experiments from English to Czech.
the current state-of-the-art works (Thongtan and Phienthrakul, 2019; Sun et al., 2019) use this metric. Similarly to the previous case, we selected the model that performs best on Czech CSFD development data. For these experiments, the mBERT did not converge. As in the previous experiment, the XLM-R-Large performs best and it achieves almost 94% accuracy that is only 3.4% below the current SotA result from (Thongtan and Phienthrakul, 2019).

<tr>
<td>XLM</td>
<td>93.66 ± 0.13</td>
</tr>
</tbody>
</table>

Table 6: Accuracy results for cross-lingual experiments from Czech to English.

Based on the results, we can conclude that the XLM-R-Large model is very capable of transferring knowledge between English and Czech (and probably between other languages as well). It is also important to note that Czech and English are languages from a different language family with a high number of differences both in syntax and grammar.

5.3 Discussion & Remarks

We can see from the results that the recent pre-trained transformer-based models beat the older approaches (lrc and LSTM) by a large margin. The monolingual Czert-B model is in general outperformed only by the XLM-R-Large and XLM-R-Base models, but these models have five times/three times more parameters, and eight times larger vocabulary. Taking into account these facts, the Czert-B model is still very competitive. It may be beneficial in certain situations to use a smaller model like this that does not need such computational resources as the ones that are required by the XLM-R-Large.

During the fine-tuning, we observed that in most cases, the lower learning rate 2e-6 (see Table 7 in Appendix A.2) leads to better results. Thus we recommend using the same one or similar order. The higher learning rates tend to provide worse results and the model does not converge.

According to the generally higher confidence interval, the fine-tuning of a smaller dataset like FB that has only about 6k training examples is, in general, less stable and more prone to overfitting than training a model on datasets with tens of thousands of examples. We also noticed that fine-tuning of the mBERT and SlavicBERT on the Mallcz dataset is very unstable (see the confidence interval in Table 3). Unfortunately, we did not find out the reason. A more detailed error analysis could reveal the reason.

6 Conclusion

In this work, we evaluated the performance of available transformer-based models for the Czech language on the task of polarity detection. We compared the performance of the monolingual and multilingual models and we showed that the large XLM-R-Large model can outperform the monolingual Czert-B model. The older approach based on recurrent neural networks is surpassed by a very large margin by the Transformers. Moreover, we achieved new state-of-the-art results on all three Czech polarity detection datasets.

We performed zero-shot cross-lingual polarity detection from English to Czech (and vice versa) with four multilingual models. We showed that the XLM-R-Large is able to detect polarity in another language without any labeled data. The model performs no worse than 4.4% in comparison to our new state-of-the-art monolingual model. To the best of our knowledge, this is the first work that aims at cross-lingual polarity detection in Czech. Our code and pre-trained models are publicly available.

In the future work, we intend to perform a deep error analysis to find in which cases the current models fail and compare approaches that use the linear cross-lingual transformations (Artetxe et al., 2018; Brychcin, 2020) that explicitly map semantic spaces into one shared space. The second step in the cross-lingual settings is to employ more than two languages and utilize the models for different domains.

Acknowledgments

This work has been partly supported by ERDF "Research and Development of Intelligent Components of Advanced Technologies for the Pilsen Metropolitan Area (InteCom)" (no.: CZ.02.1.01/0.0/0.0/17 048/0007267); and by Grant No. SGS-2019-018 Processing of heterogeneous data and its specialized applications. Computational resources were supplied by the project "e-Infrastruktura CZ" (e-
INFRA LM2018140) provided within the program Projects of Large Research, Development and Innovations Infrastructures.

References

A Appendix

A.1 LSTM Hyper-parameters
We use cross-entropy as the loss function and the Adam (Kingma and Ba, 2014) optimizer with default parameters ($\beta_1 = 0.9$, $\beta_2 = 0.999$) and with a modification from (Loshchilov and Hutter, 2017) for the FB dataset. The embedding layer is trainable with a maximum size of 300k. The max sequence length for the input $t$ tokens is 64 for the FB dataset and 512 for the CSFD and Mallcz dataset with weight decay in the optimizer set to 0. We use Czech pre-trained fastText (Bojanowski et al., 2017) embeddings\textsuperscript{17}. For the Mallcz and CSFD datasets, we use 128 units in the BiLSTM layers and a batch size of 128. For the FB dataset, we use 256 units in the BiLSTM layers and a batch size of 256 with weight decay in the optimizer set to 1e-4.

For all datasets, we use 10% of total steps (batch updates) to warm up the learning rate, which means that during the training, the linear rate is firstly linearly increasing to the initial learning rate before being decayed with the corresponding learning rate scheduler. The dropout after the BiLSTM layers is set to 0.2. We use cosine (the * symbol in Table 7) and the exponential learning rate scheduler (the ‡ symbol in Table 7) with a decay rate set to 0.05. Table 7 contains the initial learning rate and the number of epochs for the LSTM model for each dataset.

A.2 Transformer Hyper-parameters
For fine-tuning of the transformer-based models, we use the same modification (Loshchilov and Hutter, 2017) of the Adam (Kingma and Ba, 2014) optimizer with default weight decay set to 1e-2. We use different learning rates and a number of epochs for each combination of the models and datasets, see Table 7. We use either constant linear rate or linear learning rate decay without learning rate warm-up. We use default values of all other hyper-parameters.

For the cross-lingual experiments, we use only the linear learning rate decay scheduler with the initial learning rate set to 2e-6 without learning rate warm-up. For the cross-lingual experiments from English to Czech, the numbers of epochs used for the fine-tuning are 25, 5 and 9 for the XLM-R-Base, XLM-R-Large and XLM models\textsuperscript{18}, respectively.

A.3 Computational Cluster
For fine-tuning of the Transformers models we use the Czech national cluster Metacentrum\textsuperscript{19}. We use two NVIDIA A100 GPUs each with 40GB memory.

\textsuperscript{17}Available at https://fasttext.cc/docs/en/crawl-vectors.html

Abstract

Document alignment techniques based on multilingual sentence representations have recently shown state of the art results. However, these techniques rely on unsupervised distance measurement techniques, which cannot be fine-tuned to the task at hand. In this paper, instead of these unsupervised distance measurement techniques, we employ Metric Learning to derive task-specific distance measurements. These measurements are supervised, meaning that the distance measurement metric is trained using a parallel dataset. Using a dataset belonging to English, Sinhala, and Tamil, which belong to three different language families, we show that these task-specific supervised distance learning metrics outperform their unsupervised counterparts, for document alignment.

1 Introduction

Document alignment is an important precursor to build parallel corpora from noisy data sources. Document alignment is also useful in multilingual Information Retrieval, as well as for tasks such as false news detection across different languages. Traditionally, document alignment has been achieved by metadata-based methods (Resnik, 1998, 1999) and translation based methods (Uszkoreit et al., 2010; Dara and Lin, 2016). Metadata-based methods rely on exploiting the meta information of the selected data sources, which may be inconsistent across different sources. On the other hand, translation based methods assume the availability of a Machine Translation (MT) system.

To overcome these issues, recent research has exploited the use of multilingual sentence representations (multilingual sentence embeddings) such as LASER (Artetxe and Schwenk, 2019)\(^1\). Here, vector representations are derived for documents in both source and target languages. Then, for a given document in the source side, the most similar counterpart is identified from the target side. Euclidean distance and cosine distance are used in existing document alignment systems (Uszkoreit et al., 2010; El-Kishky and Guzmán, 2020). However, these similarity metrics cannot be fine-tuned for the selected task or data at hand. The alternative is to use Metric Learning, which focuses on constructing a problem-specific distance metric automatically from data (de Vazelhes et al., 2019). Metric Learning-based distance measurement techniques have been successfully employed in image classification and image identification tasks (Pacchiardi et al., 2021). In this paper, we apply two such Metric Learning algorithms on multilingual sentence representations to identify similar document pairs in a bilingual setting. We experimented with Sparse High-Dimensional Metric Learning (SDML) (Qi et al., 2009), and Information Theoretic Metric Learning (ITML) (Davis et al., 2007) algorithms. To the best of our knowledge, this is the first work to exploit the use of Metric Learning with respect to multilingual sentence representations for the purpose of document alignment.

El-Kishky and Guzmán (2020)’s system was used as the baseline. This research can be considered as the best in this line of research at the moment. They used sentence embeddings using the LASER toolkit. They used Euclidean similarity as the sentence similarity measurement. Weighted sentence similarity scores were aggregated to derive the document similarity. In this work, we replaced Euclidean distance measurement with Metric Learning based distance measurement. We used a dataset that contains documents crawled from news websites belonging to three languages Sinhala (Si), Tamil (Ta), and English (En), which belong to three different language families (Indo-Aryan, Dravidian, and Indo-European, respectively) (Sachintha et al., 2021). that Sinhala is a low-resource language. In the recent language categorization by Joshi et al. (2020), Sinhala belongs to class 0, meaning that it has exceptionally limited resources. Tamil is considered as a medium-resourced language. It is categorised as 3, meaning that it has a strong web presence, and a cultural community that backs it. We separately report results for the three language pairs, En-Si, En-Ta and Si-Ta. For all the document alignment tasks except one news dataset in En-Si, Metric Learning based distance measurement performed better than the unsupervised distance measurement techniques. To train the Metric Learning models, a very small parallel corpus of 5000 words were used. Further experiments showed that the content (i.e. the domain) in the parallel corpus has minimal impact on the performance of Metric Learning models. The above results were obtained using LASER embeddings, to be a fair comparison with El-Kishky and Guzmán (2020). We experimented with XLM-R multilingual embeddings (Conneau et al., 2020) as well, using the ITML Metric Learning model. Since XML-R showed superior performance over LASER, we conducted extensive experiments where the ITML model was built using different amounts of parallel data with respect to XLM-R. Our results show that the ITML model trained with XLM-R embeddings works equally well even with 1000 parallel sentences. Our code is publicly released.

## 2 Related Work

### 2.1 Early Document Alignment Systems

Early work on document alignment mainly relied on metadata based (Resnik, 1998, 1999) and translation based approaches (Dara and Lin, 2016). Even though most metadata based systems are language independent, these methods tend to have lower results due to the inconsistency of these metadata across different data sources. Translation based approaches outperformed metadata based systems since they depend on the textual context of the documents (Vos, 2004). However the accuracy of these highly depends on the used MT system.

### 2.2 Multilingual Embedding Based Document Alignment Systems

Guo et al. (2019) extended the Hierarchical Attention Networks (HAN) architecture (Yang et al., 2016) for parallel document mining. They compared performance of the HAN architecture for document alignment with a neural Bag of Words (BoW) document embedding model, where document embeddings were generated by simply averaging multilingual sentence embeddings. El-Kishky and Guzmán (2020) proposed a method that uses the LASER toolkit to create the multilingual sentence embeddings. They calculated the distance between each pair of sentence representations of the source and target documents, and took the sum of the calculated distances for sentence pairs with a weighting value to calculate the distance between two documents. Euclidean distance was used as the distance metric for calculating the distance between sentence embeddings. Greedy movers distance algorithm (El-Kishky and Guzmán, 2020), which is an improved version of the Earth Movers Distance algorithm (Rubner et al., 1998), was used to take the sum of distance between sentences. They have used multiple sentence weighting schemes such as sentence length, inverse document frequency (IDF) and sentence length combined with IDF (SLIDF) to improve the results further. However, their dataset is not publicly available.

### 2.3 Multilingual Contextual Embedding Models

The LASER model consists of a single encoder implemented using a biLSTM (bi-Long Short Term Memory) network, which can handle multiple languages. This guarantees that sentences that are semantically similar lie closer in the embedding space. This encoder is coupled with an auxiliary decoder, and is pre-trained on 93 languages (using parallel corpora). Sentence embeddings are obtained by applying a max-pooling operation over the output of the encoder and used to initialize the decoder LSTM through a linear transformation. The encoder and decoder are shared by all the languages and for that, a joint byte-pair encoding (BPE) vocabulary made on the concatenation of all training corpora was used. The XLM-R model is based on a Transformer model (Vaswani et al., 2017). It has an encoder

3. Multilingual Embedding Based Document Alignment Systems
4. Multilingual Contextual Embedding Models
5. Multilingual Contextual Embedding Models
trained only with a masked language model objective. In essence, XLM-R is the multilingual version of RoBERTa (Liu et al., 2019). RoBERTa improves on the popular BERT model (Devlin et al., 2019) with more data, larger batch sizes, longer training times, training on longer sequences and dynamically changing the masking pattern applied to the training data. XLM-R is trained with common crawl data from 100 languages, and has shown to outperform mBERT on multiple Natural Language Processing tasks.

3 Metric Learning

Unsupervised metrics such as Euclidean or cosine are commonly used to calculate the distance between two embeddings or vectors. This is the same for sentence embeddings. However, these unsupervised metrics cannot be optimised for the particular data set or the task. In contrast, Metric Learning uses a supervised algorithm to learn the best distance measurement metrics that are task specific, using the given data. Metric Learning has been successfully used for tasks such as pattern recognition and face identification in the field of image classification (Pacchiardi et al., 2021; Wright et al., 2010; Xiang et al., 2008). All the Metric Learning algorithms use Mahalanobis distance as the distance metric. Mahalanobis distance between two points \( x, x' \) is defined as in Equation 1,

\[
D_L(x, x') = \sqrt{(Lx - Lx')^T(Lx - Lx')} 
\]  

This can also be written as shown in Equation 2,

\[
D_L(x, x') = \sqrt{(x - x')^TMM(x - x')} 
\]

where \( M = L^TL \). The Metric Learning algorithms calculate the matrix L according to the given training data set.

Commonly used Metric Learning algorithms include: Neighborhood Components Analysis (NCA) (Goldberger et al., 2005), Large Margin Nearest Neighbors (LMNN) (Weinberger et al., 2005), Sparse High-Dimensional Metric Learning (SDML) (Qi et al., 2009), and Information Theoretic Metric Learning (ITML) (Davis et al., 2007). ITML algorithm is able to learn a distance function that generalizes well to unseen test data and is also fast and scalable. Davis et al. (2007) used LogDet divergence for regularization of Mahalanobis distance learning methods. This regularization aims at keeping the learned distance close to the Euclidean distance. It has been shown that ITML converges to a global optimal solution. SDML algorithm aims on training an accurate distance metric for high dimensional data from a small sample. In addition to the LogDet Divergence regularization introduced by Davis et al. (2007), L1-regularization on the off diagonal elements of the matrix was used to reduce the chance of over fitting.

4 Methodology

4.1 Baseline Document Alignment System

The document alignment system proposed by El-Kishky and Guzmán (2020) was used as the baseline, which was discussed in Section 2. In this method, first the sentence representations are derived from a multilingual contextual embedding model. The algorithm first calculates the Euclidean distance between each sentence pair from source to target. The calculated weight of the sentence is used as the weights (aka mass) when calculating the Greedy Movers Distance between document pairs. Then the minimum value of the weights is selected as the flow value. Then the distance of the sentence pair is updated by adding the multiplication of flow value and the subtraction of two weight values (\( |s_A - s_B| \)) as shown in Equation 3.

\[
distance = distance + ||s_A - s_B|| \times flow 
\]

In this method, each document is represented as a normalized bag of sentences. Instead of assigning equal weights to each sentence, they have used three weighting schemes for sentences: (1) sentence length (SL) weighting, (2) Inverse Document Frequency (IDF) weighting and (3) sentence length and IDF (SLIDF) weighting.

4.1.1 Sentence Length Weighting

It is common to have a great variance in the length of the sentences in a given document. Longer sentences tend to contain more content than the shorter ones. Therefore, longer sentences should have more weight when aligning documents. Sentence Length (SL) weighting scheme uses the sentence length for consideration when calculating the weights.

In the SL weighting scheme, each sentence is weighted using the ratio between the number of tokens into the length of the sentence and the sum of number of tokens into the length of the sentence for each sentence. For the \( i^{th} \) sentence in document...
A, weight $d_{A,i}$ is calculated using the equation 4.

$$d_{A,i} = \frac{\text{count}(i) \times |i|}{\sum_{s \subseteq A} \text{count}(s) \times |s|} \quad (4)$$

where $|i|$, $|s|$ - Number of tokens in sentence $i$ and $s$ respectively.

### 4.1.2 IDF Weighting

The IDF weighting scheme is a common weighting scheme in Information Retrieval. If some content is occurring a number of times in every document, that content could be less semantically informative. This could be the titles, and other website specific text. Using this fact, these sentences should get a less weight than other sentences. IDF Weighting scheme is calculated using the equation 5,

$$d_{A,i} = 1 + \log \frac{N + 1}{1 + |d \subseteq D : s \subseteq d|} \quad (5)$$

where $N$ - Total number of documents and $|d \subseteq D : s \subseteq d|$ - Number of documents in which sentence $s$ occurs.

### 4.2 Supervised Distance Metric

As our main contribution, we used supervised distance metrics calculated using Metric Learning algorithms instead of using unsupervised metric used by El-Kishky and Guzmán (2020).

We used both Sparse High-Dimensional Metric Learning (SDML) (Qi et al., 2009) and Information Theoretic Metric Learning (ITML) algorithms (Davis et al., 2007; de Vazelhes et al., 2019) for our experiments. To provide a supervised signal to the Metric Learning algorithms, a parallel corpus was used. The sentences in the parallel corpus were converted to embedding pairs. The Metric Learning models were trained using these embeddings. Once the model is trained, it is able to provide the distance value between new sentence embedding pairs. We replaced the unsupervised sentence distance calculation method used in the baseline with these trained supervised distance metrics to calculate the distance between documents.

### 4.3 Date-wise filtering

In most of the cases, an article corresponding to a news is published in all languages within the same day. Therefore, using this property of news websites, we reduced the search space to a date from the whole web domain. Then the news items from a particular day were selected and aligned.

5 Data Set

We used the dataset presented by Sachintha et al. (2021). This dataset contains news articles belonging to four news websites published in English, Tamil and Sinhala languages. From each of the websites, around 2000 documents (per language) were selected based on the published date of the articles. Table 1 shows the statistics of the dataset used for document alignment. They have identified different characteristics in these articles and have used those to filter out the ground truth alignment. In addition, they have manually aligned the dataset with the help of human annotators. The aligned dataset was verified by the same annotators by switching the data sets.

5000 sentence pairs from the parallel corpora published by Fernando et al. (2020) were used to train the Metric Learning models. This parallel dataset is specific to the parallel data has any impact on Metric Learning, a 5000 subset from the Open Subtitle Parallel Corpus (Lison and Tiedemann, 2016) was used for En-Si. This corpus consists of translations of movie subtitles.

6 Experiments

For our experiments we used the python implementation of the two metric learning algorithms (de Vazelhes et al., 2019).

The first experiment was to determine whether Metric Learning based distance measurement could outperform the unsupervised counterpart. To be a fair comparison, we used the LASER embedding model as used by El-Kishky and Guzmán (2020). Euclidean and Cosine unsupervised distance metrics, as well as ITML and SDML Metric Learning based distance metrics were calculated for both SL and IDF weighting schemes. 5000 parallel sentences from Fernando et al. (2020)’s parallel corpora were used to train the Metric Learning models for En-Ta and Si-Ta. For En-Si, SDML and ITML were trained with SL weighting for Fernando et al. (2020)’s parallel corpus and the open subtitle corpus. IDF was trained with the latter corpus only. This is to measure the impact of the type of parallel corpus on the Metric Learning models.

We conducted another experiment to compare the performance of LASER and XLM-R multilingual embedding models. First, the same 5000 sentence pairs from Fernando et al. (2020) were used to ob-

Table 2: Recall values for Document Alignment with LASER embeddings

In order to determine the impact of the parallel dataset size on the performance of Metric Learning models, we trained separate ITML models using 1000, 2000, 3000 and 5000 parallel sentences for all three languages using Fernando et al. (2020)'s corpus. Embeddings were generated with XLM-R.

7 Results

We followed the method used for document alignment evaluation in WMT16 document alignment shared task (Buck and Koehn, 2016). The ground truth documents only contain a small fraction of parallel documents. There can be many more valid cross lingual document pairs in the dataset. Therefore we evaluated the aligned document pairs using recall (i.e. what percentage of the aligned document pairs in the golden alignment set are found by the algorithm) from the ground truth.

data-set, as done by Dara and Lin (2016). Results of our system against El-Kishky and Guzmán (2020)’s system on LASER embeddings are given in Table 2. It also shows the results of the two parallel datasets used to build the Metric Learning models for En-Si. How the performance of our system varies with respect to the size of the parallel dataset used with the XLM-R model is given in Table 3. The results related to all the distance measurement techniques depend on the news source. If most of the news items are present in all the three languages, this sends a strong signal to the aligner. A very good example is the En-Si pair in Army News. Number of Sinhala and English documents in this source is roughly equal. The results confirm that Metric Learning based distance measurement has been very effective in aligning documents for all three language pairs. Even for the Newsfirst data source for the En-Si pair, metric learning (SDML) lags behind cosine similarity only by a very small margin. It is evident that XLM-R significantly outperforms LASER. XLM-R performing very well even for 1000 parallel sentence is very promising - this means that Metric Learning could be employed with languages included in the XLM-R model as long they have a very small parallel corpus. Another factor we wanted to investigate is the impact of the level of language representation in the multilingual embedding model on document alignment. Although LASER and XLM-R include data from multiple languages, they do not include data from all the languages in equal amounts. If we hypothesize that the amount of language data is proportional to the language categorization proposed by Joshi et al. (2020), results related to Sinhala has to be the lowest. However, the results do not convey this message. Thus we believe that factors such as language relatedness and language complexity might be playing a role here.

8 Conclusion

This paper presented the use of supervised distance measurement techniques on multilingual sentence embedding based document similarity calculation. Results show that this supervised approach is being able to consistently outperform the unsupervised counterparts for three document alignment tasks. Only a small parallel corpus is required to train the Metric Learning distance measurements. Thus, these techniques can be employed with respect to low-resource languages as well. The main drawback of Metric Learning algorithms is that they are very much computationally expensive. Therefore, in the future, we plan to optimize these algorithms to achieve better efficiency.

Abstract

The International Classification of Diseases (ICD) is a system for systematically recording patients’ diagnoses. Clinicians or professional coders assign ICD codes to patients’ medical records to facilitate funding, research, and administration. In most health facilities, clinical coding is a manual, time-demanding task that is prone to errors. A tool that automatically assigns ICD codes to free-text clinical notes could save time and reduce erroneous coding. While many previous studies have focused on ICD coding, research on Swedish patient records is scarce. This study explored different approaches to pairing Swedish clinical notes with ICD codes. KB-BERT, a BERT model pre-trained on Swedish text, was compared to the traditional supervised learning models Support Vector Machines, Decision Trees, and K-nearest Neighbours used as the baseline.

When considering ICD codes grouped into ten blocks, the KB-BERT was superior to the baseline models, obtaining an $F_1$-micro of 0.80 and an $F_1$-macro of 0.58. When considering the 263 full ICD codes, the KB-BERT was outperformed by all baseline models at an $F_1$-micro and $F_1$-macro of zero. Wilcoxon signed-rank tests showed that the performance differences between the KB-BERT and the baseline models were statistically significant.

1 Introduction

There are both administrative and statistical purposes of ICD coding. Administrative to reimburse the clinical unit or hospital, but also to plan healthcare. The codes are assigned by both treating physicians and designated coders. The current version of the ICD system, ICD-10, contains tens of thousands of codes divided into 22 chapters (WHO, 2016).

ICD coding is time-consuming and error-prone, either missing the main diagnosis or displaying errors in the coding in up to 20 per cent of the patient records (Jacobsson and Serdén, 2013). Therefore, it would be valuable to have a supporting tool to assist the physician or coder in choosing among the codes.

In this article, Swedish patient records in the medical speciality of gastrointestinal surgery and their already assigned ICD-10 codes are used to perform supervised learning to predict ICD-10 codes. More specifically, the part of the patient records that summarises the patient’s care period at the time of the discharge, the discharge summaries, and their associated ICD-10 codes are used. The assigned codes belong to the Swedish version of the ICD-10 system known as ICD-10-SE (Socialstyrelsen, 2018). The codes considered are both full ICD codes at the highest level of granularity and the full codes grouped into ten blocks. The research question is how the deep learning language model KB-BERT, compared to the traditional supervised learning models Support Vector Machines, Decision Trees, and K-Nearest Neighbours performs in pairing discharge summaries with the correct ICD codes.

2 Related Research

ICD coding has been a popular research area for decades. The interest increased with a public challenge hosted by the Computational Medical Center called the 2007 Computational Medicine Challenge, where contestants were asked to create a system for pairing radiology reports with the correct ICD codes. Most submitted solutions used hand-crafted rules, traditional supervised learning models such as Support Vector Machines, or a combination of these two approaches (Pestian et al., 2007). One of the top-performing systems used a combination of rule-based and machine learning elements, achieving an $F_1$-micro score of 0.89 by utilising Decision Trees to generate rules automati-
Since 2007, ICD classification has shifted away from rule-based techniques, and many recent studies use traditional supervised learning methods or deep learning approaches. Examples of conventional models used in previous ICD coding papers are Support Vector Machines, Decision Trees, K-nearest Neighbours, Naïve Bayes, and ensembles of these models. In Kaur and Ginige (2018), comparing these conventional models with Multi-layer Perceptrons resulted in Decision Trees and AdaBoost using Decision Trees being the superior classifiers at F-scores of approximately 0.9. Hasan et al. (2016) compared traditional models with Convolutional Neural Networks and concluded that the results for the Convolutional Neural Networks were comparable with the results of Support Vector Machines, but that Support Vector Machines outperformed Convolutional Neural Networks as the number of classes increased. The best-achieved accuracy score of Support Vector Machines in (Hasan et al., 2016) was 0.75. For Bulgarian, Boytcheva (2011) carried out ICD classification using Support Vector Machines. She used 6,200 and 1,300 electronic patient records for training and evaluation, respectively, obtaining a precision of 0.97, a recall of 0.74, and an F-score of 0.85.

An increasingly popular deep learning approach to ICD coding tasks is using the language model BERT (Bidirectional Encoder Representations from Transformers) developed in 2018 by Devlin et al. (2019). BERT was pre-trained on 3.3 billion words from two English corpora – the BooksCorpus and the English Wikipedia – making it an expert in understanding general English. However, BERT has also been adapted to domain-specific language. For example, Lee et al. (2020) developed BioBERT – a BERT model pre-trained on biomedical texts. When Amin et al. (2019) adopted BioBERT to perform ICD coding, they reached an F1-micro score of 0.73. Moreover, a BERT model pre-trained on clinical text was developed by Alsentzer et al. (2019) and used by Biseda et al. (2020) for ICD classification, achieving an F1-score of 0.75.

Since the original BERT and many of its domain-specific adaptations are trained on English texts, BERT has also been adapted to understand other languages. In 2020, the National Library of Sweden pre-trained a BERT model on billions of Swedish words, naming this model KB-BERT, (Malmsten et al., 2020). Malmsten et al. (2020) showed that KB-BERT outperformed the multi-lingual version of the BERT model.

As discussed in a review paper by Stanfill et al. (2010), it is difficult to compare previous ICD classification approaches since previous studies using the techniques apply them differently. Previous studies use different label sets, evaluate the classifiers’ performance differently, and use texts written in different languages. Therefore, it is favourable to investigate the alternative ICD coding methods in the context they will be used. Moreover, while many studies explore rule-based methods, traditional supervised models, and deep learning approaches to solve ICD coding tasks, few studies use Swedish data.

Henriksson et al. (2011) attempted automatic ICD classification on Swedish data using co-occurrences of words and ICD codes. Pairing clinical notes with semantically correlated ICD codes resulted in the correct ICD code being present in the top ten suggested ICD codes in 20 per cent of the cases. When considering codes at a lower level of granularity, the correct ICD codes were found in the top 10 suggested codes in 77 per cent of the cases. Optimising the dimensionality improved these results by 18 percentage points (Henriksson and Hassel, 2013).

This study explores conventional supervised learning methods and the deep learning Swedish model KB-BERT for Swedish ICD classification. The F1-micro is used to evaluate the different approaches. The F1-macro is also presented. A discussion of the results follows, addressing the implications of the study.

3 Methodology

3.1 Data

3.1.1 ICD Codes

The ICD system is hierarchical, and at the highest level of granularity, the letter initiating each code is followed by three digits. In Figure 1, the anatomy of ICD codes is displayed.

![Figure 1: The anatomy of ICD codes.](image-url)
Health personnel assign three-digit codes like the one exemplified in Figure 1 to the patient records, and a clinical coding tool would benefit from suggesting these full codes. However, since many codes only have a few associated patient records in the data available for this study, it might not be successful to train models to predict full codes. Therefore, to give the models a fair chance to perform and, thereby, be compared, both full codes at the highest granularity level and codes grouped at a higher level are considered in this article.

The grouped codes considered are ICD codes at a two-digit level, which are known as ICD blocks. Using full ICD codes can illustrate the implications of training models when having many classes, where many of the classes have few instances. On the other hand, using ICD codes at the block level can demonstrate the implications of solving an ICD classification task at a lower level of granularity with fewer classes and more instances per class.

This paper is delimited to ICD codes related to gastrointestinal diseases. The digestive diseases reside in ICD Chapter XI, containing codes starting with a K. Chapter XI consists of ten blocks. In Table 1, the two-digit ICD codes included in each block in ICD Chapter XI and descriptions of the diseases that the blocks cover are presented.

3.1.2 Multi-label Text Classification

A hospitalised patient seldom suffers from only one disease. On the contrary, one patient can have many diagnoses, implying that one discharge summary often is paired with multiple ICD codes. Pairing one text with numerous labels is a multi-label classification task, which is different from multi-class tasks where the labels are mutually exclusive. In Figure 2, an exemplary clinical note with multiple assigned ICD codes is presented.

### Discharge summary

Tidigare helt frisk kvinna med obehag i epigastrium och rilltagna smärtor i arcus under 4 dagar. Konstaterat diaphragmafräck. Beh för misstänkt gastroenterit utan framgång. CT visade tecken på akut kolecytis och operation genomfördes med framgång. Pat hemskickad med råd att vila i minst 2 v. Fetsnål kost och mindre portioner rekommenderas.

**English translation:** Previously completely healthy woman feeling discomfort in epigastrium with increasing pain in arcus for 4 days. Confirmed diaphragmatic hernia. Unsuccessfully treated for suspected gastroenteritis. CT showed signs of acute cholecystitis. Successful operation. Pat sent home to rest for 2 w min. Low fat diet and smaller portions recommended.

**Assigned ICD codes**

- **K44.9** Diaphragmatic hernia, no obstruction or gangrene
- **K80.4** Acute cholecystitis

### 3.1.3 The ICD-10 Corpus

The data used in this study is called the Stockholm EPR Gastro ICD-10 Corpus version 2 (ICD-10 Corpus)\(^1\). The ICD-10 Corpus resides in the research infrastructure Health Bank – the Swedish Electronic Health Record Bank\(^2\) which is located at the Department of Computer and Systems Sciences (DSV) at Stockholm University. Health Bank contains over 2 million electronic patient records from over 500 clinical units at Karolinska University Hospital in Stockholm between 2007 and 2014. The ICD-10 Corpus was extracted from Health Bank and consists of discharge summaries from four gastrointestinal care units.

In the ICD-10 Corpus, there are only ICD codes representing digestive diseases, which is ICD Chapter XI, containing codes starting with a K (see Table 1). Moreover, the discharge summaries were filtered to those containing more than three tokens, and discharge summaries belonging to the same patient and care period assigned the same ICD codes were merged into one discharge summary.

In Table 2, the number of discharge summaries, patients, tokens, unique tokens, full ICD codes, and ICD blocks of the ICD-10 Corpus are presented. Descriptive statistics of the number of tokens per discharge summary are available in Table 3.

3.2 Models

3.2.1 Baseline

A common approach to solving ICD classification tasks is using traditional supervised learning models. The traditional supervised learning models used in this study were Support Vector Machines, Decision Trees, and K-nearest Neighbours. These models were chosen since they are well-established and frequently used in related studies.

The implementations of Decision Trees and K-Nearest Neighbours used were the DecisionTreeClassifier class from the Scikit-learn library (Pedregosa et al., 2011) and the MLkNN class from the Scikit-multilearn library (Szymański and Kajdanowicz, 2018), respectively. Since the Scikit-learn implementation of Support Vector Machines (class SVC) is not directly suitable for multi-label data, one classifier per label was trained using the Scikit-learn classifier implementation of one-vs-rest (class OneVsRestClassifier). The default hyper-parameters were used.

For the baseline models to handle text input, the text has to be represented as numerical features. For this purpose, tf-idf weights as they are implemented in the Scikit-learn class TfidfVectorizer were used. tf-idf is short for term frequency-inverse document frequency and represents how important a word is in a specific document, compared to the importance of that word in all documents. Basic pre-processing steps in the form of removal of punctuation and stop words and de-capitalisation were also conducted. The list of Swedish stop words was taken from the Natural Language Toolkit (NLTK) (Bird et al., 2009).

3.2.2 KB-BERT

KB-BERT was used closely following the instructions in Devlin et al. (2019) for downstream tasks and fine-tuning. More specifically, the architecture takes advantage of the presence of a special token, namely the [CLS] (classification) token representation, used initially for the NSP (Next Sentence Prediction) task. This representation is utilised as sentence representation and is assumed to contain information describing each instance. The architecture of the KB-BERT classifier includes at its core the KB-BERT model (bert-base-swedish-cased) from which the [CLS] representation is used for each sample through a ReLU (Rectified Linear Unit) transformation as input to a fully connected classification layer.

In the spirit of Devlin et al. (2019), a minimal learning rate in the magnitude of $2 \cdot 10^{-5}$ was used. The number of warm-up steps was set to 155 for the model to approximately see all the data before the learning rate starts decaying. Due to memory constraints, the batch size of 32 was achieved using a batch size of 2 and a gradient accumulation of 16. The activation threshold binarising the floating numbers the KB-BERT outputs was set to the standard value of 0.5. Adam was used as the optimiser. The implementation of the KB-BERT classifier was done using the Transformers (Wolf et al., 2020), and Pytorch (Paszke et al., 2019) libraries.

---

3.3 Experiment Design
To test how well the KB-BERT, Support Vector Machines, Decision Trees, and K-Nearest Neighbours perform in pairing Swedish discharge summaries with the correct ICD codes, 90 per cent of the data was used for training the models. 10-fold cross-validation was utilised to get more reliable estimates of the models’ performance and to be able to test if the observed differences in classifier performance are statistically significant. The final performance of the KB-BERT and the best performing baseline model was estimated by training on all training data and testing on the 10 per cent of the data (the held-out set) not used for comparing the classifiers.

Performance was represented by the F1-micro score. Micro averaging was chosen over macro averaging since it was considered of greater interest to train a classifier that correctly can classify as many discharge summaries as possible, rather than as many ICD codes as possible. However, macro averaged scores are presented as well.

The Wilcoxon signed-rank test (Wilcoxon, 1945) suitable for small dependent samples was used to test the statistical significance of classifier performance. The null hypotheses that the distribution of the F1-micro scores are equal were tested against the alternative hypotheses that the distribution of the F1-micro scores are not equal for the compared classifiers. The significance level was set to 0.01.

4 Results
4.1 Full ICD codes
The combined macro and micro averaged Precision (P), Recall (R), and F1-score (F1) of the KB-BERT and the baseline models during the 10-fold cross-validation when training the models using the Full codes version of the ICD-10 Corpus (263 ICD-10 codes) are presented in Table 5.

Table 5: Combined scores for the Full codes data set during the 10-fold cross-validation.

Overall, the results were poor. All models underperformed, and the best performing model for the full codes was the Decision Trees, achieving an F1-micro of 0.29 and an F1-macro of 0.09. The KB-BERT failed to perform at all, obtaining F1-scores of zero.

As becomes evident from Figure 3, the classifier ranks remained constant during the 10-fold cross-validation, resulting in the smallest possible Wilcoxon test statistic, 0, for all pairwise comparisons of classifiers. This means that there is reason to trust that the differences in classifier performance observed in Table 5 were not only due to chance but reflect actual characteristics of the data set.

As becomes evident from Figure 3, the classifier ranks remained constant during the 10-fold cross-validation, resulting in the smallest possible Wilcoxon test statistic, 0, for all pairwise comparisons of classifiers. This means that there is reason to trust that the differences in classifier performance observed in Table 5 were not only due to chance but reflect actual characteristics of the data set.

For the KB-BERT, early stopping was used during the 10-fold cross-validation, and convergence was achieved with respect to the Binary Cross-Entropy (BCE) loss function at ten epochs during most runs. Therefore, when training the KB-BERT on all of the training data and testing it on the held-out test set, it was trained for ten epochs. Still, the KB-BERT failed to perform and obtained an F1-micro and F1-macro of zero. When training the best-achieving baseline classifier, the Decision Trees, on the full training set and testing it on the held-out test set, it achieved an F1-micro of 0.31 and an F1-macro of 0.09.

4.2 ICD Blocks
For the Blocks version of the ICD-10 Corpus, comparing the F1-micro of the KB-BERT with the baseline models during the 10-fold cross-validation, the KB-BERT was superior to the baseline models. The Support Vector Machines was the baseline model with the highest F1-micro. Macro and micro averaged Precision (P), Recall (R), and F1-score (F1) of the KB-BERT and the baseline models during the ten folds are presented in Table 6.
Table 6: Combined scores for the Blocks data set during the 10-fold cross-validation.

</tbody>
</table>

Looking at Figure 4, one can see that, as was the case with the Full codes version of the data set, the classifier ranks comparing the KB-BERT and each baseline classifier remained intact throughout the 10-fold cross-validation for the Blocks version of the data set. This implies that these Wilcoxon test statistics were 0 and that the observed differences between the KB-BERT and the baseline classifiers are likely to reflect that the KB-BERT and the baseline models perform differently on this data set. However, unlike in the case with full codes, the baseline classifiers are not statistically distinguishable.

5 Discussion

5.1 KB-BERT

The results showed that at a block level, the state-of-the-art BERT model trained on Swedish text, KB-BERT, has the potential to be a successful classifier used in an ICD coding tool. It would be interesting to explore if the performance could be further improved by, for example, fine-tuning hyper-parameters such as the activation threshold. It would also be relevant to try other versions of BERT, for instance, a BERT pre-trained on Swedish clinical texts.

While the KB-BERT was the best performing classifier on the block level, it failed to classify full codes. One explanation for this could be that deep learning models are more data-hungry than traditional supervised machine learning models, meaning the KB-BERT suffers the most from moving from ICD blocks to less frequent full codes.

It should also be noted that, like other deep learning models, KB-BERT takes substantially longer to train than the baseline models, resulting in a larger carbon footprint. For example, when considering codes at the block level, it took 300 minutes for a GPU to train (fine-tune) and test the KB-BERT using 10-fold cross-validation. The corresponding number for the slowest baseline model, the Support Vector Machines, was 22 minutes on a regular laptop computer, meaning the actual training time difference probably is even greater than our estimations. While one may argue that the prediction time matters the most, training time might still matter if the idea is that the ICD coding tool should keep learning with time.

5.2 Code Frequencies, Granularity, and Combinations

One finding that stands out is the difference between the classifiers’ performance when considering the 263 full ICD and ICD codes grouped into ten blocks. Comparing the results in Section 4.1 and Section 4.2, the best F₁-micro changes from 0.31 to 0.80 when going from full codes to block codes.

There are several possible explanations for the great difference between the results at a full code level and a block level. Firstly, many of the full codes have very few associated discharge summaries, meaning there are few examples to learn from. Some codes only have one associated discharge summary, leaving no instances to test on,
which leads to $F_1$-scores of zero. In turn, having many low-frequency codes explains the discrepancy between $F_1$-micro and $F_1$-macro scores.

Secondly, as Blanco et al. (2020) suggest, the granularity itself can be a predictor of performance. This means that going from full codes to codes on the block level could have a greater impact than decreasing the number of possible label combinations. Of course, the number of possible label combinations itself also could have impacted the results. One way to address the difficulties associated with ICD coding at the full code level is to combine KB-BERT with the per-label attention mechanism proposed in the article by Blanco et al. (2021).

5.3 Generalisability

One should note that this study’s classifier comparison only is valid for the specific discharge summaries used and that they might not represent Swedish gastrointestinal discharge summaries in general. For example, since the discharge summaries were written between 2007 and 2014, it may be the case that the writing style has changed since. Moreover, the four units that the discharge summaries were created at may not represent Swedish gastrointestinal care units in general.

Furthermore, the results are conditional on the specific instantiations of the classifiers used, and both the KB-BERT and the baseline models may have benefited from hyper-parameter optimisation.

The results of this study are also difficult to compare with the results from other related research since the data sets used differs, and they are often not publicly available because of privacy reasons.

5.4 ICD Coding Tool

This research’s long-term goal is to develop a Swedish ICD coding tool to use in health facilities. Since health personnel assign full codes to the patient records, it would be favourable if the tool suggested full codes. Therefore, it would be suitable for future work to improve the results of this study obtained for codes at the highest level of granularity.

Moreover, it would be interesting to explore how such a tool could incorporate explainability mechanisms. Explainability could be used both as a measure to make the tool trustworthy and to help the coder decide among the suggested codes.

Furthermore, a coding tool would benefit from being developed in close contact with the end-users. Therefore, a design science study with an iterative research approach would be reasonable. In such a study, classifier requirements, such as the desired trade-off between precision and recall, could be discussed.

6 Final Remarks

6.1 Summary

To summarise, the KB-BERT outperformed the baseline classifiers when the full ICD codes of the ICD-10 Corpus were grouped into ten ICD blocks, achieving an $F_1$-micro of 0.80 and an $F_1$-macro of 0.58. These results can be compared to the baseline classifier with the highest $F_1$-micro, the Support Vector Machines, which reached an $F_1$-micro of 0.71 and an $F_1$-macro of 0.42. When considering the 263 full codes, the KB-BERT could not perform at all, obtaining zero $F_1$-micro and $F_1$-macro.

The discrepancy between the results when considering full ICD codes and codes at a block level can partly be because many full codes had very few associated discharge summaries (low frequency). Furthermore, the granularity itself could have impacted the results since distinguishing one full code to another very similar full code is different from distinguishing one ICD block to another, not that similar, ICD block. The fact that one of the tasks had more than 20 times more labels than the other could also have influenced the results.

6.2 Conclusion

In conclusion, this paper contributed to the insufficient knowledge about performing ICD classification on a Swedish corpus by exploring how different classifiers solved a Swedish ICD classification task. One main finding is that KB-BERT showed great potential in predicting few high-frequency ICD codes grouped at the block level. Another main result is that the classifiers, especially the data-hungry KB-BERT, struggled when considering many low-frequency, finely-grained codes.

Since it is desirable for an ICD tool to suggest full codes rather than grouped codes, future work on Swedish ICD classification should focus its efforts on training models that perform well in predicting full codes. One recommendation is to get data from many training examples per each full ICD code to achieve this goal, thereby avoiding the low-frequency issue. Moreover, future stud-
ies would benefit from looking into different ways for classifiers to handle a great amount of finely-grained ICD codes.

Abstract
Natural language inference is a method of finding inferences in language texts. Understanding the meaning of a sentence and its inference is essential in many language processing applications. In this context, we consider the inference problem for a Dravidian language, Malayalam. Siamese networks train the text hypothesis pairs with word embeddings and language agnostic embeddings, and the results are evaluated against classification metrics for binary classification into entailment and contradiction classes. XLM-R embeddings based Siamese architecture using gated recurrent units provides promising results for this classification problem.

1 Introduction
Textual entailment is a uni-directional relationship between two text pairs. It is the method of identifying the meaning from two sentences. Sentence pairs are labeled as entailment pairs if a sentence is inferred from the context of the other sentence in the pair.

It is defined in different ways as classical definition, applied definition, and mathematical definition (Ghuge and Bhattacharya, 2014). In the classical definition, a text entails a hypothesis if the hypothesis is valid in all circumstances where the text is true. In applied definition, text entails hypothesis if the hypothesis is mostly true when a human reads it. The mathematical definition (Glickman et al., 2005) is a text that entails a hypothesis if the probability of the hypothesis is true given the text is greater than the likelihood of the hypothesis being true.

The sentence from which we derive the information is called text, and the sentence which identifies its information as derived from text is called a hypothesis. Sentence pairs are named as entailed if the hypothesis has its meaning derived from the text. Contradictory pairs indicate that the information from the hypothesis is contradictory concerning the information conveyed in the text.

Nowadays, textual entailment has become part of the primary natural language processing tasks. It is also called natural language inference. The terms text and premise are used interchangeably. The performance of the latest transformer-based approaches is evaluated in NLP tasks like entailment recognition, semantic textual similarity, and paraphrase detection. Hence, textual entailment recognition has also become an evaluation criterion for many NLP tasks. It is also a necessary sub-task in applications like multi-document summarization, information retrieval, information extraction, and question answering systems.

Many text entailment or natural language inference related works in English use different sized datasets but not in the Malayalam language. Malayalam is a Dravidian language used in the southern part of India. It is a language that has various dialects and has many inflections. Malayalam language computing is developing, with few resources, namely stemmer, POS tagger, sandhi splitter, and few datasets for paraphrasing, text classification, and sentiment analysis. It has agglutinated language structure, and new words are created through word compounding and inflection, and hence there can be many inferential compound words for a word.

The main challenge of textual entailment recognition in the Malayalam language is the absence of a dataset. Dataset creation is a tedious task that involves high costs and time. We used an in-house dataset created by machines and humans in the loop translation of the Stanford Natural Language Inference dataset. It is a very cost-effective method of dataset creation that can be adapted to any low-resource language. This work attempts to use Siamese networks with bidirectional long
short term memory and gated recurrent units to understand the similarities and differences of text-hypothesis pairs for classification.

The remaining sections are organized as follows. Section 2 briefs the works related to textual entailment recognition. Section 3 details the dataset. Section 4 discusses the design of the system for classification. The experimental settings, results, and discusses sentence similarity are in Section 5. Section 6 concludes the work.

2 Related Works

Textual entailment recognition started with a Recognizing Textual Entailment (RTE) challenge in 2005 (Dagan et al., 2005). This challenge continued for years and used different-sized datasets. As the dataset size increases, feature-based methods such as word overlap, n-gram match, set-based similarities, and syntactic similarities were replaced by machine learning and deep learning methods using different word and sentence representations.

There are numerous entailment recognition systems in English and other languages like French, German, Italian, Spanish, and Arabic. Various textual entailment frameworks have also been developed in these languages, namely EXCITEMENT Open Platform (EOP) (Magnini et al., 2014). EOP uses edit distance and classification as its algorithms. Lexical level features, syntactic and surface-level features, graph-based approaches were used to recognize entailments. The increase in dataset size has helped to use machine learning and deep learning strategies for this classification. Deep learning methods are widely used for textual entailment in English using different datasets.

SNLI (Stanford Natural Language Inference) dataset is a collection of 570k sentence pairs mainly collected through Amazon Mechanical Turk, referencing the Flickr30k corpus. This dataset helped in using deep learning techniques to text entailment recognition. Sentence models with the sum of words, recurrent neural networks, and long short-term memory networks were discussed (Bowman et al., 2015).

MNLI (Multi-Genre Natural Language Inference) dataset is a collection of 433k sentence pairs from different written and spoken English genres. Some of the genres are face-to-face, government, telephone, letters, fiction, and travel. It is an improvement from SNLI with a more diverse collection of sentence pairs, and hence its baseline performance is low compared to SNLI (Williams et al., 2018).

XNLI (Conneau et al., 2018) (Cross-Lingual Natural Language Inference) corpus is a collection of data from MNLI, derived for 15 languages, including some low resource languages like Urdu and Swahili. It uses a translation-based approach with multilingual sentence encoders and then aligning sentence embeddings for inference identification. Except for English, entailment recognition systems exist for French, Spanish, German, Greek, Bulgarian, Russian, Turkish, Arabic, Vietnamese, Thai, Chinese, Hindi, Swahili, and Urdu. In languages like Swahili, Thai and Urdu, transfer learning based approaches are used, which is helpful for small-sized datasets.

For the Malayalam language, there are works related to paraphrasing, sentiment analysis, summarization, whereas text entailment recognition is seemingly a new area for Malayalam language processing. The performance of different embedding-based approaches is one work in this language for entailment recognition (Renjit and Idicula, 2021). In this work, LASER-based embedding representation showed improved performance results for entailment recognition for the Malayalam language compared with BERT and other models.

Bidirectional LSTM based dependent reading represents text and hypothesis in encoding and inference stage (Ghaeini et al., 2018). Siamese network-based architecture with sentence embeddings from BERT experiments in the English language (Reimers et al., 2019). A neural model based on LSTM using the word by word attention is another deep learning-based method for recognizing entailments (Rocktäschel et al., 2015). Child-Sum-Tree-based inference of texts generalizes well for SNLI and other entailment datasets (John et al., 2016). Text alignment based approaches along with machine learning are used for entailment recognition in Arabic language (Boudaa et al., 2019). Another method used asymmetric word embeddings to produce similarity based word-word interactions for textual entailment (Ma et al., 2018).

Entailment recognition has been part of Competition on Legal Information Extraction / Entailment, where sentence encoding and decomposable attention models perform entailment recognition in the context of legal texts (Son et al., 2017). Automatic translation-based approaches are used in the Italian dataset, where the dataset is translated into the En-
English language for entailment recognition (Pakray et al., 2012).

3 Dataset

The subset of the Malayalam Language Inference (MaNLI) dataset is used for binary entailment recognition. It consists of 7989 text hypothesis pairs which are labeled as Entailment and Contradiction. This dataset is created from Stanford Natural Language Inference (SNLI) dataset. The sentence pairs from the SNLI dataset are translated to the Malayalam language with linguistic corrections from the Department of Linguistics, Malayalam University, Kerala.

There are 4026 entailment pairs and 3963 contradiction pairs in this dataset. The reason for the creation of this dataset is the unavailability of entailment datasets in Malayalam. Languages like Malayalam have many inherent linguistic properties like inflections, agglutinative nature, dialect-related differences, and no specific word order.

A sample from the dataset is shown in Figure 1.

Figure 1: Sample dataset

The English translation of the sample dataset is provided in Table 1.

4 Proposed Architecture

The design of this system consists of neural networks of identical architecture consisting of an embedding layer and bidirectional long short-term memory/gated recurrent unit networks. The Siamese network for sentence representation takes each sentence from text-hypothesis pair to an embedding layer. This layer uses different types of embeddings, namely Word2Vec and LASER (Language Agnostic Sentence Representations), and XLM-R. The different layers in the system are:

4.1 Embedding

The first layer is the embedding layer, where each sentence in text or hypothesis gets an efficient representation that captures its meaning in high dimensional vector space. In this layer, we used approaches, namely, Word2Vec, language-agnostic sentence representation (LASER), and XLM-R.

4.1.1 Word2Vec

Word2vec (Mikolov et al., 2013) is a word embedding neural model that produces distributed representation of words in vector space. The neural model trains in two ways, namely skip-gram and continuous bag of words, using hierarchical softmax or negative sampling (Rong, 2014). Words having semantic similarity represented through vectors are closer in high dimensional space. The embeddings from this model are input to the Keras embedding layer in the form of an embedding matrix to obtain text representation and hypothesis.

4.1.2 LASER

Language Agnostic Sentence Representations (Artetxe and Schwenk, 2019) is a toolkit modeled for more than 90 languages, including the Malayalam language. LASER embeddings are representations of sentences so that a sentence representation in two or more languages will be close to each other in their high dimensional vector space. It also uses an encoder-decoder architecture based on neural machine translation.

4.1.3 XLM-R

XLM-R (Conneau et al., 2019) is a self-supervised model that is trained on cross-lingual representations. This transformer-based masked language model is trained for 100 languages, including the Malayalam language. The cross-lingual sentences are taken from Common Crawl data.

4.1.4 Dimensionality Reduction using PCA

Principal component analysis (PCA) reduces the sentence embedding obtained from the LASER model. It compromises with accuracy, and hence selecting an adequate number of features is critical to the model. Depending on the system’s configuration, dimensions of 100, 500, and 1000 are tested for 1024 dimensional LASER embeddings. Dimension reduction of 100 leads to 0.87% loss
of features, dimension 500 causes 0.488% feature loss, and dimension 1000 led to 0.023% feature loss.

4.2 BLSTM
The bidirectional LSTM layer consists of two LSTM layers, one in forward and the other in the backward direction for sequence processing. It is used when a sequence of data is to be processed. The text and hypothesis are passed through BLSTM layers to obtain a sequence representation that embeds the complete information.

4.3 GRU
This layer has recurrent neural networks with a gating mechanism. It is similar to long short-term memory networks, and it does not have output gates. As such, it has less number of parameters with good performance on small-sized datasets.

4.4 CONCATENATION
The sequence representation of text and hypothesis are then concatenated in this layer, and batch normalization is done. Dropout configurations are then applied and passed to a Dense layer.

4.5 DENSE LAYER
The dense layer has its input from the concatenation layer and has rectified leaky unit activation function. It is then batch normalized, and dropout is applied and flattened to feed to the following dense layer.

4.6 SIGMOID CLASSIFICATION
For binary classification, the sigmoid activation function is used in the final dense layer. The sigmoid function is given by

\[ S(x) = \frac{1}{1 + e^{-x}} \]  

(1)

The system design is shown in Figure 2. The representations from the embedding layer is then passed to a bidirectional LSTM / GRU layer where each sentence gets a context representation. It is performed for both text and hypothesis in Siamese network architecture, followed by a concatenation of the outputs from BiLSTM / GRU. The concatenated text hypothesis representation is then fed to a Dense layer with ‘RELU’ activation followed by classification. Sigmoid function with binary cross-entropy loss function performs the model training and classification.

5 Experimental Results

5.1 Experimental Setup
Implementations used Google Colab platform and Spyder IDE using Python, Tensorflow, and Keras library for machine learning and Scikit-Learn for evaluations.

The parameter configurations for training the system are 100 LSTM nodes, 100 dense units, RELU activation function for dense layer, drop-out rate of 0.17, 0.25 for LSTM and 0.25 dropout for dense layer.

5.2 Results
The results are evaluated in terms of classification metrics, namely Precision(P), Accuracy, Recall(R), F1-score(F1), and Support(S). Experimental results of the Siamese network architecture detailed above are shown in Table 2.

</tr>
</tbody>
</table>

Table 5: Results based on Word2Vec with Configuration 1.

**Configuration 2:** With hierarchical softmax and skip-gram based approach resulted in Table 6. We infer that Word2Vec of 100 dimensions with hierarchical softmax and LASER embedding reduced to 1000 dimension shows good performance. Hence Word2vec is better for this Siamese network based architecture based on its performance with lesser dimensional embeddings.

**Comparison with GRU** For the same architecture, when BiLSTM is replaced with GRU, Word2Vec based system showed the same performance as below.

5.3 Sentence Similarity

As part of this classification, similarities of sentences with respect to text hypothesis pairs are measured quantitatively as entailment confidence. For example, the similarity score obtained for the classification of instances is shown in Figure 3. The entailment confidence score is helpful for sentence similarity tasks to identify the extent to which the pairs are similar. Thus it also aids in multidocument summarization tasks, in which we can avoid similar sentences in summary based on the entailment/similarity score.

6 Conclusion

In this work, we focused on the application of Siamese network architecture to recognize entailment in Malayalam language. The results show adequate performance. The use of newer embedding models leads to better accuracy but the embedding dimension is a limiting factor with the network configuration. As the embedding dimension increases, the time and space complexity increases in Siamese model architecture, where text and hypothesis are processed as sequences parallely.

Through this work, we aim to depict the performance of Siamese network based entailment recognition with respect to Malayalam language, which is a low resource Dravidian language.

Abstract
Recent research has documented that results reported in frequently-cited authorship attribution papers are difficult to reproduce. Inaccessible code and data are often proposed as factors which block successful reproductions. Even when original materials are available, problems remain which prevent researchers from comparing the effectiveness of different methods. To solve the remaining problems—the lack of fixed test sets and the use of inappropriately homogeneous corpora—our paper contributes materials for five closed-set authorship identification experiments. The five experiments feature texts from 106 distinct authors. Experiments involve a range of contemporary non-fiction American English prose. These experiments provide the foundation for comparable and reproducible authorship attribution research involving contemporary writing.

1 Introduction
Closed-set authorship attribution picks out the likely author of an unsigned document from a pool of candidate authors. Decades of research show that authors leave conspicuous “fingerprints” in their writing (Juola, 2006). A small amount of pre-existing prose (ca. 2,500 words) is often enough to learn enough about the writing “styles” of a set of candidate authors to correctly identify the author of an unsigned document. Authorship attribution techniques have found application in numerous domains. They have been used to resolve uncertainty about authorship in historical research (Mosteller and Wallace, 1964). For writers living today, widespread use of authorship attribution techniques—and related author profiling techniques (Argamon et al., 2009)—poses a privacy risk (Brennan et al., 2012). A better understanding of how authorship attribution techniques work can inform efforts to improve privacy-enhancing language technologies.

While there is no doubt that authorship attribution methods have improved over the past century, recent progress is harder to measure. Some of this difficulty is due to the field’s success. In recent decades, new methods improve on old ones by small amounts. Given small improvements, assessing whether or not the advance may be due to aleatory factors such as preprocessing or a particular dataset becomes difficult. Another reason recent progress is difficult to measure is the lack of standard benchmark tasks. Of 15 frequently-cited authorship attribution studies examined by Potthast et al. (2016), original corpora could be found for only 4 (27%) and code could be located for 0 (0%). While other fields, notably machine translation and language modeling, excel at organizing research activity around publicly-accessible benchmark tasks, contemporary authorship attribution research has no such tasks.

Recent experience suggests that without standard benchmarks—and evidence that researchers can consistently reproduce results using them—a field’s ability to self-assess progress on well-defined tasks can go astray. The field of recommender systems offers a cautionary tale. Rendle et al. (2019) documents a series of papers being published in prestigious journals over a five year period which do not, in fact, improve on earlier results. Notably, these papers used a standard dataset for their evaluations (Movielens 10M). Where these papers fell short was in their reproduction of previous results—to which their new methods were compared. The papers reported improvements on earlier results...
which were illusory; models used in earlier research, upon closer examination, outperformed the new methods. Analogous cases exist in other fields. In machine translation, although standard datasets were used, inconsistency in applying a key metric (BLEU) prevented researchers from easily reproducing or comparing results (Post, 2018).

Our paper supports reproducible research in authorship identification by introducing five standard benchmark tasks. Each task features fixed train and test sets. Four of the five tasks have a test set consisting of writing samples on fixed topics, guaranteeing that test set examples do not overlap with training set examples in terms of subject matter. Data for all tasks is available for download without any restrictions.

2 Problem Description

2.1 Problem: Models Cannot be Compared due to Unavailable or Under-specified Test Sets

Comparing the effectiveness of a new model with that of an existing model requires, at minimum, evaluating models on the same data. Because different models may perform differently when applied to texts by different authors or to texts in different genres by the same authors, comparing the performance of two models on a new dataset is often uninformative. Even when the new dataset resembles the original, researchers should worry that the poor performance of an earlier model may be due to accidental errors in re-implementation. Reliable comparisons of new models with previous methods are, in fact, picking up on content-independent authorial fingerprints, test set texts should not resemble training set texts.

For an illustration of the problem, consider the use of a corpus of 100 newspaper articles written by 10 different authors. Using such a corpus to evaluate the performance of an authorship attribution method may not yield the expected information: an estimate of how well the method will perform on similar authors in a different setting. The risk of a model using topical information is clear. Newspaper writers tend to have distinct areas of expertise (“beats”) which influence the types of subjects they write about. Writers from the same generation or similar social backgrounds may tend to write about certain topics. Senior writers may be more likely than junior writers to receive certain topics as assignments. Methods which appear to be using content-independent features may, in fact, be picking up on subtle signals of topic.

Unfortunately this kind of homogeneity in evaluation corpora is common. It features in all the corpora considered by Abbasi and Chen (2008) as well as the “C10” corpus drawn from Reuters-RCV1 (Potthast et al., 2016).

One method of addressing this problem is to use test set documents which are distinct from training set documents. Test set documents might be written in a different setting or different document genre. If, say, training set documents are work e-mails, then test set documents might be personal essays. Using test documents from a different time period would also help address the concern of topical homogeneity. Koppel et al. (2009) illustrate such a
division in a dataset involving two authors by using e-mails written before a fixed date as training and e-mails written after the date as testing.

Another method involves conducting a field experiment and eliciting prose on a fixed topic from writers. The elicited writing samples form the test set. This method is expensive but guarantees that models will not perform better by leveraging information about the topics specific authors tend to write about. Both Juola (2004) and Brennan et al. (2012) use this approach.

Authorship attribution methods are consistently presented as relying on the identification of topic-independent fingerprints. Evaluation tasks should be aligned with this presentation.

2.3 Problem: Unavailable or Restricted Corpora

The practice of restricting access to corpora appears to be more common in authorship attribution research than in the machine translation and language modeling communities. We considered including the C10, PAN12, and PAN13 authorship attribution tasks in our suite of benchmark tasks but found that all three are restricted and cannot be downloaded without permission.1 We know of no cases in current machine translation or language modeling research where performing a standard evaluation requires access to a restricted dataset. Data for the news translation tasks distributed by the Conference on Machine Translation are available for immediate download.2 Data for the widely-used language modeling benchmarks (GLUE, SQuAD) are publicly available (Wang et al., 2018; Rajpurkar et al., 2018). Of the 81 language modeling tasks cataloged by the NYU-based team developing the Jiant evaluation tool, 69 tasks (85%) can be downloaded automatically, that is, by the evaluation software itself.3

Making a dataset publicly available increases the likelihood that other researchers will reproduce results. Recent experience has shown that the probability that a result may not be reproducible or replicable is higher than previously appreciated (less than 70% according to Baker (2016)). The problem of non-reproducible results is sufficiently serious that certain conferences are exploring adopting additional measures—beyond submission of code and data—which will alleviate the problem.4

There is no reason to suspect that the reproducibility rate of authorship attribution research is conspicuously different from the rate in other areas of computational linguistics. Indeed, in the study of 15 frequently-cited authorship attribution papers, Potthast et al. (2016) document one failure to replicate results (Potthast et al., 2016, 403). If reproducing or replicating results is difficult in as many as 6% (1 in 15) of papers, then reproduction (or replication) should be a be a regular practice. And reproducing results requires that the original code and data be easy to access.

3 Improving Authorship Attribution Evaluation

The problems described in the previous section complicate a range of authorship attribution research (e.g., identification, verification, profiling). We propose a suite of five tasks which address the problems for one area of authorship attribution research: closed-set author identification involving contemporary English-language non-fiction prose. Lessons learned developing standard benchmark tasks in this area will, we hope, inform the development of analogous tasks in other areas.

Two arguments support our focus on contemporary non-fiction texts. First, collecting redistributable non-fiction prose from a diverse set of writers is relatively easy. A considerable share of the English-using population writes non-fiction prose. Demonstrating (some) competency in English composition is a requirement in secondary education across the English-speaking world. Second, many researchers are interested in the efficacy of authorship attribution methods applied to contemporary non-fiction English prose. English is, for the moment, the lingua franca of diplomacy, science, and international business. Authorship attribution methods which work on English therefore enjoy broad applicability. The stakes of author profiling research—research informed by authorship attribution research—are also significantly higher for research involving living writers than for writ-

ers active in previous centuries. Only in the former case is, say, an individual’s privacy at risk.

3.1 Reproducible Authorship Attribution Benchmark Tasks (RAABT)

Five closed-set authorship identification tasks make up the Reproducible Authorship Attribution Benchmark Tasks (RAABT). Table 1 summarizes the tasks. All tasks feature a fixed test set. Test set documents do not overlap with training set documents. In four out of five of the tasks, authors write test set documents on a fixed topic. Three of the tasks involve writing from a diverse set of adults living in North America. In aggregate, the tasks feature 106 different authors.

The tasks are published at [https://zenodo.org/record/5213898](https://zenodo.org/record/5213898).

Table 1: Summary statistics of documents used in the five tasks.

3.2 Task descriptions

1. Ad-hoc Authorship Attribution Competition, fixed topic (AAAC–fixed-topic). The first task is “Problem A” from the 2004 Ad-hoc Authorship Attribution Competition (AAAC) ([Juola, 2004, 2006]). Texts were gathered from 13 authors in 2013 undergraduate writing course at a university in the United States. For the test set documents, participants were asked to write on the topic of “work.”

2. Ad-hoc Authorship Attribution Competition, free topic (AAAC–free-topic) The second task is “Problem B” from the AAAC. Test documents are additional course essays on other topics. Test set documents do not overlap with training documents. Training documents are the same as in the first task.

3. Extended Brennan-Greenstadt Corpus, obfuscation condition (EBG–obfuscation) The Extended Brennan-Greenstadt Corpus ([Brennan et al., 2012]) (EBG) contains writing from 45 individuals contacted through the Amazon Mechanical Turk platform no later than the year 2012. Participants uploaded examples of their writing. The researchers asked for writing of a “scholarly” nature. Participants were then asked to write a short essay on a fixed topic. They were asked to describe their neighborhood to someone unfamiliar with the location. Notably, they were also asked to obscure their writing style. They were, however, not given any instructions on how to accomplish this. These essays form the test set.

Given prevailing norms on Amazon Mechanical Turk and the monetary incentive to finish quickly (payment did not depend on time spent on the task) we suspect many participants did not devote considerable time to de-
vising strategies for obscuring their writing style. We suggest that this task be treated as, in essence, an additional fixed topic task.

We note that the population of individuals who sell their labor on Amazon Mechanical Turk is quite diverse in terms of age, gender, and region (Coppock and McClellan, 2019).

4. **Riddell-Juola Corpus, control condition (RJ-fixed-topic)**

The Riddell-Juola Corpus collects texts using essentially the same techniques were used in Brennan et al. (2012). Responses were collected in March and June of 2019. According to self-reported gender and age, participant demographic characteristics are roughly balanced.

Participants were asked to respond to the same “describe your neighborhood” prompt mentioned earlier. No further instructions were given. (The instruction to obscure one’s writing style was not present.)

5. **Riddell-Juola Corpus, obfuscation condition (RJ-obfuscation)**

This task is the same as RJ-fixed-topic with one difference. Participants were told to obscure their writing using the same instruction as found in EBG-obfuscation. Again, they were given no instructions on how to accomplish this task.

Participants were randomly assigned to receive the obfuscation instruction. Therefore the authors of the test set documents in this task do not overlap with the authors of the test set documents in RJ-fixed-topic.

The training sets for the two tasks involving the Riddell-Juola Corpus are the same.

4 Accuracy of Received Methods

Table 2 reports the performance of two classic methods on the five tasks. We use a familiar 512-word function word feature set with both methods (Koppel et al., 2009). For linear SVM we use the libSVM implementation with default cost parameter \( C = 1 \) (Chang and Lin, 2011). For multiclass logistic regression we use L2 regularization \( \lambda = 1 \) (Pedregosa et al., 2011).

These baselines are intended to be reference points. They are chosen because they should be particularly easy to reproduce.

5 Discussion

Perceptions of the importance of having reproducible measures of model performance on well-understood tasks have changed over the last decade. Previously regarded as something desirable but by no means essential, reproducible benchmarks are increasingly seen as indispensable. Experience has shown that without such benchmarks, researchers risk overestimating the reliability of existing results or gaining a false sense of a field’s progress on particular problems. Our paper contributes a suite of benchmarks which can be used to anchor future authorship attribution research.

These five tasks are a start. Additional tasks would be welcome. Many forms of writing and document types in widespread use today are not featured in the five tasks we introduce here. Short text messages and informal e-mails, in particular, are ubiquitous. Yet many individuals’ habits of composition vary dramatically when writing in such genres. Standard benchmarks for cross-register and cross-genre authorship attribution would likely yield new insights into the strengths and weaknesses of existing approaches.

Abstract

Many organizations seek or need to produce documents that are written plainly. In the United States, the “Plain Writing Act of 2010” requires that many federal agencies’ documents for the public are written in plain English. In particular, the government’s Plain Language Action and Information Network (“PLAIN”) recommends that writers use short sentences and everyday words, as does the Securities and Exchange Commission’s “Plain English Rule.” Since the 1970s, American plain language advocates have moved away from readability measures and favored usability testing and document design considerations. But in this paper we use quantitative measures of sentence length and word difficulty that (1) reveal stylistic variation among PLAIN’s exemplars of plain writing, and (2) help us position PLAIN’s exemplars relative to documents written in other kinds of accessible English (e.g., The New York Times, Voice of America Special English, and Wikipedia) and one academic document likely to be perceived as difficult. Uncombined measures for sentences and vocabulary—left separate, unlike in traditional readability formulas—can complement usability testing and document design considerations, and advance knowledge about different types of plainer English.

1 Introduction

The quality of being “plain” has been held up as a stylistic ideal in English prose since the later seventeenth century (Guillory, 2017). This ideal has shown remarkable persistence (Cutts, 2020). In the United States, the plain language movement took off in the 1940s, and plainness remains a stylistic goal for many kinds of organizations in their writing on websites and other publications: medical and public health information, insurance policies, instructions to jurors, loan agreements, and Social Security benefits statements, to name just a few (Schriver, 2017; Cutts, 2020).

Since the passage of the Plain Writing Act of 2010, American federal agencies must use “plain language,” defined as “writing that is clear, concise, well-organized, and follows other best practices appropriate to the subject or field and intended audience” (United States Congress, 2010). Affecting all 2.1 million employees of the U.S. Federal government (Jennings and Nagel, 2020), the Act requires that agencies use this kind of language in many of their documents for the public, train their employees in this style, and demonstrate their compliance with the Act.1 There are several cogent rationales for plain language use: it grants access to understandable information to a greater number of people with differing literacy levels; it saves agencies the labor and money involved in clearing up confusing communications; and it may help to restore citizens’ trust in public-serving organizations, an especially important agenda in our era of misinformation, disinformation, and propaganda (Schriver, 2017). If we add to the U.S. government’s plain writing imperative the similarly simple writing style espoused by Big Tech in all of its apps, websites, and documentation, we can see that plain language is a dominant discursive goal today.2

Although our focus is on the American context, it is worth noting that plain English is pursued globally. Another U.S. government plain language mandate, the Securities and Exchange Commission’s plain writing initiatives of 1998 and 2008 not only extend plain language into the private sector but also include the requirement that foreign

2See, for example, the Microsoft Writing Style Guide and the Google Developer Documentation Style Guide.
firms listing shares on U.S. stock exchanges use plain English in their prospectuses (SEC, 2021). There is also the Canada-based organization, Plain Language Association International (International, 2021), as well as one based in the UK, Clarity, which focuses on making legalese plainer (Clarity, 2021). Plain writing is nowhere—it is supposed to be inconspicuous writing that functions like a transparent medium for information—and everywhere.

Quantitative measures of plainness are generally out of favor these days among plain English advocates. Early on, the American plain language movement was associated with readability formulas: most notably the Flesch-Kincaid formula (still available in Microsoft Word), the similar Dale-Chall formula, and the Gunning fog index (Klare, 1963). But since the late 1970s, plain language advocates have adopted usability testing and emphasized design considerations beyond words and sentences: that is, information, document, and visual design (Redish, 2000; Schriver, 2017). We enumerate the main limitations of existing readability formulas below.

At the same time, there are quantifiable features of plain writing. The American government-advocacy network, the Plain Language Action and Information Network (“PLAIN”), includes among its techniques for writers the use of “short sentences” and “common, everyday words” (PLAIN, 2021). Similarly, the SEC’s “Plain English Rule” is defined by six principles, the first two of which are “short sentences” and “definite, concrete, everyday language” (SEC, 1998b). And the Oxford Guide to Plain English’s first two guidelines that pertain to style—the guidelines immediately after “Plan before you write” and “Organize your material...”—concern sentences and words: “Over the whole document, make the average sentence length 15-20 words;” and “Use words your readers are likely to understand” (Cutts, 2020).

In this paper, we use quantitative measures of sentence length and word difficulty to evaluate some of the documents identified on the PLAIN website as good models of plain writing. But rather than combining sentence measures and word measures into a single readability score—a single score that is of little use to individual writers trying to make their writing plainer—we take the simple step of keeping each measure separate; we entertain the possibility that disjoined measures might be more illuminating and helpful to writers. We find, for example, that a text belonging to a domain (academic philosophy) oftentimes charged with jargon, does not use extremely difficult words, although it does have long sentences. Using these two separate measures, we reveal among PLAIN’s exemplars a degree of variation that complicates current understandings of plain writing. Furthermore, in order to understand better what plainness is in all of its variety, we position PLAIN’s different exemplary documents in relation to other documents written in other kinds of relatively accessible English (The New York Times, Voice of America Special English, and Wikipedia) and one academic document belonging to a genre perceived to be difficult (mentioned above). We propose that quantitative measures complement current approaches to plain writing and that advancing our knowledge about plain writing will require a better sense of the different types of plainer English.

2 The Problem with Existing Readability Measures

Plain language advocates have described several limitations to classic readability measures from the mid-twentieth century, including the Flesch-Kincaid formula. These measures, originally designed to measure children’s reading abilities, do not accurately measure the reading abilities of adult information consumers. They also generate one-size-fits-all scores regardless of audience; worse, these scores do not typically give writers helpful guidance toward improving a piece of writing through revision. Most of all, for modern proponents of plain writing, readability formulas fail to take into account all of the non-prose elements of websites and other documents. These include the organization of information, the use of headings, tables of contents, layout and formatting, visuals, and so on (Redish, 2000; Redish and Selzer, 1985). Therefore, although readability measures have in the past been used to evaluate the accessibility of government documents, such measures are not mentioned in either the Plain Writing Act of 2010 or the SEC’s Plain English Rule of 1998.

Existing quantitative approaches have additional limitations. They prove brittle in practice: most formulas measure a word’s accessibility using the word’s length in syllables or characters. The problem with this method is that many common words are long and many rare words are short: “international,” “communication,” “relationship,” and “en-
tertainment” are far more likely to be understood than “mien,” “feign,” “pang,” “dote,” and “cinch.”

The methods are also vulnerable to gaming (Redish, 2000). For example, Flesch-Kincaid readability scores can be raised by replacing lengthy words with acronyms. For example, an Internal Revenue Service (IRS) form designer describes replacing “self-employment tax” with “S.E. tax” in order to “improve” the document’s readability score (National Public Radio, 2016).

More recent measures such as Lexile (Stenner, 1996), which use word frequency in reference corpora to measure word difficulty, solve some of the problems with earlier methods. But corpus-based measures of word difficulty bring with them new problems. One is the problem of estimating the difficulty of words that do not occur in the reference corpus.

A second problem is that Lexile and other formulas provide users with a single statistic. Quantitative measures of readability use two lists of numbers: the lengths of the document’s $m$ sentences ($l_1, l_2, \ldots, l_m$) and the familiarity (or difficulty) of the document’s $n$ words ($r_1, r_2, \ldots, r_n$). Flesch-Kincaid and Lexile scores are linear combinations of two statistics, one involving sentence lengths and another involving word difficulties.3 But writers would benefit from finer-grained information than a summary score: whether their sentences could be more concise, or their vocabulary could be more commonplace, or both. It is for this reason that we disjoin the two components of popular readability formulas.

Third, today’s measures penalize the judicious, infrequent use of technical terms. Because extremely rare words naturally occur in many genres, including documents that are required to be written in plain language, penalizing a document for having a few isolated rare words—as Lexile’s averaging does—is unhelpful. For example, extremely rare words naturally occur in documents devoted to defining unfamiliar terms; countless plain language documents are devoted to this kind of explanatory, definitional work. An article written in plain language describing a coronavirus naturally uses the word “coronavirus.” Such an article should not be penalized in proportion to the negative (log) frequency of the word. Indeed, such an article’s use of the word should not be penalized at all.

Even when a document is not defining an unfamiliar term, penalizing a plain language document for an isolated rare word can be counterproductive. Technical terminology or the linguistic norm of “tecnicity” is not only an inevitable part of informational discourse, but oftentimes necessary for communicating ideas and communicating them comprehensibly (Guillory, 2004). Failing to mention that a technical term is often used to describe an item would be irresponsible since the reader may, in practice, only encounter the technical term. For example, a plain language description of how to ship goods overseas should be encouraged to mention that a list of goods for transport is called a “bill of lading,” even though the word “lading” is spectacularly rare. To the extent that penalizing documents for exhibiting technicity encourages writers to avoid technical terms, received measures of plain language can inadvertently promote less comprehensible prose. In general, there is a strong case that none of the existing quantitative measures really encourages writing that is “plain” or easier to read.

3 Methods

We gather machine-readable versions of plain language exemplars featured on the US government’s plainlanguage.gov website (maintained by PLAIN) as well as reference documents whose language is generally known (e.g., New York Times articles). For each document, we describe two empirical distributions: the distribution of sentence lengths and the distribution of word difficulties.

Note that we work with distributions and not summary statistics. Lexile, Flesch-Kincaid, and other familiar measures use averages of sentence- or word-level measurements of sentence complexity and vocabulary difficulty.

3.1 Features

Sentence lengths. We identify distinct sentences in machine-readable texts using a rule-based English language sentence tokenizer distributed with the NLTK software (Bird et al., 2009). We use the particular rule set which is distributed with version 3.5 of the software. These rules, derived from training on the WSJ portion of the Penn Treebank, have not changed since August 2013.

In order to arrive at a word count for each sen-
ence, we first tokenize the sentence using the Moses tokenizer (Koehn et al., 2007). We then remove all tokens that are not words. We define a word as a token which has characters in the following set: Unicode letters and the hyphen, with optional initial apostrophe (regular expression "‘?\p{Letter}’-+”). This definition is aligned with the Moses tokenizer, which preserves hyphenation and splits contractions. The number of tokens that remain after removing non-words is the sentence’s length.4

There are, of course, other tokenizers and other methods for identifying distinct sentences. We use established methods to facilitate others reproducing our results.

Word difficulties. We follow the existing practice of measuring the accessibility of a word by how frequently it appears in a large reference corpus. To facilitate comparison we report all frequencies as frequencies per 1 billion tokens. To transform our measure to a measure of inaccessibility we multiply by −1.

For our reference corpus, we use the English language portion of the New Crawl corpus, published in association with the ACL’s Third Conference on Machine Translation (WMT18). This corpus covers 11 years (2007-2017) and is inspired by and is a larger version of the “LM1B” language evaluation corpus (Chelba et al., 2014). After discarding duplicate sentences, we tokenize the corpus using the Moses tokenizer. This yields a corpus of 3.2 billion tokens (6.4 million types).

If a token is among the most common 100,000 types, we report its frequency per billion tokens as the measure of its accessibility. Otherwise, we estimate its frequency using regularized linear regression. Using such a model allows us to make serviceable estimates of the frequency of arbitrary tokens, including tokens which do not appear in the News Crawl corpus. Despite the corpus’s size, countless technical terms are absent, as are neologisms introduced after 2017. This model takes as input the token’s length in Unicode code points, its byte unigrams, byte bigrams, and byte trigrams. In calculating byte n-grams, we use UTF-8 encoding. The model outputs the token’s estimated log frequency per 1 billion tokens. Additional details appear in Appendix A.

For the reasons described above, in this paper we avoid using summary statistics and report empirical distributions of these two features for each analyzed document.

3.2 Documents

Plain language exemplars The US government’s website dedicated to the Plain Writing Act, www.plainlanguage.gov, offers the following documents as models of plain language documents. Given the context—a website designed to educate government officials on how to produce writing that conforms to the Plain Writing Act—we think it is appropriate to treat these documents as exemplars and not, say, marginal instances of documents conforming to the principles of the Act.

Several of the documents we use are available in the form of page images (PDFs). To reduce the labor required to transcribe text from page images, we randomly sample parts of documents. The specific sampling strategy is mentioned alongside the description of each document.

1. The 9/11 Commission Report by the National Commission on Terrorist Attacks (1,911 words). Published in 2004, the report describes events leading up to the September 11, 2001 attacks in the United States. We sample sections uniformly at random and collect paragraphs within each section.

2. Draft Grazing Manual by the Bureau of Land Management (915 words). Published in 1997, the section, “Range Improvements,” is featured on the PLAIN website. It describes regulations concerning physical improvements to lands grazed by domestic livestock or wild animals. We use the entire section.

3. National Park Service Museum Handbook, Part II by the National Park Service (1,654 words). Published in 2000, the Handbook describes how to manage National Park Service museum collections. We randomly sample sections. The handbook features technical language specific to museum operations (e.g., “archival,” “deaccessioning”).

4. Oak Ridge Reservation Annual Site Environmental Report by the Department of Energy (1,654 words). Published in 2016, the 506-page report describes the results of environmental monitoring at the Oak Ridge Reservation (ORR) in Tennessee. The ORR hosts

4For an implementation of the Moses rule-based tokenizer, we use the sacremoses Python package.
facilities associated with the maintenance of US nuclear weapons. We sample sections at random.

5. A Plain English Handbook by the Securities and Exchange Commission (1,969 words). Published in 1998, the 83-page Handbook describes “well-established techniques for writing in plain English.” The manual itself obviously uses the style and techniques it recommends, which is why we have included this document. We sample sections at random.

Reference documents

1. Voice of America Special English (2,243 words). Five articles randomly sampled from published articles on the Voice of America News in Special English website, https://learningenglish.voanews.com/. Texts written using VOA Special English, the most widely used successor of Basic English, use a vocabulary of about 1,500 words.

2. New York Times (1,783 words). A random sample of four Arts and Music section articles from The New York Times. Articles were truncated to 500 words. This sample is included as an example of writing addressed to general audience with considerable formal education.

3. Wikipedia (2,160 words). We gather paragraphs from five randomly sampled articles in the WikiText-2 corpus of “Good” and “Featured” articles (Merity et al., 2016). The articles selected are Xenon, USS Illinois, Mount Jackson, The Moth (TV episode), and Krak des Chevaliers.

4. Academic philosophy (2,025 words). We sample sections at random from Bodies that Matter (1993) by Judith Butler. We include this document as an example of non-plain writing. We considered several academic philosophy texts. Butler’s text featured distinctly longer sentences.

Although some of the reference texts are aggregations of several documents, we refer to these aggregations as “documents.”

4 Results

Figure 1 shows the distribution of sentence lengths and word difficulties for each analyzed document. All distributions exhibit positive skew. Sentence length distributions in the reference texts align well with prior expectations about document plainness. Word difficulty distributions in the reference texts are less distinctive but also roughly align with prior expectations. Plain language documents feature sentences which are shorter than those found in academic philosophy.

Sentence length and word difficulty distributions for the plain language exemplars vary with no consistent pattern. For example, the National Park Service Museum Handbook tends to use much shorter sentences than Wikipedia and the New York Times. At the same time, the Handbook’s words are not distinctly more accessible.

Two plain language exemplars, the SEC Plain English Handbook and the Oak Ridge Environmental Report, clearly differ in their use of short sentences and everyday vocabulary. 75% of sentences in the SEC Handbook use 20 words or fewer. In the Oak Ridge Report, only 52% of sentences have 20 words or fewer. The SEC Handbook uses much more accessible language. Ignoring instances of most common 500 words, 75% of words in the Handbook appear at a rate higher than 48,600 per billion tokens \( \log(48600) \approx 10.79 \). (Familiar words occurring at this rate are “easily” and “require.”) In the Oak Ridge Report, only 58% of words occur at similar rates.

5 Discussion

Our analysis indicates that writers needing to comply with the Plain Language Act can benefit from focusing on their sentences. With the exception of the National Park Service Museum Handbook, the documents that model plain writing according to PLAIN are less plain in terms of sentence length than our Wikipedia samples. Now it is possible that vocabulary simplicity causes longer sentences; this is typically true of writing in some controlled vocabulary languages, like Basic English, where sentences can run abnormally long (Igarashi, 2015). But we have found among our documents that the Voice of America Special English sample has the most commonplace words and shorter sentences, and the document with the longest sentences (the Oak Ridge Reservation Annual Site Environmental Report) also uses the rarest words. A preliminary recommendation, then, is that government agencies aiming to write plainly use shorter words—an achievable goal. A future area of research would be
to examine further the relationship between word rarity and sentence length with a larger sample of exemplary and reference documents.

In terms of vocabulary accessibility, the SEC Plain English Handbook is indeed exemplary, a valuable benchmark for other federal agencies striving to write in plain language. Its stylistic recommendations for translating abstract and obscure financial terminology form a helpful model for agencies writing about other subjects and domains (SEC, 1998a). Controlled vocabularies can also prove to be useful guides toward plain writing: in particular, Voice of America’s Special English strikes a good balance between vocabulary familiarity and sentence brevity. The style of the Oak Ridge Reservation Annual Site Environmental Report warrants reconsideration as an illustration of plain writing. We also hope to refine further our measure of word difficulty so that it is most useful for government employees.

A future line of inquiry would also consider how plainness manifests differently in different genres of informational writing. For example, do handbooks and manuals (e.g., the National Park Service Museum Handbook and the SEC Plain English Handbook) tend to exhibit briefer sentences than reports (e.g., the Oak Ridge Reservation Annual Site Environmental Report)? Our current findings are suggestive but not conclusive on this matter. But one hypothesis is that manuals and handbooks for practical purposes achieve sentence brevity more easily, whereas reports and other retrospective accounts have longer sentences due to these genres’ goal of a comprehensive account.

Theoretical humanistic writing, although much maligned for the use of jargon and other difficult words (Culler and Lamb, 2003), also merits further investigation. Our sample of philosophical academese (Butler’s Bodies that Matter) features rare terms less frequently than our Wikipedia sample and, surprisingly, at a similar rate as three plain writing exemplars (the National Park Service Museum Handbook, the Draft Grazing Manual, and the Oak Ridge Reservation Annual Site Environmental Report). According to our findings, Butler’s writing is marked not by the use of jargon but rather by long sentences.

Finally, perhaps what we are dealing with is plainer writing rather than plain writing. Plainness is not a single, fixed quality possessed by any document but rather an ideal that different documents approach in various ways and with different
resulting textual features. Also, what seems unquestionably plain for one audience may not be plain for another. And, as we have seen, several documents deemed to represent plain writing are in fact quite variable in two of the enduring stylistic indicators of plainness, sentence length and word difficulty. Writing oriented to the plainness ideal and therefore made plainer than it would have otherwise been (hence all the before and after examples found in discussions of plain language) generates varieties of plainer writing.

A Estimating Word Frequencies

We follow the existing practice of measuring the accessibility of a word by how frequently it appears in published writing. Although this practice sounds easy to implement, doing so is complicated by the need to make estimates of the frequency of arbitrary words, including rare words, proper nouns, and neologisms. For high frequency words, estimates derived from frequencies in large corpora of...
everyday texts (e.g., newspapers, magazines, general interest books) are serviceable. For many other words, this approach is not viable. Uncommon technical terms and proper nouns which appear in dictionaries are frequently absent from even the largest corpora. Neologisms and rare plural forms (e.g., *crowdfundings*, *virtuosas*) may not appear in dictionaries or large corpora but surely merit being assigned estimated frequencies higher than random character strings.

We solve this problem by using a simple model to estimate the frequency of uncommon words. We use regularized linear regression, also known as ridge regression, to predict a word’s frequency per billion tokens. We extract the following features from the token: length in Unicode code points, byte unigrams, byte bigrams, and byte trigrams. The model is trained to predict the token’s log frequency.

We train the model using token frequencies for all types which occur at least 50 times per billion tokens, reasoning that the News Crawl corpus contains a variety of incidental corruptions which we do not wish to model. We also exclude from the training data the most common 50,000 types, reasoning that the characters of extremely common words are not useful in predicting the frequency of rare words. We verify the model produces reasonable estimates by holding out 10% of the training data and asking the model to predict the log frequency of the held-out types.

The chief flaw with this particular approach is that it relies on a relatively homogeneous corpus of news articles. Words which tend to appear in news articles have inflated frequencies (e.g., *said*). Regularized linear regression also inflates the frequency of extraordinarily rare tokens (e.g., rare technical terms). Neither of these flaws is consequential in the present context. To study plain language we only need a general sense of how frequently a given word appears in everyday use.

Although the model is of token frequency, we only ever use frequencies of words. As described earlier in this paper, we define a word as a token which consists primarily of Unicode letters.
Word Discriminations for Vocabulary Inventory Prediction

Frankie Robertson
University of Jyväskylä
frankie@robertson.name

Abstract

The aim of vocabulary inventory prediction is to predict a learner's whole vocabulary based on a limited sample of query words. This paper approaches the problem starting from the 2-parameter Item Response Theory (IRT) model, giving each word in the vocabulary a difficulty and discrimination parameter. The discrimination parameter is evaluated on the sub-problem of question item selection, familiar from the fields of Computerised Adaptive Testing (CAT) and active learning. Next, the effect of the discrimination parameter on prediction performance is examined, both in a binary classification setting, and in an information retrieval setting. Performance is compared with baselines based on word frequency. A number of different generalisation scenarios are examined, including generalising word difficulty and discrimination using word embeddings with a predictor network and testing on out-of-dataset data.

1 Introduction

Given a small sample of words, how well can we predict whether a learner knows some out-of-sample word? This is the task of vocabulary inventory prediction. A clear motivation for the topic is to enable quicker and more precise placement testing. For example, a 40 word self-assessed word knowledge quiz used as a benchmark in this paper is quick enough that an L2 learner returning to a language learning app after a long break, in which they may have either forgotten a lot or had a lot of extra exposure to their target language, can be placed again quickly without excessive disruption.

This paper addresses the following research questions:

1. What are the empirical differences in performances between difficulty parameters produced by estimation of Item Response Theory (IRT) models and those based on word frequency in terms of their application to vocabulary inventory prediction?

2. How well can the IRT parameters of difficulty and discrimination be regressed based on word embeddings?

3. Which approaches from the field of Computerised Adaptive Testing (CAT) help to select good items to query? Does the addition of a discrimination parameter help with question selection?

4. Does the addition of a discrimination parameter help with the final prediction step?

2 Related Work

Milton (2009) refers to the common assumption when quantifying vocabulary acquisition that words are learnt in approximately descending order of frequency as the frequency assumption. It has been used in the field of reading research, for example in estimating vocabulary size, but can also provide a simple baseline for the task of vocabulary inventory prediction.

Avdiu et al. (2019) approached the problem through feature engineering, taking frequency profiles of different genres and associating learners with them according to their responses. They used a large section of the data for training, without testing a scenario in which learned data is to be generalised to new learners with less data available, as in this paper.

Item Response Theory (IRT) (Tatsuoka et al., 1968; Baker, 2001) is widely used to determine item difficulties and examinee ability in academic assessments. A key drawback of traditional IRT is that the actual content of the items is ignored. Instead, items are only understood in terms of their responses. This leaves no possibility of generalising item parameters to unseen items. Recent work
has begun to generalise difficulty scores based on representations based on items’ textual content using deep neural networks. For example Benedetto et al. (2021) first fit an IRT model on questions from a cloud technology certification exam, before training a transformer model to regress the resulting difficulty scores, allowing generalisation to new questions without a pre-testing stage.

Ehara (2019) approaches the problem of vocabulary prediction by fitting a Rasch (1960) model, equivalent to a 1-parameter logistic IRT model. The problem was modelled such that an equivalent neural network was constructed which included features based on Glove (Pennington et al., 2014) word embeddings. As with Avdiu et al. (2019), a single stage of training was performed so that the ability of the learners was learnt simultaneously with the weights of the prediction network. This network did not beat a word frequency and logistic regression baseline. In this paper, a 2-parameter logistic IRT model is fitted as an initial step, before proceeding to generalise these parameters using a word embedding based regressor.

Computerised Adaptive Testing (CAT) (Lord, 1977; Wainer, 2000) has not been widely applied to the task of vocabulary inventory estimation. A CAT system selects questions based on a examinee’s previous answers in order to converge on an accurate ability estimate faster. Related, but outside of CAT/IRT setting, Ehara et al. (2014a) builds graphs made from a combination of multiple corpora combined and apply label propagation to find a fixed set of queries to in-effect give a more accurate ability estimate than choosing at random. Restricting ourselves to the adaptive setting, the main prior art is the website http://testyourvocab.com/, which uses CAT to estimate vocabulary size based on word frequencies. To the best of the author’s knowledge, there is no prior work attempting to quantify how accurate the ability estimates obtained when applying CAT to the problem of vocabulary inventory estimation are.

3 Method

3.1 Datasets

Three datasets are used in this paper. The first, SVD12K, is due to Ehara et al. (2012) and contains 12 000 words rated on a 5-point scale by 16 learners of English, most of whom have Japanese as their native language. Following Ehara et al. (2014b), the first learner is discarded due to lower quality data. The learners in SVD12K were all students of the University of Tokyo and we speculate that it is quite possible they have all learnt English for similar purposes, i.e. academic usage, and may have even attended the same English classes.

The other two datasets are used as additional test sets, so as to see how well the techniques generalise beyond the potentially rather narrow distribution of SVD12K. Both of the two extra datasets are constructed such that they should be mainly composed of learners with Japanese as their L1, i.e. testing of generalisation beyond learner L1 is not considered here. Ehara (2018) introduce EVKD1, a dataset consisting of responses to a 100 word 4-way multiple choice test given to 100 participants, administered using a Japanese crowdsourcing platform. Respondents were asked to choose the correct definition of a word given in a context sentence. The final dataset is a section of responses to the website TestYourVocab\(^1\) limited to responses from 2018 by participants who selected their country as “Japan”. This dataset has a different selection of responses for each person.

3.2 Fitting an IRT Model

Given a matrix of responses \( r_{i,j} \) indexed by items \( i \) and respondents \( j \), an IRT model predicts latent features of the items and respondents. Respondents are assigned abilities \( \theta_i \), while in 2-parameter IRT models, items are assigned difficulties \( a_j \) and discriminations \( b_j \). Typically we predict binomial responses based on an Item Characteristic Curve

\[ a_j \sim \mathcal{N}(1.2, 0.25) \]
\[ b_j \sim \mathcal{N}(0, 1) \]
\[ \theta_i \sim \mathcal{N}(0, 1) \]

Figure 1: Plate diagram showing the Bayesian network corresponding to the 2-parameter logistic IRT model.
(ICC) like so:

\[
ICC_j(\theta) = \left(1 + e^{-a_j(\theta - b_j)}\right)^{-1}
\]

\[
P(r_{i,j}|\theta_i, a_j, b_j) = ICC_j(\theta_i)
\]

\[
Q(r_{i,j}|\theta_i, a_j, b_j) = 1 - ICC_j(\theta_i)
\]

The data of Ehara et al. (2012) is rated on a 5-point scale, suggesting a graded IRT model. A typical formulation may try and learn separate difficulty and discrimination parameters per item-level pair, significantly increasing the number of parameters to be learnt. In order to reduce the amount of data necessary to fit the IRT model, we learn only one difficulty discrimination per item and create fixed global offsets \(l_{1...s} \geq 0\) to create offset difficulties for the thresholds. We then model:

\[
P(r_{i,j} \geq k|\theta_i, a_j, b_j) = ICC_j(\theta_i - \sum_{s=1}^{4} l_s)
\]

And note that:

\[
P(r_{i,j}^* = k) = P(r_{i,j}^* \geq k) - P(r_{i,j}^* \geq k + 1)
\]

\[
P(r_{i,j}^* \geq 1) = 1
\]

\[
P(r_{i,j}^* \geq 6) = 0
\]

We estimate the Maximum A Posteriori (MAP) with Stan (Carpenter et al., 2017). The priors are illustrated alongside Figure 1. After fitting the model we revert to considering the binominal case by defining \(P(r_{i,j}) := P(r_{i,j}^* = 5)\).

### 3.3 Frequencies as a Difficulty Baseline

A simple frequency baseline for difficulty was constructed based on the word frequencies of the wordfreq (Speer et al., 2018) library. The wordfreq library incorporates frequencies from multiple corpora of different registers, ensuring balanced coverage by taking equal contributions from each register after removing outliers. Internally, wordfreq stores log frequencies on an 800 point scale. These are first negated and then standardized according to their mean and standard deviation based on the words in the SVD12K dataset so that they lie in the same range as the IRT difficulties.

To the best of the author’s knowledge, given good frequency data, this baseline has not yet been significantly surpassed on this task in the setting where there are only a small number responses available from the learner, making it effectively state-of-the-art.

### 3.4 Generalising IRT Item Parameters

In order to generalise the difficulty and discrimination parameters beyond the words present at IRT model estimation time, a Multi-Layer Perceptron (MLP) was trained as a regressor for both parameters. Words are input to the network as Numberbatch 19.08 (Speer et al., 2017) embeddings. These 300 dimensional embeddings, based on lemmas rather than word forms, are constructed by combining multiple distributional word embeddings with information from the ConceptNet lexical knowledge graph. They were chosen because most vocabulary tests are either based on lemmas or word families rather than word forms, and because they have performed well in previous studies.

The architecture shown in Figure 2 was implemented using PyTorch (Paszke et al., 2019). The GeLu activation function (Hendrycks and Gimpel, 2016) and BatchNorm (Ioffe and Szegedy, 2015) are used as non-linearities. Since full batch training is used here, the BatchNorm damping parameter, which is intended to stabilise random variations in minibatches, is not used. The Adam optimizer (Kingma and Ba, 2015) was used with a learning rate of 0.003. Training was performed for 50 iterations and the best iteration on the validation set created by 1:11 validation:train split was chosen.

### 3.5 Computerised Adaptive Testing

The aim of Computerised Adaptive Testing (CAT) (Lord, 1977; Wainer, 2000) is to estimate a learner’s ability parameter \(\theta\) as accurately as possi-
ble with as few queries as possible. Key parts of a CAT system are initialisation, next item selection, and \( \theta \) estimation. After initialisation, the system repeatedly queries a new item from the learner and re-estimates \( \theta^* \) until a termination condition. Here, we terminate after having made 40 queries, and always initialise \( \theta^* \) to be 0.

Next item selection rules are typically formulated as choosing an next item so as to maximise some measure of merit. Here we consider the maximisation of Fisher information introduced to the field of CAT by Lord (1977), and denoted as Max-Info. For the 2-parameter logistic IRT model the Fisher information is defined as:

\[
I_j(\theta) = a_j^2 ICC_{a_j,b_j}(\theta)(1 - ICC_{a_j,b_j}(\theta))
\]

An alternative next item selection rule is due to Urry (1970), and denoted as such, and simply picks questions close to the current estimate of \( \theta \). Note that this is equivalent to the max entropy heuristic in active learning, which queries the data point about which the current version of the classifier is most uncertain.

There are two approaches for estimating \( \theta^* \). The first, denoted Full-ICC, starts from a binomial IRT model introduced in Section 3.2 and incomplete response data \( U = \{u_{ij} \mid j \in J, u_{ij} \in \{0,1\}\} \). We then obtain \( \theta^* \) by maximum likelihood estimation:

\[
\mathcal{L}(\theta) = \prod_{u_{ij} \in U} P(r_{ij} \mid \theta, a_j, b_j)^{u_{ij}} \times Q(r_{ij} \mid \theta, a_j, b_j)^{(1-u_{ij})}
\]

\[
\theta^* = \arg \max_{\theta} \mathcal{L}(\theta)
\]

The second, denoted Difficulty Only, ignores the discriminations of the items, which is equivalent to setting all \( a_j = 1 \). Substituting the resulting \( ICC \) expressions into the likelihood reveals an equivalence with logistic regression. Namely, after fitting a logistic regression model on the responses \( U \), we get a model with coefficient \( m \) and intercept \( c \). We then find that \( \theta^* = -\frac{c}{m} \).

In early iterations, there may only be positive or negative responses. In this case we apply the method of Dodd (1990), which averages the previous theta estimate with either the maximum or minimum item difficulty value depending on the direction in which \( \theta^* \) would otherwise diverge.

As a non-CAT baseline, there is stratified random selection, denoted Rand. In order to guarantee a reasonable range of item difficulties are asked, strata for the words are created by ordering by frequency and splitting into 5 equal sized strata. The random selection procedure then chooses 40 items randomly, taking equally from each stratum.

The catsim Python library (De Rizzo Meneghetti and Aquino Junior, 2017) is used for the implementations of all CAT techniques.

### 3.6 Evaluation

The vocabulary inventory prediction task can be viewed as a binary classification problem. The Receiver Operator Characteristic (ROC) curve plots the recall of the positive class against the recall of the negative class by varying the classifier threshold. Statistics based on ROC curve, such as Area Under ROC (AUROC) enjoy the key advantage of threshold invariance. On the other hand, we typically do have to pick some threshold and for this reason, a metric based on a default threshold of 0.5 is given: Matthews Correlation Coefficient (MCC). The second angle on the problem that is of known and unknown word retrieval. In this case Average Precision (AP) acts as a threshold invariant measure of retrieval performance. We consider AP+ and AP- for measuring retrieval performance from the two classes of known and unknown respectively.

AUROC does not change significantly based on exact ability estimate of the learner due to its lack of a fixed threshold. Here, we use it only to explore different ways the difficulty parameter can be obtained and the effect of including the discrimination parameter. Being based on a fixed threshold, MCC is highly sensitive to the actual ability estimate, and so it gives a more realistic picture of performance practically. The metrics AP+ and AP- are used to measure an upper bound on the performance on the retrieval tasks.

Intuitively, we can see low values of discrimination as reflecting a degree of uncertainty about a word’s true difficulty. The information retrieval perspective is particularly relevant here since the presence of the discrimination parameter means that, for example in unknown word retrieval, words that are highly discriminating but less difficult could be returned earlier than words with low discrimination that are more difficult, potentially improving performance.

### 4 Experiments

We first evaluate how well the item/word parameters from the IRT model can be regressed with
Table 1: Table containing the both the raw Mean Absolute Error (MAE) and the MAE normalised by the true standard deviation of difficulties and discriminations as predicted in two word generalisation scenarios.

the chosen architecture. Next we move on to consider how well various CAT approaches can estimate learners’ abilities. Finally, the results for the final task of vocabulary inventory prediction are presented, first cross validating on the SVD12K dataset and then training on the whole SVD12K dataset and testing on the extra datasets.

Four generalisation scenarios are considered across experiments:

**Gen-None** No generalisation; The IRT model is fitted on the same data as the test data.

**Gen-Word** Generalising only to new words; 3-fold cross validation is performed on words, with the IRT model being fitted on $\frac{2}{3}$ training words, before fitting the MLP on the results to predict the out-of-vocabulary $\frac{1}{3}$ of words.

**Gen-Respondent** Generalising only to new learners; 3-fold cross validation is performed on participants, with the IRT model being fitted on $\frac{2}{3}$ participants, from which the item parameters are used as-is on the out-of-sample $\frac{1}{3}$ of participants.

**Gen-Both** Generalising to new words and learners; 9-fold cross validation is performed, consisting of the product of 3-fold cross validation on participants with 3-fold cross validation on words.

### 4.1 Predicting Item Parameters

Table 1 gives the results evaluating the performance of the IRT parameter regressor. When looking at the results normalised by true standard deviation, it is clear that the parameter of discrimination is more difficult to predict. The lower error in predicting difficulties in the Gen-Words scenario suggests that the more accurate IRT predictions made with more data do indeed provide an easier target for the network to fit. However, the actual errors are quite close, and the generalisation scenarios tend to give similar results, so for this reason Gen-Words is not considered further in the later results.

### 4.2 $\theta$-estimation

We now turn to the matter of how well $\theta$ is estimated using different approaches. The results are shown in Table 2.

For both next item selection methods and $\theta$-estimation methods, including the discrimination parameter seemed to decrease performance. Noteworthy is that the best overall score is obtained by difficulty-based CAT for the Gen-Both and Gen-Resp, with this setting in the Gen-Both scenario outperforming the others, showing that the regressed word difficulties perform well for this task. For the Gen-None scenario, including the full ICC when estimating $\theta$ appeared to help. It may be that having non-regressed discrimination values based on responses from more respondents helped in this case.

However, since discriminations appear to not be generally useful for finding $\theta$ in any generalisation scenario, they are not used further in the next section and the Urry (1970) next item rule is used together with the difficulty only $\theta$ estimator.

### 4.3 Vocabulary Inventory Prediction

We now evaluate the final task of vocabulary inventory prediction. Table 3 shows the results on this task using the metrics introduced in Section 3.6. The experiments compare the use of dif-

4.4 Generalising Vocabulary Inventory Prediction

We now turn to a scenario in which all the data from the SVD12K dataset is used for training, equivalent to the Gen-None scenario, but the resulting item parameters are tested on external datasets. We test on the EVKD1 data set and TestYourVocab dataset introduced in Section 3.1. The results are given in Tables 4 & 5.

Since the EVKD1 set is a 4-way multiple choice test, we account for correct answers by guessing by using an item response curve with a guessing probability of $0.25$, similar to the 3-parameter logistic IRT model:

$$ICC_{a_j,b_j}(\theta) = 0.25 + \frac{0.75}{1 + e^{-a_j(\theta_j - b_j)}}$$

Since there is a limited number of training words available in these datasets, in these experiments, no CAT is used, and instead the difficulty parameter is estimated based on 40 words taken at regular intervals from the frequency ranked list. There are three generalisation scenarios: $Freq$, where only frequency data is used; $Pred$, where only predictions from the generalisation model are used; and $Mix$, where item parameters are used directly from the IRT model fitted on SVD12K where possible, falling back to predictions when items available in SVD12K. Other variations are as in Section 4.3. For both datasets, frequency based difficulties outperform difficulties estimated from SVD12K, suggesting these do not generalise well to other datasets. The inclusion of the discrimination parameter appears to have a consistent small negative effect across all these experiments.
5 Discussion

We now summarise and discuss some of the main results of the experiments. Firstly, the discrimination parameter does not appear to help with query item selection, however it remains somewhat inconclusive whether it can help with estimating the learner ability \( \theta \) since this was the best configuration in the Gen-None case. It may be that with sufficiently high quality estimates of the discrimination values, using this for \( \theta \)-estimation would help more. The approach which appeared best overall in this case however, and which was used for later experiments on the SVD12K dataset ignored the discrimination parameter altogether for both steps of the CAT stage.

The difficulty parameter generalises reasonably well, while the discrimination parameter generalises quite poorly when regressed using a MLP based on Numberbatch representations of the word items. Since item difficulty here is closely related to frequency, it seems quite possible that a lot of the generalisation is happening based on frequency information encoded in the word embeddings. When considering how well both parameters generalised, we should note that only one type of word embedding and regressor was tried, and others may generalise this parameter better.

The regressed difficulties perform better than the frequency data on in-dataset data, while performing worse on out-of-dataset data. Given all datasets contained mostly Japanese learners of English, this suggests that both the IRT parameter and the MLP generalising may have over fitted on narrow attributes of the particular cohort of University of Tokyo students making up SVD12K. Conversely we see that that high quality, balanced word frequency data generalises rather well.

Usage of the discrimination parameter for vocabulary inventory prediction was largely inconclusive, with some evidence against it. In many cases, it appeared to decrease performance on metrics such as AUROC, however some tasks showed a promising but insignificant boost in AP-

It is unclear exactly why the discrimination parameter failed to provide significant improvements in either next-item selection, \( \theta \)-estimation or vocabulary inventory prediction. It is possible that the amount of response data was not sufficient either in terms of the number of respondents, or in terms of representing a diverse range of abilities, to obtain accurate word discrimination estimates. Apart from simply finding and integrating more vocabulary knowledge data, one direction for future work is trying to find corpus derived measures which correlate with word discrimination, analogously to the negative correlation between word frequency and word difficulty. This would also effectively address the failure to generalise the word discriminations parameter to out of vocabulary words.

We hope the methods of evaluating the different sub-tasks of the vocabulary inventory prediction task in the settings demonstrated here can help establish practices for evaluating this task more thoroughly. We also hope that the framing given here inspires others to tackle the problem in the challenging, but more broadly applicable setting of vocabulary inventory prediction having a small, limited number of queries.

The code to replicate all experiments is made available at https://github.com/frankier/vocabirt.

Abstract

Lexical simplification (LS) aims at replacing words considered complex in a sentence by simpler equivalents. In this paper, we present the first automatic LS service for French, FrenLyS, which offers different techniques to generate, select and rank substitutes. The paper describes the different methods proposed by our tool, which includes both classical approaches (e.g. generation of candidates from lexical resources, frequency filter, etc.) and more innovative approaches such as the exploitation of CamemBERT, a model for French based on the RoBERTa architecture. To evaluate the different methods, a new evaluation dataset for French is introduced.

1 Introduction

It is widely acknowledged that reading difficulties, either due to insufficient education or to mental deficiencies for example, can hinder access to information, which is likely to result in a loss of autonomy and freedom (Mutabazi and Wallenhorst, 2020). Faced with this challenge, researchers imagined applying natural language processing (NLP) to automatically transform sentences in a text in order to make it more readable, thus facilitating access to information. This is the objective pursued in the field of Automatic Text Simplification (ATS), in which the main goal is to preserve grammaticality and meaning while carrying out effective transformations to make the text simpler.

ATS is generally investigated at the sentence level (Seretan, 2012; Brouwers et al., 2014) using rule-based systems. In parallel, lexical simplification was also investigated, based on lexicons or resources (Billami et al., 2018; Carbone, 2018; Hmida et al., 2018). Due to the lack of training data, machine translation approaches - which are standard for English - were applied to French (Rauf et al., 2020) only very recently, with mixed results. As a result, the situation of ATS for French is clearly lagging behind that of English. The only simplification package freely available for the research community has been published recently (Wilkens and Todirascu, 2020) and it remains preliminary and focused exclusively on syntax. AMesure, a web platform designed to help writers of administrative texts to write in plain language (François et al., 2020) is more encompassing. However, it is limited to detecting complex phenomena and suggesting simplifications.

In this paper, we aim to fill the gap in lexical simplification (LS) tools and resources for French by developing a tool in which several standard approaches of LS are available and by building a reference dataset to evaluate our results. This library, called FrenLyS for French Library for Simplification, follows the LS process first described...
by Shardlow (2014) as a sequence of four steps: identifying complex terms, generating candidates for substitution, selecting the best candidates, and ranking them according to their degree of readability. Our work draws from similar packages in other languages, such as LEXenstein (Paetzold and Specia, 2015) for English, the EASIER tool (Alarcon et al., 2019) and LexSis (Bott et al., 2012) for Spanish or the work by Qiang et al. (2021).

The article is structured as follows. Section 2 presents the state of the art of lexical simplification. In Section 3, we describe the different approaches we implemented for each of the LS steps. Section 4 describes the methodology used to evaluate our approaches, which includes a new reference dataset for French. In section 5 we report and discuss the performance of each of these approaches on our evaluation dataset.

2 Related Work

The task of lexical simplification was first investigated by Carroll et al. (1998) who exploited a rather simple solution: they obtained candidates for substitution using WordNet synonyms (Miller, 1995) and ranked them according to their frequency. As a result of this work, researchers tried to improve different aspects of this process, either by collecting synonyms (De Belder and Moens, 2010), or by ranking the candidates (Biran et al., 2011a), etc. In his survey of the field, Shardlow (2014) provided a clear view of the different challenges within LS, identifying four steps in which recent work can be classified.

Complex Word Identification The first step in lexical simplification is the complex word identification (CWI). This step has been the object of several shared tasks (Paetzold and Specia, 2016c; Yimam et al., 2018) and aims at identifying in a text the words or expressions likely to be problematic for a target audience of readers and on which the LS system should be applied. As Gooding and Kochmar (2019) pointed out, early works on the complex word identification operated by simplifying all words (Thomas and Anderson, 2012; Bott et al., 2012) or were based on a threshold \( t \) over a given metric of simplicity (e.g. word frequency) that separates simple from complex words (Biran et al., 2011b). Another approach consists in finding complex words with the help of a lexicon: if the word appears in the resource it is considered as complex, otherwise as simple. This method has been mostly used for lexical simplification of medical texts (Chen et al., 2016; Deléger and Zweigenbaum, 2009). Other more recent attempts either used machine learning to classify words as either complex or simple based on some features such as word length, word frequency, number of senses, etc. (Shardlow, 2013; Alarcon et al., 2019).

Substitution Generation Once complex terms have been identified, the next step is to produce candidates that can replace for the target complex word. This step, called substitution generation (SG), is most often carried out querying linguistic lexical resources, as evidenced by the work of Carroll et al. (1998), Bott et al. (2012), or Hmida et al. (2018). They generate synonyms by querying lexical databases such as WordNet or synonym resources such as ReSyf (Billami et al., 2018). As it is not always easy to find lexical databases and as those might have limited coverage, Horn et al. (2014a) proposed to use parallel corpora – Wikipedia and Simple Wikipedia – to automatically extract lexical simplification rules. Deléger and Zweigenbaum (2009) resorted to paraphrases to replace target complex words, a strategy that is more relevant for specialized languages. A currently popular approach was first suggested by Glavaš and Štajner (2015). It consists in obtaining synonyms in an unsupervised way relying on semantic representations such as embeddings. The complex word to be substituted is projected in the semantic space in order to generate the N closest semantic neighbors. More recently, Qiang et al. (2019) used BERT in a similar fashion.

Substitution Selection In order to obtain semantically correct sentences, each candidate has to go through a disambiguation step. The substitution selection (SS) step aims to decide which of the candidates collected at generation step best fits the context of the sentence to be simplified. De Belder and Moens (2012) proposed to carry out the task of disambiguation using a Latent Words Language Model (LWLM): they use Bayesian networks to represent words and their contextual meaning. Other studies took advantage of word sense disambiguation systems to explicitly label the senses of both the target and the candidates, in order to select a candidate having the same sense as the target (Thomas and Anderson, 2012; Nunes et al., 2013). A third line of research leveraged semantic models to compare the semantic similari-
ity of each candidate with the sentence to simplify. Bott et al. (2012) exploited a vector space model, whereas Paetzold and Specia (2015) rather used a word embedding model. It is also possible to perform this step in a simpler way, by removing all candidates who do not share the same part of speech as the word to be replaced (Paetzold and Specia, 2013).

### Substitution Ranking

After having identified the complex words, generated synonyms, and selected the most coherent ones, the final step of LS consists in ranking the remaining candidates according to their reading ease. The first LS systems generally resorted on frequency (Carroll et al., 1998; De Belder and Moens, 2010; Specia et al., 2012) where it is considered that more frequent words are easier to understand. Specia et al. (2012) showed that this simple rule actually represents a very strong baseline, as it outperformed 9 out of the 11 ranking systems engaged in this task of SemEval 2012 (Specia et al., 2012). Other studies proposed simplicity metrics that can be combined word characteristics: Biran et al. (2011a) and Bott et al. (2012) combine frequency with word length. Finally, it is also possible to use statistical ranking algorithms (Horn et al., 2014a; François et al., 2016) that we can combine with neural networks (Paetzold and Specia, 2017a).

### Available datasets

In parallel to the design of new LS methods, the development of reference datasets to train and evaluate those methods is key. Several datasets for lexical simplification are available for English, such as SemEval 2012 (Specia et al., 2012), LSeval (De Belder and Moens, 2012), LexMTurk (Horn et al., 2014b), NNSeval (Paetzold and Specia, 2016b), and BenchLS (Paetzold and Specia, 2016d). Other languages are not so well resourced: there are only 2 datasets for Japanese – SNOW E4 (Kajiwara and Yamamoto, 2015) and BCCWJ (Kodaira et al., 2016) –, but, to our knowledge, none for French. In French, the only available resource for text simplification is the ALECTOR corpus (Gala et al., 2020). It consists in 79 parallel texts with information about complex words, but there are no validated simpler synonyms, which are required to assess LS approaches.

### 3 Proposed Approach

Our system is the first to offer several methods for generating candidates for substitution, selecting them based on semantic similarity with the target word and ranking them by difficulty in French. Most of these methods have been previously applied to English, and we adapted them to the case of French. A few are new. All of them are described hereafter.

It should be noted that FrenLyS does not implement any complex word identification algorithm. We believe this is a very complex task, which should be addressed as a whole and actually is (Yimam et al., 2018), especially because CWI requires to take into account the readers’ characteristics. Methods based on lexical characteristics or word lists overlook the reader’s characteristics and Lee and Yeung (2019) have rightly stressed that current approaches offer the same substitutions regardless of users. This tool is therefore based on the prerequisite that complex words already have been identified. For the sake of the evaluation of our tool, we relied on a manual annotation of complex words in our test set (see Section 4).

### 3.1 Substitution Generation

The task of substitution generation aims to generate candidate synonyms to replace complex words. To carry out this step, FrenLyS proposes three methods: synonyms are directly obtained from a resource of synonyms (see ReSyf generator), or are generated by embeddings, either produced by FastText (see FastText generator) or by the BERT architecture (see CamemBERT generator). We also propose a 4th approach (see CamemBERT union) that combines CamemBERT with Resyf or with FastText to take advantage of the contextual information that the model can provide.

#### ReSyf generator

This module generates candidates from the graduated and disambiguated synonyms resource ReSyF (Billami et al., 2018). It is built from the semantic network JeuxDeMots and contains 57,589 entries that are connected to 148,648 synonyms (both in their lemma form). Its main asset is that synonyms corresponding to different meanings of a word have been manually and automatically clustered into different synsets. Another interesting feature of ReSyF is that the synonyms gathered in the same synset are ranked according to reading ease. Based on those characteristics, our method simply consults ReSyF using the lemma of the complex word and returns the lemmas of the top three simplest synonyms in each corresponding ‘synset’. At this step, we do not try
to disambiguate the meaning of the word to substitute, as this is the role of the substitution selection step.

**FastText generator**  *FastText* (Bojanowski et al., 2017) is a library for efficient learning of word representations. Its advantage for our task is that it proposes character n-gram embeddings: we can thus obtain a vector representation even for a word that does not exist in the training corpus. Thanks to this technique, we return, for any given complex word, its k-nearest semantic neighbors (the inflected forms) based on cosine similarity.

**CamemBERT generator**  In the same way that Qiang et al. (2019) generated synonyms with *BERT*, we rely on a pre-trained version of *CamemBERT* (Martin et al., 2020), based on the RoBERTa architecture, on the French subcorpus of the multilingual corpus OSCAR. Our method employs the masked language model (MLM) that masks some percentage of input tokens and predicts the masked words from their right and left contexts (Qiang et al., 2019). The idea is to mask the complex word and use the top predicted words (inflected forms) as candidate for substitution. As *FastText*, *CamemBERT* proposes a solution to deal with out-of-vocabulary tokens through their decomposition in wordpieces.

**CamemBERT union**  This method is based on the 2 following observations: ReSyf and *FastText* generators only care about the complex word and not its context while *CamemBERT* only cares about the context but does not know the complex word. The solution is to combine the advantages of both approaches by computing the *CamemBERT*-score for each substitute generated by ReSyf or *FastText*. For this purpose, we predicted the n best candidates with the *CamemBERT* generator and the k best candidates for the other method. Then we retain only the words that are in the intersection of the two generators and sort them by their new score.

### 3.2 Substitution Selection

This step takes the list of candidate synonyms and selects only those that are acceptable in the context of the complex word to replace.

We have decided to implement two of the four approaches covered in section 2, as they rely on very different strategies: either by eliminating candidates that do not have the same part of speech (see POS selector), or by leveraging language models such as *FastText* to verify the semantic compatibility between the candidate and the context (*FastTextWord selector, FastTextSentence selector*).

**POS selector**  Following Paetzold and Specia (2013), we decided to include a function within our generation methods that checks whether the generated candidates and the word to be replaced share the same parts of the speech. To do this, we used the possible tags for this word as given in the Delaf dictionary. If the intersection of POS-tags for the 2 words (complex word and candidate) is empty, the candidate is rejected.

**FastTextWord selector**  For each synonym, this selector first retrieves the *FastText* embeddings of the complex word and this synonym and compute the cosine similarity between both vectors. The more similar the meanings of both words are, the closer their vectors are. We therefore select candidates for which the cosine similarity with the complex word is greater than the heuristic threshold of 0.5.

**FastTextSentence selector**  Instead of directly comparing the vectors of the complex words and their synonyms, as in the previous approach, we use the context of the complex word for vectorization: we compute the cosine distance between the vectors of the synonyms and the vector of the complex sentence. We select the candidates with a similarity score greater than the heuristic threshold of 0.35.

### 3.3 Substitution Ranking

Finally, the last part of our system classifies the synonyms according to their degree of reading ease.

For this step, we referred to common ranking methods in the literature (cf. section 2) as we relied on frequency (see Lexique3 ranker) and in a slightly more original way, we provide a method that ranks words according to the number of meanings they have and frequency (see FreNetic ranker). We also propose a method that combines various linguistic prescriptors through an SVMRank algorithm (Herbrich et al., 2000) (see SVM ranker).

**Lexique3 ranker**  For this method, we use the commonly acknowledged fact that the more frequent a word is, the simpler it is. To obtain the

---

1The Delaf (Courtois, 2004) contains about 792,260 entries (inflected forms). For each entry, the dictionary provides the following information: lemma, pos and inflectional information (e.g. dictionaries,dictionary.N).
frequency of the candidates for substitution, we use the French lexical database Lexique3 (New, 2006) which provides, for 140,000 words of the French language, their frequencies of occurrences in literary texts and movie subtitles. We have chosen to use the frequencies estimated on the corpus of film subtitles because it contains a more up-to-date vocabulary.

**FreNetic ranker** In the same way as Elhadad (2006), this ranker exploits polysemy as a measure of familiarity and therefore of difficulty. Words from the general lexicon are more polysemous while technical terms tend to be monosemic. To collect the number of senses, we relied on FreNet², a python API for WOLF (Sagot and Fiser, 2008), a free French Wordnet. Synonyms are therefore ranked according to their number of meanings (more is easier). When several words get the same number of senses, we decide to further rank them based on their frequencies.

**SVM ranker** We also propose to perform the ranking task using a SVMRank algorithm described in François et al. (2016). It is able to rank any set of words using 21 word characteristics such as word frequency, presence of the word in a list of simple words, number of phonemes, number of letters, number of senses, number of orthographical neighbors, etc. To train it, we used the Manulex vocabulary list (Lété et al., 2004) that includes 19,038 lemmas annotated with their level of complexity. Based on that information, we prepared training pairs of two words, one of which is known to be more complex than the other, which were fed to the SVMRank algorithm. In their paper, François et al. (2016) report an accuracy of 77% with 10-fold cross-validation and a mean reciprocal rank of 0.84, obtained on a reference dataset of 40 synsets including a total of 150 synonyms that were ranked by 40 human annotators.

4 Evaluation Process

It is usual to create evaluation corpora with the help of human annotators but this requires time and lots of annotators, which may also overlook some valid synonyms. Therefore, we opted for a hybrid approach, i.e. we chose to use our synonym generation methods to propose an exhaustive list of synonyms and then we called upon annotators to select them in context and rank them according to their difficulty. The advantage of this approach is that it combines several methods from very different generations, including a synonym dictionary that was created from propositions submitted by humans (Lafourcade, 2007). In this way, we still collect data made by humans but *a priori*. We explain the corpus creation process in the next section before discussing the evaluation measures we used.

4.1 A Tailor-Made Evaluation Corpus

We decided to fill the lack of resources evaluation in French LS by proposing a dataset of annotated sentences, collected from two sources. The first set of sentences was sampled from the French reference dataset ALECTOR (Gala et al., 2020): it includes sentences with complex words and candidates for substitution³. Complex words have not been directly annotated in these sentences. However, they were read by various profiles of readers through an interface and reading times have been collected. Based on this information, we have manually identified seemingly complex words. Once the two sets of sentences were collected and the complex words were identified, we had to generate substitutes, and manually select them and classify them, as was described in the following subsections.

**Generate and select candidates** For each complex word, we produced synonyms that we annotated, using all our generation methods. The relevance of these synonyms in the context of the original sentence was then assessed by 3 expert linguists. They had to assign a score of 1 if the word is considered correct, otherwise 0. In this process, we applied the following guidelines : a word is considered synonymous as long as its replacement does not change the meaning of the sentence. To obtain a wide range of synonyms, we decided to accept hyperonyms and hyponyms – provided they fit the context – and to accept synonyms even if their register was different from that of the original word. This task is very complicated since there is no perfect synonymity and the validity of a candidate can therefore be perceived differently from

--²https://github.com/hardik-vala/FreNetic
one annotator to another one. However, thanks to the annotation guidelines and a discussion session between the annotators to discuss the criteria, the inter-rater agreement (Fleiss’ K) between the three annotators, computed on a sample of 500 candidates, is 0.638, which corresponds to a substantial agreement (Artstein and Poesio, 2008).

**Ranking of substitutes** Finally, for this last annotation, we resorted to on 20 non expert annotators aged from 20 to 57 years, whose native language is French. They had to rank the synonyms validated at the previous step by reading ease. To that end, we used the online LimeSurvey tool⁴ to deliver 2 different questionnaires of 25 items. The survey is presented as follows: each question includes a target sentence and the complex word in bold, as well as a list of synonyms in the left column. The task of the participants is to drag all the synonyms into the right-hand column to rank them, the top word being considered the most difficult.

Once all annotations have been collected, we proceed to average all annotators: in the same way as Specia et al. (2012), we assign each substitution a score based on the average of the scores assigned to it.

### 4.2 Evaluation Metrics

To compare our different methods of generation and selection, we used the following metrics as described in Paetzold and Specia (2016a): potential, precision, recall and F1. For the evaluation of ranking methods, we also employ the metrics rank-at-i and recall-at-i as mentioned in Paetzold and Specia (2016a).

### 5 Results

This section presents the results for each step of simplification and compares the different methods proposed in FrenLys. In view of the absence of comparable work for French, we put our results into perspective with those of Paetzold and Specia (2017c) for English and Qiang et al. (2021) for Chinese.

#### 5.1 Substitution Generation

As we can see in Table 1, FastText generator, a method based on non contextual embeddings, slightly outperforms Resyf generator, based on a dictionary (F1 is 0.25 vs. 0.23). Resyf has a higher potential and recall, but suffers from a lack in precision, which is due to the fact that no sense disambiguation is carried out in synonym selection. In contrast, FastText reject candidates that do not correspond to the most frequent meaning of a form (as FastText computes only one vector per form, the most frequent sense has the largest influence on it). CamemBERT is clearly the less efficient technique. It is not a complete surprise, as it can generate words that fits the context, but are not valid synonyms of the complex word.

Table 1: SG FrenLys results

We therefore tried to combine the advantages of CamemBERT (suitability to the context) with those of Resyf and FastText (better synonym generation). Considering the union between CamemBERT and FastText seems to hurt the performance (0.17 in F1 instead of 0.25), whereas combining CamemBERT and ReSyF produces our best results (0.26 in F1). It seems that ResyF selects valid, but not necessarily context-appropriate synonyms, which are filtered by BERT based on the context. Although not directly comparable, the F1 of our best method is in line with those of Paetzold and Specia (2017c) and Qiang et al. (2021). At the potential level, the difference observed could be explained by a variation in the number of synonyms produced by the generators: potential is correlated with the number of generated synonyms.

#### 5.2 Substitution Selection

We apply each of our selection methods on the union of all generated synonyms. The results obtained are presented in Table 2.

Results clearly reveal the importance of selecting synonyms that share the same POS as the word to substitute. This allows our system to reach a F1 of 0.31 for the generation of synonyms. It is however surprising that the POS approach outperforms both CamemBERT and FastText.

Table 2: Benchmarking results for SS with substitutions generated by all generators

Once more, our results appears to be comparable with those of Paetzold and Specia (2017c), as our F1 is clearly higher, but we were not able to obtain such a high potential. It is interesting to notice that our selectors mostly improve precision.

5.3 Substitution Ranking

Finally, we tested our different ranking methods on the part of corpus that has been also annotated for the reading ease of synonyms. Results are displayed in Table 3.

<table>

</tbody>
</table>

Table 3: Benchmarking results for SR

Ranking candidates based on frequency remains a strong baseline, as the Lexique3 ranker has a TRank-at-1 of 0.42 and a Recall-at-3 of 0.73. This means that, in 42% of our test sentences, using only the frequency allows to correctly predict the synonym defined to as the simplest by human judges (gold). Using the number of senses per words in addition to frequency does not bring much improvement, only 2% for TRank-at-1. In contrast, a much more sophisticated ranker using 21 word features, clearly improves performance, as it is able to select the easier synonyms in 50% of the cases. In this step, our results remain lower than those of Paetzold and Specia (2017c) in terms of TRank-at-1.

6 Conclusion

To conclude, we described the first tool for French lexical simplification that carries out three of the four classic LS steps. Our tool, FrenLyS, will be made available to the scientific community via a freely accessible web service\(^5\).

FrenLyS includes five synonym generators, based on the two principal approaches in the field: using a resource and querying embeddings. Whereas Hmida et al. (2018) had concluded that using ReSyF as a resource was able to outperform the approach of Glavaš and Štajner (2015), we found that relying on FastText was more efficient. However, our best method combines a synonym database with CamemBERT as a way to filter inappropriate synonyms in context. These two sources bring information about the complex word semantic (ReSyf) and its context (CamemBERT), which comes close to the twofold strategy of Qiang et al. (2019). They indeed generate synonyms based on one sentence in which the complex is masked (contextual information) and the same sentence in the complex word is present in order to keep the semantic information conveyed by the complex word.

FrenLyS offers three of them and the results showed that using a simple POS filter is sufficient to improve the F1 of our generators. Ranking synonyms can be done through three techniques, the best of which integrates 21 word characteristics into a SVM ranker. The results obtained for ranking seem lower than those of Paetzold and Specia (2017c). This could be due to variations in the test data, but maybe also to the use of a neural classifier. We plan to improve our ranking algorithm using a neural ranker in the future to investigate this issue.

Finally, in addition to the implementation of the first complete LS tool for French, this paper also proposes the first evaluation dataset for French LS. This dataset will be distributed through the same web site as the API\(^6\). We hope that the availability of both resources could help boosting current LS research in French, which lacks behind similar research for other European languages.

Acknowledgments

This project was partially funded by the "Direction de la language française” from the Federation Wallonia-Brussels (AMesure project). We also want to thank Dr. Rémi Cardon for his in-depth reading and comments.

Spelling Correction for Russian: A Comparative Study of Datasets and Methods

Alla Rozovskaya
Department of Computer Science
Queens College, CUNY
arozovskaya@qc.cuny.edu

Abstract
We develop a minimally-supervised model for spelling correction and evaluate its performance on three datasets annotated for spelling errors in Russian. The first corpus is a dataset of Russian social media data that was recently used in a shared task on Russian spelling correction. The other two corpora contain texts produced by learners of Russian as a foreign language. Evaluating on three diverse datasets allows for a cross-corpus comparison. We compare the performance of the minimally-supervised model to two baseline models that do not use context for candidate re-ranking, as well as to a character-level statistical machine translation system with context-based re-ranking. We show that the minimally-supervised model outperforms all of the other models. We also present an analysis of the spelling errors and discuss the difficulty of the task compared to the spelling correction problem in English.

1 Introduction
The spelling correction task has been a fundamental Natural Language Processing (NLP) problem ever since the origins of the field and has enjoyed a lot of attention in the NLP research. It is not surprising, since correcting spelling mistakes is of practical relevance for various higher-level NLP tasks and downstream applications dealing with noisy data, such as named entity recognition, dependency parsing, information retrieval, topic modeling, machine translation, essay scoring, speech recognition, automatic text correction (van Strien et al., 2020). Running a spellchecker is now a common pre-processing step performed in essay scoring (Flor, 2012a), grammatical error correction (Chollampatt and Ng, 2018; Rozovskaya and Roth, 2016; Grundkiewicz and Junczys-Dowmunt, 2018) and numerous other applications. Nevertheless, even for English, performance of spellchecking tools is not as good as one would expect, especially in noisy domains (Flor et al., 2019). Kantor et al. (2019) evaluate three publicly available spellcheckers on English learner data and find that the highest recall achieved is that of 69%, and the best precision is 57%, which indicates that the task is far from being solved. Further, their simple in-house implementation outperforms by a large margin all of the common publicly available spellcheckers.

One reason for the slow progress on the task might be the lack of common benchmark datasets. As a result, proposed methods are being evaluated either on isolated spelling errors extracted from a corpus without context or on artificially created datasets. Recently, Flor et al. (2019) released a dataset annotated for spelling errors in English learner essays and provided an evaluation of a minimal supervision system that combines features based on the misspelled word itself and the context in which it appears. They report strong performance on that corpus, as well as competitive results on a dataset from the medical domain.

We address the problem of correcting non-word spelling mistakes in Russian, a language with rich morphology. Our goal is two-fold: first, to implement various established spelling methods with known results for English and determine how they perform on Russian. Our second goal is to perform cross-corpus comparison, by evaluating on several Russian datasets that contain diverse data (texts by native Russian speakers in the social media domain, as well as Russian learner texts).

We implement four models. First, we use two baselines that do not take context into account: Aspell spellchecker and the model proposed in Kantor et al. (2019) that was shown to outperform Aspell and several other grammar checkers.

\[\text{Context in this work refers to the sentence (or the n-gram window) in which the misspelled word occurs.}\]
ers for English. We then implement two models that also take into account contextual information when proposing a correction: a statistical machine translation (SMT) approach and a minimally-supervised method. The minimally-supervised model follows the approach of Flor et al. (2019). This model is compared against a character-level SMT spellchecker that takes context into account by incorporating a word-based language model (LM) as well as other context features at the re-ranking level (Chollampatt and Ng, 2018). We evaluate these four methods on three Russian datasets that contain annotated spelling mistakes. We perform a detailed error analysis and identify the challenges pertaining to the Russian language. We show that even though spelling correction of non-word errors is considered to be an easy task, performance on a morphologically-rich language is challenging and leaves a wide gap for future research.

This paper makes the following contributions: (1) we implement and evaluate four established approaches to spelling correction and evaluate these on three Russian datasets; (2) we show that the minimally-supervised approach outperforms the other methods and is the most robust; (3) we perform error analysis identifying challenges of spelling correction for Russian.

Section 2 reviews related work on the spelling correction of Russian and on the established methods well-studied for English. Section 3 describes the three datasets of spelling errors used in this work. Section 4 presents the models. In Section 5, we present the results, and in Section 6 we perform error analysis of the results. Section 7 concludes.

2 Related Work

A non-word misspelling is a spelling error, such that the resulting string is not a valid word in the language. This is different from real-word (context-sensitive) errors, for example confusing “their”, “there” and “they’re” (Wilcox-O’Hearn et al., 2008). Context-sensitive errors also subsume grammar errors made by non-native speakers (e.g. confusing “a” and “the”), but these typically are addressed using a different set of methods (Ng et al., 2014).

Most of the spelling correction research has been focused on the English language. When dealing with a language that has rich morphology, such as Russian, specific challenges may arise. For example, the rich morphology of Russian, as we show, affects the candidate generation algorithm, where a substantially higher number of competing candidates is being generated, including those that are morphological variants of the same lemma. There is very little spelling work on other languages with complex and diverse morphology. For instance, Oflazer (1996); Mohit et al. (2014); Rozovskaya et al. (2015) address a variety of errors in Arabic, including grammar and usage errors, but they do not focus on spelling.

Previous studies on Russian spelling mainly addressed correcting spelling errors in search queries (Baytin, 2008; Panina et al., 2013), which is a special subtask of spelling correction, as the surrounding context for candidate selection is not considered or is considered in a quite restrictive way. Sorokin et al. (2016) introduced the first competition on spelling correction for Russian, which focused on correcting texts collected from Russian social media websites. Sorokin (2017) presents a follow-up study, where they show that the use of morphological information for candidate selection is beneficial for languages with well-developed morphology, such as Russian. We use the corpus released in this competition and show that it is quite different from the other two corpora used in this work.

Approaches to non-word spelling correction

Broadly speaking, the approaches to correcting non-word spelling errors can be broken down into those that only consider the characteristics of the target token when ranking correction candidates, and those that also take into account contextual information. Among the former are those that compute edit distance (Levenshtein, 1966; Damerau, 1964) and phonetic similarity between the misspelling and the candidate correction (Toutanova and Moore, 2002).

One standard approach to correcting non-word spelling errors follows the noisy channel model formulation (Shannon, 1948). This approach incorporates non-contextual information, such as the edit distance and phonetic similarity between the misspelling and the candidate correction, and the candidate frequency (Kernighan et al., 1990; Church and Gale, 1991; Toutanova and Moore, 2002). Essentially, weights for different edit operations are estimated from a large training corpus of annotated spelling errors. However, this approach requires a lot of supervision: thousands
of annotated errors paired with their corrections are used to estimate probabilities associated with each edit. While the noisy channel model can also incorporate contextual information, in general, adding new features from a variety of sources is not straightforward in the noisy channel formulation.

Flor et al. (2019); Flor and Futagi (2012) proposed a minimally-supervised model that combines contextual and non-contextual information. In Flor et al. (2019), they evaluate the model on two spelling corpora: an English learner corpus and a corpus from the biomedical domain, showing competitive results. Importantly, unlike the noisy channel model, their model only requires a small amount of supervision and is robust on out-of-domain data. In this work, we describe an implementation of this model for Russian.

SMT methods for Spelling Correction
Character-level statistical machine translation has been widely used for spelling correction of natural data as well as OCR post-correction, which can be viewed as a subtask of spelling correction. Neural network (NN) approaches, in particular, seq2seq models have recently been used for spelling correction. We do not evaluate NN methods in this work, as we have very limited amounts of training data. For an analysis and evaluation of NN approaches for spelling correction, we refer the reader to Schnober et al. (2016) and Amrhein and Clematide (2018).

3 Datasets
We use three Russian datasets annotated for misspellings. The first one, RULEC-GEC, is a learner corpus collected at the University of Oregon and consists of essays written by learners of Russian as a foreign language and heritage speakers (Alsufieva et al., 2012; Rozovskaya and Roth, 2019). The dataset was corrected and annotated by native Russian speakers and is error-coded. It is annotated exhaustively for various grammar and usage errors, and contains a large proportion of spelling errors, especially for heritage speakers (over 42% of all errors), and over 18% of all errors in the foreign group. We only focus on mistakes that are marked as spelling errors. The corpus is partitioned into training, development, and test. Since we focus on the spelling errors, we evaluate only with respect to those mistakes and ignore other annotated errors in the data.

The second corpus, henceforth RU-Lang8 (Trinh and Rozovskaya, 2021), is a dataset collected from the online language learning platform Lang-8 (Mizumoto et al., 2011) and annotated by native speakers. The dataset contains texts by learners of a variety of foreign languages. The annotation is publicly available for research. RU-Lang8 contains 54,000 tokens split up into development and test partitions. We only use the test partition in this work for evaluation, as the models are developed and tuned on the RULEC-GEC data. RU-Lang8 differs from RULEC-GEC: the latter consists of essays written on a University setting in a controlled environment, while the Lang-8 data was collected online; the majority of texts are short paragraphs or questions posed by language learners. RU-Lang8 is thus more informal and contains data by learners of multiple first language backgrounds (unlike RULEC-GEC, whose authors are from the United States).

The third corpus, RUSpellRU, is a dataset released as part of the competition on automatic spelling correction for the Russian language, which focused on social media texts. The dataset is a collection of essays from Russian blogs and social media. This is another unique dataset, very distinct: it contains a lot of colloquialisms, slang expressions and social media spelling conventions (Sorokin et al., 2016). Since the corpus contains social media texts, the misspellings include, in addition to typos, a lot of slang and colloquial forms common in social media spelling, such as the use of digits inside the words or unconventional spellings, e.g. using phonetic spelling instead of standard one.

Statistics on the datasets, including the total number of tokens as well as the spelling error rates (percentage of tokens containing a spelling error), are shown in Table 1. We observe that the RUSpellRU dataset is the most noisy one, and its error rate is more than five times higher than in the RULEC-GEC corpus, where the percentage of tokens containing a spelling mistake is the smallest among the three. On the other hand, the RUSpellRU dataset is produced by native Russian speakers, while the other two are produced by learners of Russian and thus also contain other, grammar and usage-related errors.

Table 2 analyzes the spelling errors with respect to the type of edit – replacement, split, or merge. A merge is a misspelling where a space is incor-

4 The Models

4.1 Minimally-Supervised Spelling Correction Model

We implement the model described in Flor and Festag (2012), Flor (2012a), that is evaluated in the original papers on the English learner corpus of TOEFL and GRE essays. It was also evaluated on the TOEFL-11 corpus as well as a corpus of biomedical English texts (Flor et al., 2019). Implementation of the model for Russian and its evaluation on the Russian data with its rich morphology is one of the contributions of the current work.

Finally, in Table 3 we analyze the replacement errors with respect to the edit distance between the source word and the correction. In the RULEC-GEC and RUSpellRU datasets, over 80% of replacement edits are within edit distance 1, where each type of change, including transposition errors, has a cost of 1. This analysis is consistent with findings in English corpora of misspellings (Flor et al., 2019). The RU-Lang8 corpus, however, contains a higher proportion of errors with edit distance greater than 1. Only 68.4% of errors are within edit distance of 1.

The Models

In this section, we describe the minimally-supervised model, the character-level SMT speller, and the two baselines that do not use context.

4 The Models

4.1 Minimally-Supervised Spelling Correction Model

We implement the model described in Flor and Festag (2012), Flor (2012a), that is evaluated in the original papers on the English learner corpus of TOEFL and GRE essays. It was also evaluated on the TOEFL-11 corpus as well as a corpus of biomedical English texts (Flor et al., 2019). Implementation of the model for Russian and its evaluation on the Russian data with its rich morphology is one of the contributions of the current work.

Finally, in Table 3 we analyze the replacement errors with respect to the edit distance between the source word and the correction. In the RULEC-GEC and RUSpellRU datasets, over 80% of replacement edits are within edit distance 1, where each type of change, including transposition errors, has a cost of 1. This analysis is consistent with findings in English corpora of misspellings (Flor et al., 2019). The RU-Lang8 corpus, however, contains a higher proportion of errors with edit distance greater than 1. Only 68.4% of errors are within edit distance of 1.

4 The Models

In this section, we describe the minimally-supervised model, the character-level SMT speller, and the two baselines that do not use context.
names, in particular those that are foreign names, or rare words, may be missing and would be mistakenly flagged as potential misspellings. Nevertheless, recall (detecting potential misspellings) is more important than maintaining high precision in this step. Our dictionary is based on the Yandex corpus (Borisov and Galinskaya, 2014). The corpus size is over 18 million tokens, and the resulting dictionary contains 2.3 million word types. To reduce the number of false positives, for the words not in the dictionary, we also check whether the token is recognized as the last or first name by the Mystem morphological analyzer (Segalovich, 2003) (if it appears non-capitalized in non-initial sentence position) or if the stem of the word is recognized as a known stem. The recall of the detection algorithm is shown in Table 4. The lowest recall of 65.7 is achieved on the RULEC-GEC dataset, while the highest recall is obtained on RU-Lang8 (79.9%).

We further analyze the recall of the detection algorithm by classifying the spelling mistakes in the gold data that were missed (Table 5). In the RULEC-GEC dataset, 22.8% of these errors are context-sensitive spelling mistakes, i.e. spelling errors that involve confusing valid words and which are not covered in this task. 20.6% are spelling errors that are multi-token (i.e. require merging two or more tokens), while 18.4% are context-sensitive grammar mistakes (e.g. noun case) which were miscategorized by the annotator. Another 15.4% of mistakes are capitalization errors. Only 16.9% of the missed errors (category Other) as well as 5.9% of errors that involve spelling mistakes on proper names are in fact spelling mistakes that should have been detected at this stage. Similarly, on RU-Lang8 dataset, 40.3% of missed errors are context-sensitive errors, and the actual mistakes that were missed (categories Other and Proper Name) include 33.8% of all missed tokens. In the RUSpellRU corpus, these errors comprise 8.5%.

If we exclude the non-relevant errors that are counted as missed, the recall of the detection stage improves to 89.2% for the RULEC-GEC corpus, 92.2% for the RU-Lang8 corpus, and 96.7% on the RUSpellRU dataset.

**Candidate Generation** We consider several approaches to candidate generation based on the edit distance between the source and the target strings. Candidates are generated using the dictionary described in the previous section. Candidates include all dictionary words within edit distance that does not exceed half the length of the misspelled string; the maximum distance is set to three, as the number of candidates grows very quickly due to the rich morphology of Russian (see Table 6). For example, on average, 3 candidates are generated with edit distance of 1 for RULEC-GEC. This number increases to 313 when an edit distance of 3 is used instead. This is because, due to the morphological complexity, morphological variants of the same base word are included as different candidates (also discussed in Section 6). In English, candidates up to edit distance of 6 are included (Flor et al., 2019), but doing so would explode the search space.

The candidate generation algorithm is evaluated

Table 7: Description of all the features used in candidate ranking with the minimally-supervised model.

in Table 6. As the edit distance increases, the recall of the candidate generation (i.e. proportion of errors for which gold is among the generated candidates) improves, however, the number of candidates per error increases exponentially. We note, though, that, while on the RULEC-GEC and RU-Lang8 datasets, the recall increases to over 90% with the edit distance set to 3, on the RUSpellRU corpus, the highest recall achieved is 78.8%, even though 83.6% of misspellings are within edit distance of 1, as shown in Table 3. This indicates that a large number of colloquial and slang words present in the corpus are not found in the dictionary.

**Ranking of Candidate Corrections** The ranking step is the most challenging one and is the focus of most work on non-word spelling correction (Fivez et al., 2017). Ranking of correction candidates in the minimally-supervised model uses both the features of the misspelling-candidate pair and the contextual information. Flor (2012b) tuned feature weights manually on a set of misspellings, extracted from a corpus of TOEFL and GRE essays. In this work, similar to (Flor et al., 2019), feature weights are learned using a linear algorithm (Averaged Perceptron (Rosenblatt, 1958), implemented within Learning Based Java (Rizzolo and Roth, 2007).

We implement the following features: orthographic similarity (inverse edit distance), character-difference, candidate word frequency, and n-gram support. The features are listed in Table 7 and described below.

**Orthographic similarity** is computed as inverse edit distance, $1/(eDist + 1)$, where $eDist$ is the edit distance (including transpositions) between the misspelling and the correction candidate (Levenshtein, 1966; Damerau, 1964).

**Character difference** is a feature that encodes the specific letter change between the original and the candidate. This feature is active with replacement, deletion, and character insertion errors for candidates whose edit distance is 1. The feature is expected to reflect some common and well-known character confusions, both among native and non-native Russian writers, e.g. omitting the “s” at the end of a word after character “ц” or incorrectly using a instead of o in an unstressed position. Note that this feature is similar to the concept of encoding phonetic similarity, which we omit in this implementation.

**Candidate frequency** A more frequent word is more likely to be the intended word than a rare word (Flor, 2012a). Unigram word frequency is computed for each correction candidate using the Yandex corpus.

**N-gram support** For each correction candidate, all n-grams in the window of four context words on each side are taken into account by the n-gram support feature. We use co-occurrence counts computed from a large corpus collected over the Web (235 million tokens), henceforth the Sharoff corpus. The n-gram support feature is a summation over the counts of all n-grams of length 2 to 5 (excluding the unigram count of the candidate itself, since its frequency is reflected in the candidate frequency feature). For each error, the n-gram count value is normalized by the highest candidate count for that error.

For each misspelled token, with the exception of the letter difference feature, the feature scores of its candidate corrections are normalized, by dividing the score of the candidate feature by the highest-scoring candidate on that given feature.

**4.2 The SMT Speller**

We implement a character-level statistical machine translation (SMT) speller (Chollampatt and Ng, 2017). Input to the character-level SMT component is a sequence of characters that make up the unknown (misspelled) word and output is a list of correction candidates (words). In Chollampatt and Ng (2017), the misspelled words are those words that have not been observed in the source side of the parallel training data used to train the translation model. In this work, the unknown words are identified using the same detection algorithm described in Section 4.1. We do this for two reasons: first, due to lack of large amounts of parallel data

---

The corpus was kindly shared by Serge Sharoff.
and the morphological complexity of Russian, the number of unknown words for a word-level SMT system would be too high. Second, we wish to keep the detection step fixed, which allows for a fair comparison of the re-ranking algorithms.

The character-level translation model, in line with Chollampatt and Ng (2017), is trained on pairs of misspellings and their corrections from the RULEC-GEC training corpus (774 pairs) and an additional set of 1,000 correct words selected uniformly at random from the target side of RULEC-GEC training data. The language model that is part of the SMT system is a 5-gram character-level model trained on the Yandex corpus (22 million tokens). The SMT model is tuned on the misspelling-correction pairs from the RULEC-GEC development set. The character-level SMT model is tuned using MERT (minimum error-rate training) on characters, with character-level edit operation features and a 5-gram character LM.

For each unknown word, the character-level SMT produces 100 candidates that are then rescored to select the best candidate based on the context. The rescoring is done following Chollampatt and Ng (2017) and uses word-level n-gram LM features: LM probability and the LM OOV (out-of-vocabulary) count denoting the number of words in the sentence that are not in the LM’s vocabulary. The word-level n-gram LM is trained on the Sharoff corpus, using the KenLM toolkit (Heafield et al., 2013).

### 4.3 Further Baseline Systems

We compare to two other methods that do not make use of context information: Aspell, and a re-ranking approach proposed in Kantor et al. (2019). The latter has been recently used in grammar and spelling correction research and showed good results in English.

**Kantor et al. re-ranking** Kantor et al. (2019) implement an approach to English spelling correction, that is quite simple but is surprisingly effective and outperforms substantially other commonly used open-source spellcheckers: Enchant, Norvig, and Jamspell. Briefly, the approach relies on a large dictionary compiled from a native corpus to identify misspelled tokens. In re-ranking, for each misspelling, the most frequent candidate correction (with a minimum count of 20) within an edit distance of 1 (transposition is treated as a distance of 1) is returned. If no such candidate exists, they check if the misspelled word can be split into two words that are in the word-count data or in the dictionary. They implement their re-ranking method (keeping the minimum count for words at 5, since Russian is a morphologically-rich language). Our list of incorrect tokens is generated using the same candidate detection step described above (Section 4.1). Only the re-ranking is different.

### 5 Results

In all cases, the models are trained on the RULEC-train corpus and tuned on the RULEC development data. All results are reported on the test partitions of the three datasets. Key results of the minimally-supervised model on the three datasets are shown in Table 8. We observe that the performance on RU-Lang8 is significantly lower than on the other two datasets. We conjecture that this may be due to the fact that RU-Lang8 has a small proportion of errors with corrections being within an edit distance of 1 from the misspelled token (see Table 3).

The results of the minimally-supervised model and of the other models implemented in this work are shown in Table 9. The minimally-supervised model outperforms all of the other models significantly on all three datasets. The relative performance of the models on each dataset is consistent: we note that Aspell has the poorest performance. This is followed by the SMT approach and the approach by Kantor et al. (2019). The two approaches are quite close, although the SMT method has high precision on RULEC-GEC and the RUSpellRU datasets. The minimally-supervised method achieves a substantially higher recall than all the other methods. It also achieves the highest precision on RULEC-GEC and RUSpellRU, although on the RU-Lang8 corpus its pre-

### Evaluation of different edit distance values in candidate generation

Next, we evaluate performance as a function of edit distance values for candidate generation. In all cases, we use the full feature set. Results are shown in Table 10. We observe that there is no clear benefit to using an edit distance greater than 1: on the RULEC-GEC corpus, recall slightly improves, while precision drops. On the RU-Lang8 dataset, precision improves with a larger edit distance, while recall remains the same. On the RUSpellRU dataset, recall does not change, while precision drops. For this reason, we use an edit distance of 1 in candidate generation, as the number of candidates is much smaller, as discussed above. It should be noted that, while using only edit distance 1 is optimal for the scoring with the system, it is not sufficient, as there are still many misspellings in each of the datasets (as shown in Table 3) that have corrections within higher edit distances. We leave this for future work.

### Feature ablation

Finally, we perform feature ablation to evaluate the contribution of the various features in the minimally-supervised model. Results are shown in Table 11. The n-gram support feature is shown to be the most important: dropping this features results in performance loss of 2-3 points on each dataset. This result demonstrates the significance of the contextual information in spelling correction.

### 6 Error Analysis

#### Candidate re-ranking

We perform error analysis of the candidate re-ranking component that is part of the minimally-supervised approach. From each dataset, we analyze 100 errors, on which an incorrect candidate is preferred. Results are shown in Table 12. *Morph. variant* refers to incorrect candidates that is an inflectional morphological variant of the correct suggestion. *Wrong cand.* denotes an incorrect suggestion that is not morphologically related to the correct suggestion. *Dist.* denotes corrections that have an edit distance greater than 1 to the source word. Since we currently only consider candidates within edit distance of 1, these errors cannot be corrected. *Lex. change* refers to misspellings that are also word usage errors. It is interesting to note that all three corpora have the same proportion of errors (50%) that could not be corrected.

corrected due to the edit distance of the correct candidate being greater than 1. Further, the corpora have similar distributions overall regarding mistakes when selecting a morphological variant (17-23%). This shows that for languages with rich morphology, morphological variants present an issue for spelling correction, since morphological variants typically differ by one character change, and thus correction candidates typically include multiple morphological variants of the same word. A similar conclusion, although not quantified, was drawn in the RUSpellRU competition for the social media data (Sorokin et al., 2016). We confirm this finding for various corpora and quantify it. Both of the learner corpora also have grammatical errors, and some of these were mistagged as spelling mistakes (14% and 20% in the RULEC and RU-Lang8 corpora, respectively). In contrast, because the RUSpellRU corpus contains data from native speakers, it is not expected to have many grammar-related errors.

7 Conclusion

In this paper, we implement four models for spelling correction for Russian and evaluate these on three diverse datasets that contain spelling mistakes. We present a comparative analysis of spelling mistakes contained in the three datasets. Evaluation results show that the minimally-supervised model outperforms two baseline models that do not use context when selecting a candidate correction, and another model that uses a character-level SMT and a language model in re-ranking. We perform feature ablation of the minimally-supervised model showing that contextual information contributes to the performance. We also carry out error analysis that reveals that one common source of errors in Russian in selecting the appropriate correction candidate is the presence of morphological variants. This study should provide insight into the spelling correction problem for languages with rich morphology.

Abstract

In translating text where sentiment is the main message, human translators give particular attention to sentiment-carrying words. The reason is that an incorrect translation of such words would miss the fundamental aspect of the source text, i.e. the author’s sentiment. In the online world, MT systems are extensively used to translate User-Generated Content (UGC) such as reviews, tweets, and social media posts, where the main message is often the author’s positive or negative attitude towards the topic of the text. It is important in such scenarios to accurately measure how far an MT system can be a reliable real-life utility in transferring the correct affect message. This paper tackles an under-recognised problem in the field of machine translation evaluation which is judging to what extent automatic metrics concur with the gold standard of human evaluation for a correct translation of sentiment. We evaluate the efficacy of conventional quality metrics in spotting a mistranslation of sentiment, especially when it is the sole error in the MT output. We propose a numerical ‘sentiment-closeness’ measure appropriate for assessing the accuracy of a translated affect message in UGC text by an MT system. We will show that incorporating this sentiment-aware measure can significantly enhance the correlation of some available quality metrics with the human judgement of an accurate translation of sentiment.

1 Introduction

Standard quality measures for assessing the performance of machine translation systems, such as BLEU (Papineni et al., 2002), are domain agnostic; they evaluate the translation accuracy regardless of the semantic domain or linguistic peculiarities of the source text. Consequently, they give equal penalty weight to inaccurate translation of n-grams, which may lead to performance overestimation (or underestimation). For example, the Arabic high-rated Goodreads book review showing the reviewers overall satisfaction of a novel: ‘الرواية رهيبة عيبها الوحيد الجزء الآخير’ (‘The novel is great, its only flaw is the last part’) is mistranslated by the available online translation tool which wrongly outputs a negative sentiment (‘The novel is terrible, its only flaw is the last part’). Despite the distortion of the affect message, this translation receives an equally high score as a correct translation (‘The story is great, its only flaw is the last part’), but which uses story instead of novel. This is because BLEU mildly penalises the wrong translation as it swaps only one uni-gram (‘great’) with its opposite (‘terrible’). Yet, the mistranslation of this particular uni-gram is a critical error as it is most pivotal in transferring the sentiment, and hence the MT performance is over-estimated.

There have been numerous efforts to address the common pitfalls of n-gram-based evaluation metrics by incorporating semantic and contextual features. However, despite research evidence of its analytical limitations, BLEU is still the de facto standard for MT performance evaluation (Mathur et al., 2020a; Reiter, 2018). Moreover, although the introduction of more semantically-oriented metrics showed a better correlation with human judgement, still the estimation of sentiment preservation in UGC has not yet been investigated. This is par-
tially due to the fact that the domain and linguistic style of the WMTs datasets typically used for metric evaluation (e.g. newstest2020, Canadian Parliament, Wikipedia, UN corpus) is quite different than the non-standard noisy UGC where sentiment is the main content of a telegraphic message (Ma et al., 2018; Barrault et al., 2019; Mathur et al., 2020b). Assessed over these WMT datasets, some metrics manifest an almost perfect correlation with human evaluation on the segment-level (e.g. WMT20 participating metrics record results of up to 0.97 Pearson correlation on the newstest2020) (Mathur et al., 2020b). However, research has also shown that metrics usually report weaker correlation with low human assessment score ranges (Takahashi et al., 2020a,b).

In this paper, we argue that the high correlation of some metrics may not be replicated with a different domain such as sentiment-oriented UGC, specifically when there is a mistranslation of sentiment-critical word(s). For this reason, we propose a ‘sentiment-closeness’ measure that can accommodate for a better evaluation of the MT system’s ability to capture the correct sentiment of the source text.

To present our sentiment quality measure, we first briefly explain in Section 2 why metrics commonly used for MT quality estimation may not always be efficient in assessing sentiment-critical translation errors. In Section 3, we present an experiment to quantitatively assess the divergence of the analysed metrics from a human judgement of a correct/incorrect translation of an affect message. Section 4 presents our proposed solution for fine-tuning quality metrics for a better correlation with human judgement. Section 5 presents the results of incorporating our sentiment-measure in different quality metrics. In Section 6 we conduct an error analysis of our empirical approach and discuss its limitations. Finally, Section 7 presents a conclusion on our conducted experiments.

2 Available Metrics

Automatic evaluation metrics usually take the output of an MT system (hypothesis) and compare it to one or several translations produced by human translator(s) (reference). Based on their matching methods, the most commonly used automatic metrics can be broadly categorised into: surface n-gram matching and embedding matching. Surface n-gram methods work by calculating exact matching, heuristic matching or an edit distance between the aligned n-grams of the reference and hypothesis translation(s). The embedding methods, on the other hand, calculate a similarity score between learned token representations, such as contextual embedding vectors, with or without the aid of external linguistic tools. In the following sections, we briefly explain the methods behind three canonical metrics as representative of each category. We illustrate why the theoretical foundation of each metric may not be optimum for evaluating the translation of sentiment-oriented UGC.

2.1 Surface N-gram Matching Metrics

BLEU The standard metric for assessing empirical improvement of MT systems is BLEU (Papineni et al., 2002). Simply stated, the objective of BLEU is to compare n-grams of the candidate translation with n-grams of the reference translation and count the number of matches; the more the matches, the better the candidate translation. The final score is calculated using a modified n-gram precision multiplied by a brevity penalty so that a good candidate translation would match the reference translation in length, in word choice, and in word order. The disadvantage of the BLEU metric which is relevant to our present study is that it treats all n-grams equally. Due to its restrictive surface n-gram matching, it does not account for the semantic importance of an n-gram in the context of a text. Accordingly, BLEU would incorrectly give a high score to an MT output if it scores exact match with the reference except for one uni-gram, even if this uni-gram completely changes the sentiment of a text (e.g. ‘terrible’ and ‘great’ as in the Goodreads example above). Online built-in MT tools have been shown to frequently transfer the exact opposite sentiment word for some dialectical expressions in UGC translated into English (Saadany and Orasan, 2020). Therefore, the BLEU evaluation of an MT performance would be misleadingly over-permissive in such cases where only one or two sentiment-critical words are mistranslated.

METEOR METEOR (Banerjee and Lavie, 2005) incorporates semantic information as it evaluates translation by calculating either exact match, stem match, or synonymy match. For synonym matching, it utilises WordNet synsets (Pedersen et al., 2004). More recent versions (METEOR 1.5 and METEOR++2.0) apply also importance
weighting by giving smaller weight to function words (Denkowski and Lavie, 2014; Guo and Hu, 2019). The METEOR score ranges from 0 (worst translation) to 1 (best translation). There are two shortcomings to the METEOR metric which do not make it a robust solution for evaluating sentiment transfer. First, the synonym matching is limited to checking whether the two words belong to the same synset in WordNet. However, WordNet synonymy classification is different than regular thesauruses. For example, ‘glad’ is a synset of ‘happy’ and hence considered a synonym, whereas ‘cheerful’ is not a direct synset to ‘happy’ and hence would be considered a mismatch by METEOR. The following two examples illustrate further the limitations of using WordNet synonymy by METEOR:

**Example 1**
Scores: [METEOR: 0.46]
- Hypothesis: “The weather is sunny, what a happy day”
- Reference: “The sun is shining, what a cheerful day”

**Example 2**
Scores: [METEOR: 0.48]
- Hypothesis: “I’m not sure why, but I feel so happy today”
- Reference: “I don’t get it, but I feel so sad today”

The METEOR scores for Examples 1 and 2 clearly diverge from a human evaluation of a good translation. In the first example, although the translation conveys the correct emotion (‘happiness’), it receives a similar METEOR score to the hypothesis in the second example which gives the exact opposite emotion of the source (‘happiness’ instead of ‘sadness’). The inadequate scoring is a result of the WordNet taxonomy which causes the metric to equally treat both pairs (‘sad’, ‘happy’) and (‘cheerful’, ‘happy’) as non-synonym synsets and hence unmatched chunks.

The second problem with METEOR which may affect its efficacy in evaluating sentiment transfer relates to its weighting schema for function and non-function words. The following example clarifies the gravity of this problem:

**Example 3**
Scores: [METEOR: 0.92]
- Hypothesis: “If he had blown himself up in your country, God would forgive him”
- Reference: “If he had blown himself up in your country, God would not forgive”.

The hypothesis in Example 3 is the translation output of Twitter’s built-in MT system for an Arabic tweet commenting on a terrorist attack¹. The MT failure to translate the negation marker flips the sentiment of the author from ‘anger’ against the terrorist to ‘sympathy’. Despite this, the METEOR score is 0.92 which is within the highest upper bound, ranking it as a good translation. On the other hand, the METEOR score for a correct translation of sentiment with a negation marker is 0.93. The main culprit for this inaccurate scoring is the lexical weighting which causes the metric not to penalise the missing of a negation marker which produces a sentiment-critical error. Due to the grave consequences of such mistranslations, it becomes critical to have a sentiment-sensitive metric that is capable of spotting similar errors.

### 2.2 Embedding-based Metrics

BERTScore Recently embedding-based metrics have proven to achieve the highest performance in recent WMT shared tasks for quality metrics (e.g. Sellam et al. (2020); Lo (2020); Mukherjee et al. (2020)). We take BERTScore as a representative metric for this approach (Zhang et al., 2019). BERTScore computes a score based on a pair wise cosine similarity between the BERT contextual embeddings of the individual tokens for the hypothesis and the reference (Devlin et al., 2018). Accordingly, a BERTScore close to 1 indicates proximity in vector space and hence a good translation. The main problem with embedding-based metrics, such as BERTScore, is that antonyms contain similar distributional information since they usually occur in similar contexts. Example 4 illustrates this point:

**Example 4**
Scores: [BERTScore: 0.85]
- Hypothesis: “What is this amount of anger, I don’t understand!”

¹https://twitter.com/gaston810/status/673950532340465664
Example 4 shows the mistranslation produced by Twitter’s Translate Tweet tab of an Arabic tweet. Although the sentiment polarity is flipped in the candidate translation above, the hypothesis receives a BERTScore of 0.85 which indicates a high cosine similarity to the reference in vector space and hence a good translation. Clearly, the metric score is not comparable to a human perception of the emotion reflected by the source.

Figure 1 illustrates the reason behind this misleadingly high score. Figure 1 is a 2-D visualisation of BERT’s contextual embedding vectors for the hypothesis translation (in blue) and the reference (in red). Both sentences are very close in the embedding space due to the exact match of their individual tokens. The only mismatch is between the antonyms ‘happiness’ and ‘anger’. As shown in the figure, the pre-trained embedding vectors of the opposite polarity nouns are also quite close because of their common contextual information. An embedding metric such as BERTScore, therefore, may not penalise antonyms which typically occur in similar contexts.

Recently, there have been different approaches to overcome some distributional problems of contextual embeddings. Reimers and Gurevych (2019), for example, introduce SBert, a modification of the pretrained BERT network, which should mitigate the antonymy problem. They use Siamese network structures where the embeddings of similar sentence pairs are independently learned via two parallel transformer architectures. We measured how far this technique could solve the opposite sentiment problem by measuring the SBert sentence similarity of the hypothesis and reference in Example 4. The cosine similarity of the SBert sentence embedding vectors for the hypothesis and reference in Example 4 reached 0.61. A correct translation of the reference, however, such as ‘What is all this cheerfulness, I don’t understand’ has a cosine similarity score of 0.79. This small similarity difference (0.18) would be misleading if taken as an evaluation of how far the sentiment poles in the two hypotheses are different. A more sentiment-targeted measure is needed for assessing mistranslations due to this antonymy problem.

In the following section, we conduct an experiment to quantify the divergence of the above mentioned metrics from the human perception of a proper sentiment transfer in a translated text.

3 Evaluation of Mistranslated Sentiment

We have shown in the previous section that three canonical MT evaluation metrics do not give a penalty proportional to sentiment-critical errors on segment-level by an MT online tool. In order to quantify how far the aforementioned quality metrics diverge or correlate with human judgement of sentiment transfer, we measure the performance of each metric on a dataset of tweets that had sentiment-critical translation errors. To compile this data, first we used the Twitter built-in translation system (Google API) to translate a dataset of tweets annotated for sentiment. The source dataset amounted to $\approx 7,000$ tweets in three languages: English, Arabic and Spanish. We translated the Arabic and Spanish into English and the English was translated into Spanish and Arabic.

To extract instances where the MT system failed to translate the sentiment correctly, we built an English sentiment-detection classifier by fine-tuning a Roberta XML model (Liu et al., 2019) on an English dataset of 23,000 tweets annotated for sentiment. The English classifier was used to predict the sentiment of the Google API output for the translation of the Arabic and Spanish tweets into English and the English back-translation of the English tweets translated into Spanish and Arabic.

The classifier’s predicted sentiment was compared to the gold standard emotion of the source text, and
instances of discrepancy were extracted as potential mistranslations of sentiment. Finally, from the extracted instances, we manually built a translation quality evaluation dataset.

The quality evaluation dataset, henceforth QE, consisted of target tweets where the error is exclusively a mistranslation of the sentiment-carrying lexicon. In these tweets, the mistranslations either completely flip the sentiment polarity of the source tweet, similar to Examples 3 and 4 above, or transfer the same polarity but with a mitigated sentiment tone. The tweets with exclusive sentiment translation errors amounted to 300 tweets. We also added 100 tweet/translation pairs where the MT system transfers the correct sentiment. Reference translations of the QE dataset were created by native speakers of the respective source languages. Essentially, the reference translations aimed at correcting chunks that caused a distortion of the affect message and retained as many of the hypothesis n-grams as possible to detect how far each metric is sensitive to sentiment mismatching and not to the mismatch in other non-sentiment carrying words. The translators were also asked to assign a score to each pair of source-hypothesis tweet, where 1 is the poorest sentiment transfer and 10 is best sentiment transfer. The average scores of annotators were taken as the final human score.

To quantify the ability of the three metrics explained in Section 2 to assess the transfer of sentiment in the QE dataset, we compared their scores of the translation hypotheses with the human judgement scores for sentiment transfer on the segment-level. We followed the WMT standard methods for evaluating quality metrics and used absolute Pearson correlation coefficient $r$ and the Kendall correlation coefficient $|\tau|$ to evaluate each metric’s performance against the human judgement. Figures 2 and 3 show heatmaps visualising the Pearson and Kendall correlation coefficients for the studied metrics and the human scores, respectively.

As seen from Figures 2 and 3, both BERTScore and METEOR achieve a better correlation with the human judgement than BLEU which achieves only 0.16 and 0.12 Pearson and Kendall correlations, respectively. However, the relatively overall low correlations (max $r = 0.39$ and max $|\tau| = 0.27$) raise important doubts as to the reliability of these accepted metrics for ranking MT systems which translate sentiments. Bearing in mind that 75% of the segments in the QE dataset have critical translation errors that seriously distort the sentiment, the low correlation results highlight the need for a sentiment-targeted measure that can improve a metric’s efficacy in capturing mistranslated sentiment by an MT system in real-life scenarios.

4 Sentiment-Aware Measure (SAM) for Machine Translated UGC

In this section, we propose a new measure for assessing MT performance that takes into account the sentiment similarity between the MT system translation and the reference. This sentiment measure should be used as a fine-tuning tool to adjust a quality score in cases where it is used to assess the translation quality of sentiment-oriented text. The SAM score is calculated by using the SentiWord dictionary of prior polarities (Gatti et al., 2015). SentiWord is a sentiment lexicon that combines the high precision of manual lexica and the high coverage of automatic ones (covering 155,000 words). It is based on assigning a ‘prior polarity’ score for each lemma-POS in both SentiWordNet and a number of human-annotated sentiment lexica (Baccianella et al., 2010; Warriner et al., 2013).
prior polarity is the out-of-context positive or negative score which a lemma-POS evokes. It is reached via an ensemble learning framework that combines several formulae where each lemma-POS is given the score that receives the highest number of votes from the different formulae. SentiWord prior polarity scores have been proven to achieve the highest correlation with human scores in sentiment analysis regression and classification SemEval tasks (Gatti et al., 2015).

We assume that our sentiment adjustment factor, SAM, is proportional to the distance between the sentiment scores of the unmatched words in the system translation and the reference, the higher the distance the greater the SAM adjustment. To calculate the SAM score, we designate the number of remaining mismatched words in the system translation and reference translation by \( m \) and \( n \), respectively. We calculate the total SentiWord sentiment score for the lemma-POS of the mismatched words in the translation and reference sentences using a weighted average of the sentiment score of each mismatched lemma-POS. The weight of a hypothesis mismatched word \( w_h \) and a reference mismatched word \( w_r \) is calculated based on the sentiment score of its lemma-POS, \( s \), as follows:

\[
\begin{align*}
    w_h^i &= |s_i|, \quad i = 1, 2, \ldots, m. \\
    w_r^i &= |s_i|, \quad i = 1, 2, \ldots, n.
\end{align*}
\]

Then the total sentiment score for hypothesis \( S_h \) and reference \( S_r \) is given by:

\[
\begin{align*}
    S_h &= \sum_{i=1}^{m} \alpha_i s_i, \quad \alpha_i = \frac{w_h^i}{\sum_{i=1}^{m} w_h^i} \\
    S_r &= \sum_{i=1}^{n} \beta_i s_i, \quad \beta_i = \frac{w_r^i}{\sum_{i=1}^{n} w_r^i}
\end{align*}
\]

The normalised SAM adjustment is given by:

\[
p = \frac{|S_r - S_h|}{2}
\]

and the translation final score will be given by:

\[
\text{Score} = C_{hr} (1 - p)
\]

where \( C_{hr} \) can be any metric’s matching score between a translation hypothesis and a reference segment. For this experiment, we will measure \( C_{hr} \) as the BLEU, METEOR and BERTScore scores. To illustrate how SAM score adjusts a metric score with respect to the transfer of sentiment, table 1 shows the SAM score adjustment for Examples 3 and 4 above.

As can be seen from Table 1, the metric score \( C_{hr} \) (here METEOR and BERTScore, respectively) is significantly reduced due to the sentiment distance between the mismatched words \( (w_h, w_r) \) as well as their mismatched weights \( (S_h, S_r) \). The reduced scores are more representative of the distortion of sentiment produced by the MT system in Examples 3 and 4. The SAM adjustment, therefore, is a targeted-measure that can fine-tune a metric according to the ‘sentiment-closeness’ of the translation and the reference.

5 Assessing SAM performance

To check how far the SAM measure can improve the evaluation of sentiment, we assessed the performance of the three chosen metrics on the QE dataset utilised in the experiment in Section 3 with the SAM adjustment. Figures 4 and 5 show heatmaps of the Pearson and Kendall correlations of the SAM adjusted metrics with the human judgement in the QE dataset.

Compared to metric scores without the SAM adjustment, Figures 4 and 5 show that the combination of SAM with the three metrics consistently leads to an improvement in each metric’s correlation with the human judgement of a correct sentiment transfer in our dataset. Overall, BERTScore records the highest Pearson correlation coefficients and Kendall rank dependence (0.59 and 0.44, respectively). This means that it is better able to penalise critical translation errors in our QE dataset. Moreover, compared to their scores without SAM,

\[\text{Figure 4: Absolute Pearson correlations with SAM Adjustment for the QE dataset}\]

More examples of SAM adjustments are in Appendix A.

Figure 5: Kendall correlations with SAM adjustment for the QE dataset

both BERTScore and METEOR record 20% and 18% higher correlation, respectively. It is also worthy of notice, that although the Pearson correlation of BLEU improves from 0.16 to 0.33 with the SAM adjustment, the correlation is still relatively small. Knowing that BLEU score is usually the gate-keeping tool for accepting improvement in MT research, the results cast doubt on the efficacy of this non-semantic method to penalise sentiment-critical translation errors.

6 Error Analysis and Limitations

Human sentiment can be expressed in intricately subtle ways so that the mistranslation of the affect message is not necessarily reflected in divergence of polarity scores. We conducted an error analysis on instances where the SAM adjustment scores were not able to capture the MT’s failure to transfer the correct sentiment due to different linguistic phenomena. The first phenomenon we identified is related to structure shifting. For example, the sentiment distance between the source tweet ‘I was saddened by him’ and its mistranslation ‘I made him sad’ is very small despite the flipping of sentiment direction in the translation. The three metrics with and without the SAM adjustment failed to penalise this type of distortion in the QE dataset. Second, some words in the lexicon did not have a score representative of their sentiment weight. For example, most prepositions in the SentiWord lexicon are neutral, yet by checking the data, it was found out that a mistranslation of a preposition can distort the affect message. For example, the source tweet ‘What is the benefit of me in this world’ was mistranslated by the MT system as ‘What is the benefit for me in this world’; the wrong preposition causes the translation to lose the sad tone in the source tweet. Again, similar instances were not adequately measured with the three metrics with and without the SAM adjustment. Third, some nuanced sentiment-carrying words specific for the informal style of tweets caused a mistranslation of sentiment which was not captured by our approach. For instance, a one-word tweet referring to a political figure as ‘Prick’ was mistranslated as ‘Sting’. The source is a slang word used to refer to a mean, contemptible man. The translation wrongly received a high score since both ‘prick’ and ‘sting’ had very similar negative sentiment weights. The translation, however, fails to reflect the aggressive sentiment in the source tweet. The BLEU metric, on the other hand, succeeded in giving a penalty to similar short mistranslated tweets without the SAM adjustment.

One other limitation to the current approach for assessing the translation of sentiment is that it relies on an English sentiment lexicon. The applicability of this approach to other languages depends on the availability of a similar high-precision and high-coverage sentiment lexicon. We have overcome this problem by using the English backtranslations of the Arabic and Spanish tweets in the QE dataset. There are, however, multilingual translations of English sentiment lexica that are commonly used in the sentiment-analysis of non-English text. It remains to be tested how far a translated sentiment lexicon is capable of measuring sentiment transfer among different language pairs by the SAM scoring approach.

7 Conclusion

The most frequent scenario in which an MT system is used to translate sentiment-oriented text is for the translation of online UGC such as tweets, reviews or social media posts. The users of the MT online tool take these translations at face-value as there is
no human intervention for accuracy checking. It is important, therefore, to ensure the reliability of the MT system to accurately transfer the author’s affect message before it is used as an online tool. The reliability of an MT system with such big data is commonly measured by automatic metrics. We have shown that conventionally accepted metrics may not always be an optimum solution for assessing the translation of sentiment-oriented UGC. We presented an empirical approach to quantify the notion of sentiment transfer by an MT system and, more concretely, to modify automatic metrics such that its MT ranking comes closer to a human judgement of a poor or good translation of sentiment. Despite limitations to our approach, the SAM adjustment serves as a proxy to the complicated task of manually evaluating the translation of sentiment across different languages.

Abstract

There is an incredible amount of information available in the form of textual documents due to the growth of information sources. In order to get the information into an actionable way, it is common to use information extraction and more specifically the event extraction, it became crucial in various domains even in public health. In this paper, We address the problem of the epidemic event extraction in potentially any language, so that we tested different corpora on an existed multilingual system for tele-epidemiology: the Data Analysis for Information Extraction in any Language (DANIEL) system. We focused on the influence of the number of documents on the performance of the system, on average results show that it is able to achieve a precision and recall around 82% but when we resorted to the evaluation by event by checking whether it has been really detected or not, results are not satisfactory according to this paper’s evaluation. Our idea is to propose a system that uses an ontology which includes information in different languages and covers specific epidemiological concepts, it is also based on the multilingual open information extraction for the relation extraction step to reduce the expert intervention and to restrict the content for each text. We describe a methodology of five main stages: Pre-processing, relation extraction, named entity recognition (NER), event recognition and the matching between the information extracted and the ontology.

1 Introduction

Infectious diseases are responsible for the morbidity and mortality and like we see today with the Covid-19 pandemic, surveillance provides us with information to improve our knowledge of their epidemiology (space-time dynamics, evolution of clinical and microbiological characteristics), in order to identify an appropriate control and prevention measures. The growth of digital data sources provide an avenue for data-driven surveillance, referred to as Epidemic Intelligence. The purpose of epidemic intelligence is to detect, analyze and monitor potential health threats over time (Nash and Geng, 2020). It requires the development of tools dedicated to the collection and processing of unstructured textual data published on the Web. Information Extraction (IE) (Martinez-Rodriguez et al., 2020) is one of the areas of active research in artificial intelligence and made it possible to analyze data from web sources. Different tasks of the IE systems have been suggested such as named entity recognition (NER) to identify real-world objects such as names of people, locations, names of diseases, etc. The relation extraction, which aims to find a semantic relation between two entities in a text (Elloumi et al., 2012). The event extraction is also an important task in the field of IE to detect, from the text, the occurrence of events with specific types, and to extract arguments (i.e. typed participants or attributes) that are associated with an event (Hettiarachchi et al., 2021). In 2007, the open information extraction has appeared and has introduced a new extraction paradigm unlike the traditional IE methods, relations are automatically detected instead of specifying target relations in advance and it enables a fast extraction over huge datasets (Niklaus et al., 2018). In this paper, we applied some experiments on the DANIEL system in order to evaluate its performance especially in the multilingual event extraction in the epidemiological field and we have exploited corpora from several diverse language families namely, English, Greek, French, Spanish, Portuguese, Russian, Polish, and Chinese. On the latter we proposed a new approach which reduces the expert intervention by using a multilingual OIE systems for a relation extraction, an automatic NER, and an ontology applied for any epidemiological event. The remainder of this paper...
Figure 1: The architecture of the DANIEL system

is organized as follows. Section 2 reviews works related to epidemic surveillance and event extraction systems, Section 3 describes the dataset used in the experimental study, in Section 4 we present the results. Finally, we provide a discussion about our new proposition and a conclusion in Section 5.

2 Related work

Many systems have been proposed in the domain of IE and which reflects the basis that were taken to build our approach. We made a study on three different approaches that take us to our perspectives for our new system.

2.1 The DANIEL System

The system proposes techniques for identifying emerging infectious disease threats in online news text, it’s based on two main steps: Corpus creation and evaluation. Figure 1 illustrates the architecture of the DANIEL system (Mutuvi et al., 2020a).

**Corpus creation** The system uses the Program for Monitoring Emerging Diseases (PROMED) platform to create the corpus. Firstly, the source URLs where the article was originally published, together with the other meta-data such as title, description, location, date were formatted and stored in a JSON format making the corpus easily reusable and reproducible. Then a language filtering was performed to ensure that only documents belonging to the languages of interest were retained using the K-means clustering algorithm. The boilerplate content such as navigation links, headers and footers was eliminated from HTML pages, it is among the data cleaning tasks. The final pre-processing task was de-duplication which involves eliminating perfect duplicate and near-duplicate content so that only one instance of each text was preserved.

**Evaluation** DANIEL is a multilingual news surveillance system, it aims to extract disease-location for each text in its corresponding language. It describes an event as a disease outbreak and the place where it occurred. It avoids grammar analysis and the usage of language-specific NLP toolkits (e.g., Part-of-speech tagger, dependency parser), it considers the text as a sequence of strings instead of words. The named entities presented by a list of diseases and a list of locations in JSON files in different languages. The named entity extraction depends on a ratio \( r \) which has a default value that can be fine-tuned by the user. The ratio \( r \) is depicted in the following equation:

\[
\frac{\text{length}(\text{substring})}{\text{length}(\text{entity name})}
\]

This ratio is a kind of threshold for the different size of the substrings. For example \((r=0.8)\) means that substrings sharing 80% of the named entity.

The news articles are grouped into various categories such as politics, wellness, travel, entertainment, sports and healthy living, among others. The models classify a news article as either relevant or non-relevant, depending on whether it alerts about a disease outbreak or not as described in (Mutuvi et al., 2020a).

2.2 The BioCaster System

BioCaster (Collier et al., 2008) ingests documents through RSS feeds. An Automatic classification of the reports was performed for topical relevance using a naïve Bayes algorithm. A named entity recognition is then accomplished for relevant documents for 18 term types based on the BioCaster ontology. The BioCaster ontology includes information in eight languages focused on the epidemiological role of pathogens as well as geographical locations with their latitudes/longitudes. At this stage disease-location pairs are plotted onto a public portal called the Global Health Monitor, to gain a geographically contextualized view of an outbreak anywhere in the world in Google Maps which can be filtered by pathogen, syndrome or text type. The event extraction is based on matching entity classes, skipwords, string literals, regular expressions, entity types as well as guard lists which include verbs of infection, common victim expressions. This is done by using a Simple Rule Language (SRL) as described in (Collier et al., 2008).
2.3 Event Detection based on Open Information Extraction and Ontology System

The approach proposes an event extraction by using an OIE system for a relation extraction without supervision, an automatic NER, and an ontology applied for any management change event (Sahnoun et al., 2020). The approach admits 2 phases as shown in Figure 2 that depend on each other: A learning phase and a recognition phase. The learning phase consists of modeling an event by an ontology (classes, subclasses and instances in relations), and constructing a set of rules manually. The recognition phase includes the RE, the NER and an automatic reasoning between the rules and the input ontology adaptation.

The rules construction is an important step which drives to a possible event extraction. For the relation extraction the system uses OLLIE, it is an Open information extraction tool which extracts the relationship triplets that contains three textual components (Arg1, Rel, Arg2) where the first and the third stand for the pair of arguments and the second indicates the relationship. For the Named Entity Recognition step, the system can detect a person, an organization, location, etc., in any part of the triplet using the python library SPACY1.

For the ontology input adaptation, verbs will be passed through a lemmatization layer to convert verbs to their infinitive form. An instance is every token recognized by a NE, then it will be added to the ontology and linked by relations whenever the following conditions are achieved:

- The number of named entities is greater than or equal to 2 to have a possible relationship among them.
- The lemmatized verb and the other relations between delimiters “;” should be included in the relation list of the ontology and Named Entities can be linked with these relations.

The last step is reasoning by inferring logical consequences of a set of rules to affect for each instance its role (event) as described in (Sahnoun et al., 2020).

3 Dataset and Evaluation

We tested the Daniel system on three large datasets in different languages (low- or high-resource), the first (Daniel-corpus) contains 2089 of relevant and irrelevant files (Romain et al., 2013), then we extend the dataset (BIG-corpus) (Mutuvi et al., 2020b) to include additional languages so that it covers news articles from several, diverse language families: Germanic (English, en), Hellenic (Greek, el), Romance (French, fr), Slavic (Polish, pl and Russian, ru) and Sino-tibetan (Chinese, zh). It includes 7046 irrelevant files and 1653 relevant files, and the third present the fusion of the two precedent corpora. The statistics of the dataset are presented in Table 1 and Table 2. The experimental study was carried out according to the two measurements of the true positive rate (TPR), the false positive rate (FPR), depending on the threshold r (1). The true positive rate (TPR) (2): Called also sensibility measures the likelihood of actual positive results. The false positive rate (FPR) (3): It’s the probability that a positive result will be given when the true value is negative.

\[
TPR = \frac{TP}{TP + FN} = \text{Recall} \quad (2)
\]

\[
FPR = \frac{FP}{FP + TN} \quad (3)
\]

We used a ROC curve to visualize the performance of the binary classifier. It’s a plot of the TPR versus the FPR for every possible classification threshold. A classifier that does a very good job separating the classes will have a ROC that hugs the upper left corner of the plot 2. Conversely, a classifier that does a poor job will have a ROC.

1https://www.ekino.com/articles/handson-de-quelques-taches-courantes-en-nlp

2https://www.dataschool.io/roc-curves-and-auc-explained/
curve that is close to the diagonal line. The purpose of AUC, which stands for Area Under the Curve. A very poor classifier has an AUC of around 0.5 and a perfect classifier has an AUC close to 1. After Evaluating the Daniel system and by taking into account the influence of the number of documents on the performance of the system, we resorted to the evaluation by event, each disease-location pair (e.g. flu in Spain) is considered as a unique event, regardless of the number of documents in which it has been reported, and then we check whether it has been detected or not.

Figure 3: ROC curve for the DANIEL corpus (2089 files) (Romain et al., 2013)

### 4 Results

#### 4.1 Evaluation By Documents

Figure 3 depicts the tracing of the ROC curve for the first corpus (Daniel-corpus) for 2089 files, the system represents its performance with a threshold of 0.8: The TPR has for percentage of 89% while we find only 4% of FPR that explains that the system has detected a significant number of events in the relevant documents. The Daniel-corpus contains texts in five different languages: Greek, English, Chinese, Russian and Polish as it shows in Figure 5. For the five languages, the ROC curve hugs the upper left corner of the plot for each curve (i.e. the system detects well the events for each language). Figure 4 demonstrate that the ROC curve is close to the diagonal for the BIG-corpus, we have 39% of TPR and 10% of FPR for a threshold of 0.8 results are not satisfactory for this corpus, so when we have increased the number of documents the TPR decreased. We merged the two corpora in order to obtain a more representative corpus, the results of the subsequent corpus are shown in figures 6 and 7. The results have been slightly improved for Spanish, Portuguese, Greek, Russian, Polish and Chinese the system gives a high-performance but this not the case for English and French. For a threshold of 0.8 we observe a TPR of 42% and a 9% FPR.

#### 4.2 Evaluation By Event

Table 3 shows the results of the evaluation by event for the DANIEL-corpus, demonstrating that there are 66 events out of 86 are missed if no entity linking is performed. The total number of unique
events in the corpus is not the sum of unique events in each subcorpus. In the cumulated corpora there are 16 events that are reported in more than one language.

Table 3: Evaluation by unique event for the DANIEL-corpus with a threshold of 0.8 (NB: this a strict scenario where no entity linking has been performed)

The results of the relevant documents for The BIG-corpus in Table 4 shows that there is 75 of events detected between 939 unique events (in all languages) so the number of events detected is not great if we consider that we have a much larger corpus. Table 5 presents an example of an event extraction in the form of a peer of disease-location, the real date that documents have mentioned the event and the date when it was detected.

5 Conclusion and Perspectives

In this paper we have focused on the study of some systems in the epidemiological field such as Daniel and BioCaster, and an event extraction system which is based on a methodology that opens the door for a new proposition using the open information extraction and the ontology. We propose a procedure to an eventual epidemic event extraction

which consists of five main stages: Pre-processing, relation extraction, named entity extraction and the matching between the information extracted and the ontology. The first task is to Retrieve articles from PROMED in different languages, then a pre-processing step based on a Data cleaning task to Eliminate the boilerplate content from the corpus.

The text then will be passed to a relation extraction using an open information extraction to restrict the content of a text into triplets of relationships so that it is in form (Arg1, verb, Arg2) and we can differentiate between the nominal part and the verbal part. In the nominal part where we can find the named entities and in the verbal part we can visualize verbal expressions in the epidemiological context. The relation extraction method aim to represent semantic relations between entities. The entities have numerous applications in building knowledge representation models that report relations between words, such as ontologies, semantic networks.. In this work, we will investigate the area of multilingual open information extraction for the Portuguese, English and other languages (Claro et al., 2019). The extracted relations will be passed to a named entity recognition layer. The system can detect the location, the date, the percentage and the name of disease... For the event extraction we can use the simple rule language (SRL) with a capability to match regular expressions and guard lists include verbs of infection, common victim expressions, occupation names. The ontology in our approach present the event which is an object that admits an existence in the space of time and depends on other objects in relation. An ontology is a set of concepts, as well as relationships between these concepts that’s why the event was modeled by an ontology. The matching between the extracted information and the ontology will bring us to an eventual event extraction as depicted in Figure. 8, we can use an ontology already existed like the BioCaster ontology but it is not available online so we’re going to do it ourselves.

We are looking for evaluating the results of the test obtained and compare them by another systems like BioCaster and DANIEL.

Abstract

Legal judgment prediction (LJP) usually consists in a text classification task aimed at predicting the verdict on the basis of the fact description. The literature shows that the use of articles as input features helps improve the classification performance. In this work, we designed a verdict prediction task based on landlord-tenant disputes and we applied BERT-based models to which we fed different article-based features. Although the results obtained are consistent with the literature, the improvements with the articles are mostly obtained with the most frequent labels, suggesting that pre-trained and fine-tuned transformer-based models are not scalable as is for legal reasoning in real life scenarios as they would only excel in accurately predicting the most recurrent verdicts to the detriment of other legal outcomes.

1 Introduction

At the intersection of machine learning and law, legal judgment prediction (LJP) is a task that consists in predicting either the outcome of a lawsuit (Skalak, 1989; Nallapati and Manning, 2008; Katz et al., 2017; Aletras et al., 2016; Liu and Chen, 2017) or some other case attributes such as legal areas (Șulea et al., 2017; Soh et al., 2019) or charges (Xiao et al., 2018).

One specificity of court rulings is that they are based on the application of legal articles to the factual description of the case. That is to say, a judge must determine whether some law articles are relevant to a case, and if applicable, whether the legal principles they embody are violated. Therefore, articles as domain-specific knowledge can be used as leverage for improving LJP performance, as shown by Luo et al. (2017) and Long et al. (2019) for charge prediction and divorce judgment prediction respectively. Xu et al. (2020) also went further by using articles for distinguishing confusing charges in a charge prediction task.

Meanwhile, transformers (Vaswani et al., 2017) and BERT models (Devlin et al., 2019) in particular have been widely used in NLP tasks with the assumption that such models, if first pre-trained on massive corpora and then fine-tuned on the dataset of a given task, could suffice for achieving significant improvements. On one hand, this turned out to be true with the CAIL2018 dataset (charge prediction task) as shown by Wang et al. (2020). On the other hand, Holzenberger et al. (2020) mentioned in a statutory reasoning entailment task that a transformer model does worse than a rule-based model, even after further pre-training on the domain corpus. Furthermore, in an employment notice prediction task, Lam et al. (2020) emphasized that domain adaption of such models could even harm performance. These elements raise the question of how well a pre-trained transformer model can handle a legal NLP task and how well the input from domain-specific knowledge such as legislative text can improve the LJP performance. To the best of our knowledge, in the case of LJP tasks aimed at verdict prediction, no experiment has tested so far the application of pre-trained BERT models on both tribunal decision text and cited law articles text combined altogether, which we intend to do in this work.

We designed a multilabel classification task in which the model must predict the ruling outcomes on the basis of the facts description. One can imagine that such a predictive engine could be used for legal assistance for those who may not afford the services of a legal expert. Unlike Luo et al. (2017), we put the article prediction aside in order to focus solely on the verdict prediction and assess in which conditions input article-based features can improve classification. For our experiments, we use a landlord-tenant disputes corpus used by West-
erman et al. (2019) and Salaün et al. (2020) from which we extracted fine-grained targets labels and article features in order to encompass as much as possible the variety of rulings, thus making the task more representative of real life cases. We present the preprocessing of the dataset along with the creation of article-based features in Section 2. The architectures of the models are shown in Section 3 along with three methods for integrating the information from the articles mentioned in the decisions. Discussion of the results and concluding remarks are provided in Sections 4 and 5 respectively.

2 Preparation of the Dataset

The Administrative Housing Tribunal is a court of Quebec in Canada with an exclusive jurisdiction in landlord-tenant disputes. We got access to an exhaustive corpus of 667,305 decisions in French issued from 2001 to 2018 publicly accessible through SOQUIJ portal. Documents average and median lengths amount to 307 and 235 tokens respectively with a standard deviation of 371.

Figure 1: Excerpt of a decision translated from French. The text in italics is the verdict while underlined text contains references to articles.

Each decision is split in two by applying heuristics based on the syntax of the documents: the pre-verdict section, used as text input (text before the italics in Figure 1), and the verdict section containing the legal solution chosen by the judge in charge of the case (text in italics in Figure 1). The pre-processing of both sections are described in subsections 2.1 and 2.2 respectively.

2.1 Preprocessing of Input Features

As one of our goal is to assess the conditions in which articles help to improve predictions, we applied heuristics on the pre-verdict text to extract a total of 1,790 unique cited law articles, 33.8% of which were mentioned only once across the entire corpus. Also, not all articles are related to housing law. We address this by keeping only 445 articles from the Book Five - Obligations of Civil Code of Quebec (C.C.Q.) which establishes the rules concerning the contractual obligations between landlords and tenants and whose frequency in the corpus has a minimum of two. Three examples are shown on Table 1 for the decision in Figure 1. Article distribution is heavily skewed: the 3 most frequent articles cover 72%, 42% and 27% of all documents respectively while all other articles do not exceed 4%. Mean and median frequency of the articles amount to 2571 and 17 respectively. Section 3 further describes the use of these articles as input.

The pre-verdict section contains both fact description and legal analysis. As the latter can give hints about the verdict that the model is expected to predict, we removed from the pre-verdict section any paragraphs containing citations of articles (underlined text in Figure 1) and we capped the maximum input text length at 128 tokens. By doing so, we force the model to make predictions on the sole basis of fact descriptions.

2.2 Making Target Labels from the Verdict Section of the Decisions

We carefully combined NLP-engineered tools (regular expressions and the like) and some housing law expertise in order to pseudo-automatically identify 23 labels that we believe are representative of the rulings and that cover the diversity of the verdicts at a fine grain. These labels are cumulative and three are shown as an example in Table 1 for the decision in Figure 1. The average and median numbers of labels per decision both amount to 3 with a standard deviation of 1.5. Nearly half of all rulings involves an eviction (48.1%) and a termination of the lease (46.1%), hinting that a significant part of the cases

<table>

</tr>
</tbody>
</table>

Table 1: Civil Code of Quebec articles and verdict labels extracted from the decision shown in Figure 1.
involve an unfavourable outcome for tenants sued by landlords. Further investigation confirms a bias favourable for landlords as 80.3% of cases with the top frequent label `monetary_penalty_for_defendant` have a tenant as the (penalized) defendant.

Overall, 0.05% of all instances were not assigned any labels and 18.2% did not contain any articles. For the design of our experiments, all instances with no article or no verdict label were excluded, thus resulting in a final corpus of 544,857 documents with an average of 3.3 labels per instance (standard deviation of 1.4 and median of 4). The average and median numbers of articles per document both amount to 2. Our instances are randomly divided into training, validation and test sets with a 60-20-20 ratio.

3 Models

We aim at designing a multilabel classification task in which a model has to return the labels corresponding to the verdict on the basis of the pre-verdict section of each decision. Our baseline is a One-Versus-Rest Logistic Regression, i.e. each label has its own classifier. The input text is vectorized through character-based TF-IDF spanning bi-grams to 8-grams (character-based features outperformed token-based). Only the top 100k n-grams are retained. We also use CamemBERT (Martin et al., 2019), a variant of BERT (Devlin et al., 2019) that was pre-trained on generic French corpora. We further pre-trained the `camembert-base` default parameters (unsupervised masked language modelling task) from Wolf et al. (2020) on the train set during 20 epochs. We eventually fine-tuned them during the multilabel classification task. The batch size and the maximum number of fine-tuning epochs are set at 50 and 20 respectively. Training is stopped when no further improvement is obtained in terms of exact match on validation set. We use the Adam optimizer (Kingma and Ba, 2015) with a learning rate at $10^{-5}$ (all other hyperparameters are left at default value). The optimization criterion is the binary cross entropy with logits loss for numerical stability during optimization. Therefore the final output is that of a logit function, with scores ranging from $-\infty$ to $+\infty$. A label is returned whenever its associated output value exceeds 0. We use a vanilla CamemBERT model whose only input is the pre-verdict text and three other variants described in the next subsections.

3.1 One-Hot and Node2Vec Encoding of Articles

For each instance, the mention/absence of each article is one-hot encoded through a 445-dimensional vector, each dimension corresponding to one article. We have one model named BERT-OH (Figure 2 part a) in which the BERT output of a decision text (768-dimensional vector corresponding to the first token from hidden states) and the articles one-hot vector are concatenated and passed through fully connected layers before outputting the verdict labels. Given the heavily skewed distribution of these articles among the documents, these discrete one-hot vectors are sparse and likely not very expressive (in the case of Figure 1 for instance, all dimensions except three would be zeroed because of only three articles extracted as shown in Table 1).

![Architecture diagrams of BERT-OH, BERT-N2V both on part a) and BAF on part b).](https://example.com/figure2.png)

Figure 2: Architecture diagrams of BERT-OH, BERT-N2V both on part a) and BAF on part b).

As a result, we thought of a continuous and more expressive representation that could embed the articles organization within the law. In the one-hot vector approach, each article is assigned one dimension independent from the other as if all articles were completely unrelated to each other. But when having a closer look at the C.C.Q. Book Five - Obligations on Figure 3 that concentrates the rules related to landlord-tenant disputes, the articles are

---

\(^{2}\) Exact match achieved by further pre-trained models is around one percent point greater than models with default pre-trained parameters.

\(^{3}\) Screenshot from CANLII [http://canlii.ca/t/533nd](http://canlii.ca/t/533nd) last accessed on January 20th 2021
actually organized into titles, chapters, divisions, paragraphs and so on, down to the articles themselves. As each subcategory becomes more and more precise, the articles encompassed in it are related to closer and closer legal concepts. For instance, articles 1957 to 1970 are especially dedicated to repossession of a dwelling and eviction and can be expected to relate to the same legal objects. Therefore, we wanted to make an embedding that could capture the structural closeness between articles, that is, two articles located in the same subsection would have closer representations.

Another argument in favour of using embeddings based on the topological relatedness among articles is the fact that articles with close numbers have a tendency to co-occur together in the decisions, as shown on the diagonal of Figure 4 along which distinct articles with close numbers tend to belong to the same subsections and to have higher correlation values.

One method for representing the topological organization of the law is Node2Vec (Grover and Leskovec, 2016). We first built a tree whose root is Book Five - Obligations and added all of the subsequent sections as nodes. Articles were added as leaves. Next, the edges were placed by linking each node/section to the subsequent nodes/sections that it encapsulates. For instance, in Figure 3, CHAPTER IV - LEASE is linked to DIVISION IV - SPECIAL RULES FOR LEASES OF DWELLINGS which is linked to § 7 - Right to maintain occupancy, and so on, until placing the edges between I. - Beneficiaries of the right and each of the leaves/articles 1936 to 1940. An edge between two nodes cannot “skip” any node of intermediate level between the two if there is any. Overall, we made a graph with 1,565 nodes (subsections and articles) and 1,564 edges. From this graph, we made an embedding for each article such that articles belonging to the same subsection and related to the same legal concepts, would have embeddings close to each other. Following the Node2Vec technique, we generated 200 random walks from each node (article or section) that gave a total of 313k sequences of 200 nodes by following the edges. Then, we trained a Word2Vec model (Mikolov et al., 2013) on these sequences during 10 epochs and with a window size of 10, so that each node is assigned a Node2Vec embedding (256-sized vector) that captures the proximity of the neighbouring nodes. We eventually only kept the Node2Vec representations of the leaves that correspond to the 445 retained articles. For the sake of clarity, the vectors of two articles randomly drawn would have a higher cosine similarity if the articles belong to the same subsection than if they belong to distinct ones. For the BERT-N2V (node2vec) model, the input contains the pre-verdict text (passed through CamemBERT) plus an average of the Node2Vec embeddings of all articles mentioned in the documents (e.g. average embedding of articles 1619, 1971 and 1883 in Table 1 for the case in Figure 1).

3.2 Applying BERT on the Law Articles Text

The one-hot and the Node2Vec encodings are still shallow representations of the articles as they do not even use the text of Civil Code of Quebec. At most, Node2Vec is only capturing a topological representation of how the 445 articles are organized.
in the law. This is why we considered another model called BAFA (BERT model with Adapters applied on Facts and Articles, Figure 2 part b) that is given as input the pre-verdict text of the decision and the text of all articles cited in it. The 445 retained articles have a average length of 34 tokens (median of 32 and standard deviation of 17). The pre-verdict section and the articles are encoded through two distinct CamemBERT models so that one is fine-tuned on the decision text and the other on the law text. The BERT output (i.e. first token of hidden states) of the decision is then passed through a 12-head attention mechanism as a query while the BERT output obtained from each cited articles are concatenated (up to 22 cited articles per decision) and passed as a key-value pair. The output of the attention mechanism is then passed through two fully connected layers. As we use two distinct CamemBERT modules, the batch size is reduced to 4 and we added adapters (Pfeiffer et al., 2020) as an attempt to speed up computation.

To the best of our knowledge, there is no other work that uses the fine-tuning of pre-trained BERT models on the text of cited articles for verdict prediction of court decisions. When it comes to LJP tasks formalized as text classification, many of most recent works usually aimed at charge prediction or law articles prediction on the sole basis of the facts description (Xiao et al., 2018; Zhong et al., 2018). Şulea et al. (2017) made a ruling prediction task comparable to ours but without the text of the articles. When it comes to experiments that actually use the text of law articles, Hu et al. (2018) and Xu et al. (2020) used it for improving prediction of confusing charges only while Luo et al. (2017) and Long et al. (2019) used a combination of recurrent neural nets with attention mechanisms for encoding it into their models for charge prediction and divorce verdict respectively. Still, none of these works involve transformer architecture. Concerning the experiments that use BERT, Chalkidis et al. (2019) and Wang et al. (2020) used pre-trained models for prediction of violation of human rights article and of charges respectively on the basis of the facts only.

4 Results and Discussion

The classification results are shown in Table 2. For each label, we compute the F1 score (harmonic mean between precision and recall) obtained by each model and add the label distribution across the test documents. For each model, the last two rows of Table 2 present two overall scores based on metrics that we believe are constraining enough and appropriate for the evaluation of systems that could one day be deployed in real life scenarios. F1 macro average is unweighted average of all labels F1 scores, and thus penalizes models that delivers poor F1 scores for a large number of labels. It measures the ability of the model to predict a large variety of rulings. We also compute exact match which corresponds to the ratio of instances for which a model is able to return the exact set of labels assigned to them. Therefore, an instance is considered as misclassified whenever its prediction has a label in excess or one missing.

4.1 Gains Obtained across Verdict Labels with Article-Based Features

One goal of our experiment is to assess how articles can improve the prediction of cases in which they are cited. Figure 5 shows a heatmap detailing the correlation among articles and verdict labels. In the top left corner, monetary_penalty_for_defendant, eviction, termination_lease and proportional_enforcement are strongly correlated with articles 1619, 1971 and 1883 which respectively define: the computation of an additional indemnity that can be added to damages; a rule that allows the termination of the lease if rent is over three weeks late in payment; a rule so that the tenant may avoid lease termination by paying the due rent plus interest before the judgment. Although these articles make a consistent legal ground with the aforementioned verdict labels, inputting them into the models through any representation (be it one-hot/node2vec/BERT encoding) added very little improvement for the F1 scores of these labels (by at most 2.8 percent point on average relative to CamemBERT alone), very likely because of their already high frequency in the corpus. Furthermore, on the heatmap on Figure 5, tenant_ordered_pay_rent is strongly correlated with article 1973 that defines the conditions allowing the judge to grant lease termination (unless the payment of the rent is over three weeks late, the judge may choose to either terminate the lease immediately or either order the tenant to pay the rent) and the article-based features help in dramatically improving the corresponding F1 score by 18-22 percent points compared to a sole CamemBERT setting. We also observe that landlord_repossesses_rental_unit and
monetary_penal­ty_for_applicant are strongly asso­ciated with several articles, especially 1963 and 1967 which establish respectively the conditions by which the judge can authorize a landlord-applicant to repossess their dwelling from which a tenant refuses to depart and the indemnities that the landlord must pay to the tenant for moving expenses when repossession is granted. Article-based models also improved the F1 scores of these two labels, though not as important as for tenant_ordered_pay_rent, with average gains of 4.1 and 10.1 points respectively. All in all, the inclusion of article-based features has a negligible impact when the labels already have a high support in the documents, but the improvement is more significant for labels that are rarer (landlord_repossesses_rental_unit, monetary_penalty_for_applicant and tenant_ordered_pay_rent have supports below 5%) and that have a high correlation value with the articles cited in them (for the three aforementioned labels and their articles, the average correlation is around 0.75). A counter-example to that principle would be agreement_between_parties and tribunal_sets_new_rent whose correlation values with cited articles are not that important (below 0.5) and for which no significant improvement on F1 scores is observed with article-based features.

### 4.2 Comparing Performance among Models

In general, BERT-based models do better than the baseline in terms of macro-averaged F1 score and exact match. Furthermore, the scores show that article-based features help in outperforming a sole CamemBERT model with higher exact match scores by up to 3.1 percent points and a higher F1 score macro-average by up to 3.8 points. The best F1 macro average score is achieved by the model with node2vec (63.2%) while best exact match score is obtained by CamemBERT with one-hot vectors (67.0%). Still, such results must be nuanced: the performance gains are mostly obtained with either high frequency labels (five most frequent plus lease_already_terminated) or labels that are strongly correlated with certain articles, which can explain the marginal improvements achieved in the coarse scores at the bottom of Table 2. Furthermore, the use of article-based features...
Figure 5: Heatmap of the correlation matrix of the verdict labels and the 30 most frequent articles. The verdict labels and the articles are sorted by decreasing frequency on their respective axes.

seem to sometimes harm the performance for low-frequency labels relative to vanilla BERT (defendant ordered some action, penalty misc, tribunal cancels past ruling, discontinuance claim, schedule new audience, tribunal upholds past ruling), which suggests that such features add noise rather than help the model in accurately predicting these verdicts.

Although BAFA used the text of both decisions and articles, both encoded through two distinct BERT models, the overall performance is disappointing compared to the variants with one-hot and node2vec features: despite achieving the best F1 scores for some top frequent labels, the overall coarse scores remain below those of BERT-OH and BERT-N2V. Plus, the training of BAFA also is significantly longer4.

For illustrative purposes, if we were to compare the performance achieved by our models in this task with other similar works, we could cite:

- Aletras et al. (2016) and Chalkidis et al. (2019) who achieved respectively an accuracy of 79% and a F1 macro-average score of 80.2% in binary classifications for violation of human rights;

- Şulea et al. (2017) who achieved an accuracy of 92.8% for an 8-mutually-exclusive classes classification task for ruling prediction (our task has 23 cumulative labels);

- Luo et al. (2017) got a macro-average F1 score of 95.4% in a charge prediction task that use articles text as input; in another charge prediction task, Zhong et al. (2018) achieved 49.1% and 70.9% for that score on two other datasets (our task is about verdict prediction).

Two main points can be made from these results. First of all, shallow articles embeddings (one-hot and node2vec) do better than BERT-encoding of law text at allowing a marginal improvement over some low-support labels (though not all), with BERT-N2V reaching the highest F1 macro-average score at 63.2%. A tentative explanation is that directly inputting the text of the cited articles adds noisy information that confuses rather than helps the model in the task while a “fuzzier” representation of the articles gives a broader information about articles (Node2Vec embeds the topological position of articles in Civil Code of Quebec) without forcing the model to combine the legal terminology of the law and the text input of the decisions. The second point is that although article-based models outperform vanilla CamemBERT, this is mainly due to the marginal improvement over some of the top frequent labels and to the improvement over some verdict that are strongly correlated with certain articles. This suggests that such models only excel in predicting the most recurrent and stereotypical landlord-tenant disputes (eviction of a non-paying tenant; moving indemnities for a tenant whose rental unit is repossessed by the landlord).

All in all, these models would be unusable for providing legal assistance for a large variety of cases as they would only excel in predicting accurately the most frequent rulings to the detriment of other types of cases. Also, as these models deal with housing law domain that is related to sensitive social issues (Gallié et al. (2016) emphasized that tenants are less confident in dealing with judicial proceedings), we tried to extract some significant patterns from the self-attention weights in the CamemBERT architecture that could help in understanding what causes the model to return some prediction, but found nothing prone to interpretation, which is consistent with a statement from Jain and Wallace (2019).

4.3 Discussion about the Experiment Setting

The results obtained seem consistent with observations from Holzenberger et al. (2020) who stated that even a further pre-trained BERT model struggles with a legal entailment task, thus suggesting that the fine-tuning of pre-trained BERT models on statutes and law articles text is not sufficient

4Over 1 hour per epoch for a one-BERT model, over 14 hours per epoch for two BERTs combined.
for solving tasks in very specific domains such as tax law or housing law. Regardless of the method used for inputting articles into the models, all of the approaches combining description of the facts and articles just excel at predicting the most frequent verdicts, which suggests that they would be unusable as is at a higher scale as they would not be able to provide satisfactory legal assistance for cases different from the most recurrent ones. Bender et al. (2021) emphasized the risks involved in using large pre-trained models that tend to encode and amplify biases already present in the training data. To paraphrase the title of their paper, their remarks are consistent with our observations as we end up with “legal parrots” which would not be able to accurately address the variety of real world landlord-tenant disputes.

The fact that article-based features allow for significant improvement under the condition that the labels are strongly correlated with articles also raises questions about the setting of LJP experiments: in the charge prediction task made by Xiao et al. (2018), charges and laws with frequency below 30 were removed from the CAIL2018 dataset and each charge label is strongly associated with one specific article. In contrast, in our corpus, each label is not always strongly correlated with some law article, as shown in Figure 5. Some works using the CAIL2018 dataset such as that from Wang et al. (2020) made further changes in the dataset by removing target labels with frequency below 100. Unlike them, in our work, we were much more permissive during the creation of our corpus as we retained articles with a frequency of at least 2 and made labels to exhaustively cover as many verdicts as possible (i.e. 1102 unique combinations of labels), even though some labels could have been merged together (e.g. landlord_repossesses_rental_unit and monetary_penalty_for_applicant tend to co-occur together) or discarded/weighted down. For instance, schedule_new_audience and applicant_forbidden_seek_recourse have a low frequency and are rather technical legal details that would be more relevant for a legal expert than for a layman seeking general advice. If we computed F1 average score weighted by each label’s support, BERT models would have an average performance of 91.6%, but that coarse metric is mostly pulled upwards by scores achieved for most frequent labels. We must also emphasize that in our dataset there is no 1-to-1 correspondence between labels and articles as in CAIL2018 in which articles not relevant to specific charges were removed beforehand. This illustrates the difficulty in automating legal reasoning over cases and unfiltered law articles in a realistic context.

5 Concluding Remarks

We designed a LJP task as text multilabel classification for verdict prediction based on a collection of landlord-tenant disputes in French for which we used a further pre-trained CamemBERT model and applied different types of features derived from the articles cited in the decisions (one-hot, Node2Vec, BERT encoding of the text of articles). By doing so, we noticed that leveraging articles as input features (regardless of the representation used) made either marginal improvements for F1 scores of most frequent labels, either significant improvements for labels that are strongly correlated with certain articles. The use of article-based one-hot features achieves best exact match score (67.0%) while node2vec features achieve best F1 macro average score (63.2%). The model that encodes the text of the articles with BERT does not outperform the two previous methods.

As future work, we plan on comparing how models perform under both “realistic” setting (several rare target labels with no or few connections with the law available, as we did in this work) and “laboratory” setting (where low frequency targets and laws are aggressively filtered out). We also plan to assess whether the patterns observed in our work (performance improves when articles are strongly correlated with labels) also exist in other LJP datasets beyond housing law and Canadian cases. Furthermore, we plan to study further the attention weights and the mechanisms underlying the significant prediction improvement observed for certain labels when the input contains the text of articles that are highly correlated with the corresponding verdicts.

Abstract
Hyperpartisan news show an extreme manipulation of reality based on an underlying and extreme ideological orientation. Because of its harmful effects at reinforcing one’s bias and the posterior behavior of people, hyperpartisan news detection has become an important task for computational linguists. In this paper, we evaluate two different approaches to detect hyperpartisan news. First, a text masking technique that allows us to compare style vs. topic-related features in a different perspective from previous work. Second, the transformer-based models BERT, XLM-RoBERTa, and M-BERT, known for their ability to capture semantic and syntactic patterns in the same representation. Our results corroborate previous research on this task in that topic-related features yield better results than style-based ones, although they also highlight the relevance of using higher-length n-grams. Furthermore, they show that transformer-based models are more effective than traditional methods, but this at the cost of greater computational complexity and lack of transparency. Based on our experiments, we conclude that the beginning of the news show relevant information for the transformers at distinguishing effectively between left-wing, mainstream, and right-wing orientations.

1 Introduction
Media such as radio, TV channels, and newspapers control which information spreads and how it does it. The aim is often not only to inform readers but also to influence public opinion on specific topics from a hyperpartisan perspective.

Social media, in particular, have become the default channel for many people to access information and express ideas and opinions. The most relevant and positive effect is the democratization of information and knowledge but there are also undesired effects. One of them is that social media foster information bubbles: every user may end up receiving only the information that matches his/her personal biases, beliefs, tastes and points of view. Because of this, social media are a breeding ground for the propagation of fake news: when a piece of news outrages us or matches our beliefs, we tend to share it without checking its veracity; and, on the other hand, content selection algorithms in social media give credit to this type of popularity because of the click-based economy on which their business are based. Another harmful effect is that the relative anonymity of social networks facilitates the propagation of toxic, hate and exclusion messages. Therefore, social media contribute to the misinformation and polarization of society, as we have recently witnessed in the last presidential elections in USA or the Brexit referendum. Clearly, the polarization of society and its underlying discourses are not limited to social media, but rather reflected also in political dynamics (e.g., like those found in the US Congress (Andris et al., 2015)): even in this domain, however, social media can provide a useful signal to estimate partisanship (Hemphill et al., 2016).

Closely related to the concept of controversy and the “filter bubble effect” is the concept of bias (Baeza-Yates, 2018), which refers to the presentation of information according to the viewpoints or interests of the journalists and the news agencies. Detecting bias is very important to help users to acquire balanced information. Moreover, how a
piece of information is reported has the capacity to evoke different sentiments in the audience, which may have large social implications (especially in very controversial topics such as terror attacks and religion issues).

In this paper, we approach this very broad topic by focusing on the problem of detecting hyperpartisan news, namely news written with an extreme manipulation of the reality on the basis of an underlying, typically extreme, ideology. This problem has received little attention in the context of the automatic detection of fake news, despite the potential correlation between them. Seminal work from (Potthast et al., 2018) presents a comparative style analysis of hyperpartisan news, evaluating features such as characters n-grams, stop words, part-of-speech, readability scores, and ratios of quoted words and external links. The results indicate that a topic-based model outperforms a style-based one to separate the left, right and mainstream orientations.

More recently, in (Kiesel et al., 2019), the features that participants used in SemEval-2019 task 4 on hyperpartisan news detection have been summarized: n-grams, word embeddings, stylometry (e.g., punctuation and article structure), sentiment and emotion features, named entities, quotations, hyperlinks, and publication date. Using the same dataset from SemEval-2019, (Anthonio, 2019) evaluated features like bag-of-words, bag-of-clusters, word embeddings and contextual character-based embeddings, POS n-grams, stylistic features and the sentiment; the authors found that dense document representations work better across domains and tasks than traditional sparse representations. Finally, (Hosseinia, 2020) found effective to use personality information in hyperpartisan news detection after topic-based sub-sampling of the news training data. The datasets proposed in (Kiesel et al., 2019) were manually labeled and the largest one was labeled in a semi-automated manner via distant supervision.

Instead of employing the datasets from (Kiesel et al., 2019), we build upon previous work and use the dataset from (Potthast et al., 2018): this way we can investigate hyperpartisan-biased news (i.e., extremely one-sided) that have been manually fact-checked by journalists from Buzzfeed, and contrast our results with what they achieved. The articles originated from 9 well-known political publishers, three each from the mainstream, the hyperpartisan left-wing, and the hyperpartisan right-wing. To detect hyperpartisanship, we aim to explore the trade-off between the performance of the models and the transparency of their results. Taking this into account, we apply two approaches diametrically opposite to each other in the text classification state of the art. On the one hand, we use three transformer-based models, which have shown outstanding performance, but high complexity and lack of transparency. On the other hand, we use a masking-based model that requires fewer computational-resources and showed a good performance in related tasks such as authorship attribution (Stamatatos, 2017a).

The masking technique transforms the original texts in a form where the textual structure is maintained, while letting the learning algorithm focus on the writing style or the topic-related information. This technique makes it possible for us to corroborate previous results that content matters more than style. Moreover, we aim to find explainable predictions of hyperpartisanship with the attention mechanism of the transformer-based models. With this purpose, we expect to derive the explanation by investigating the scores of different features used to output the final prediction. Based on this, we contrast the transparency of both approaches by comparing the relevant parts of the texts that they highlight.

The rest of the paper is structured as follows. In Section 2 we describe our method to hyperpartisan news detection based on masking. Section 3 presents details on the dataset and the experimental setup. In Section 4 we show the obtained results and discuss about them. Finally, Section 5 concludes with some directions for future work.

2 Masking and Transformer-based Models

2.1 Investigating Masking for Hyperpartisanship Detection

The masking technique that we propose here for the hyperpartisan news detection task has been applied to text clustering (Granados et al., 2011), authorship attribution (Stamatatos, 2017a), and deception detection (Sánchez-Junquera, 2018) with encouraging results. The main idea of the proposed method is to transform the original texts to a form where the textual structure, related to a general style (or topic), is maintained while content-related (or style-related) words are masked. To this end, all the occurrences of non-desired terms are re-
placed by symbols. Let \( W_k \) be the set of the \( k \) most frequent words, we mask all the occurrences of a word \( w \in W_k \) if we want to learn a topic-related model, or we mask all \( w \notin W_k \) if we want to learn a style-based model. Whatever the case, the way in which we mask the terms in this work is called Distorted View with Single Asterisks and consists in replacing \( w \) with a single asterisk or a single # symbol if the term is a word or a number, respectively. For further masking methods, refer to (Stamatatos, 2017a).

Table 1 shows a fragment of an original text and the result of masking style-related information or topic-related information. With the former we obtain distorted texts that allow for learning a topic-based model; on the other hand, with the latter, it is possible to learn a style-based model. One of the options to choose the terms to be masked or maintained without masking is to take the most frequent words of the target language (Stamatatos, 2017a). In the original text from the table, we highlight some of the most frequent words in English.

### 2.2 Transformer-based Models

Transformer-based models have been trained with huge general language datasets. Such is the case of the Bidirectional Encoder Representations from Transformers (BERT). BERT is designed to pretrain deep bidirectional representations from an unlabeled text by jointly conditioning on both left and right context in all layers (Devlin et al., 2018). This text representation allows the model to capture complex patterns going beyond merely the use of words and capturing semantic and syntactic patterns in the same representation.

The framework of BERT consists of two steps: pre-training and fine-tuning. For the pre-training, the collected data included BooksCorpus (800M words) and English Wikipedia (2,500M words). The BERT_{BASE} model has 12 layers with 12 self-attention heads, and uses 768 as hidden size, with a total of 110M parameters; and the BERT_{LARGE} model has 24 layers with 16 self-attention heads, and uses 1024 as hidden size, with a total of 340M parameters. The vocabulary contains 30K tokens. For fine-tuning, the model is first initialized with the pre-trained parameters, and all of the parameters are fine-tuned using labeled data from the downstream task, which in our case are 1555 news annotated with the political orientation. The first token of every sequence is always a special classification token ([CLS]), which is used as the aggregate sequence representation for classification tasks. In our work, we add to the [CLS] representation two dense layers and a Softmax function to obtain the binary classification.

In this paper we evaluate three transformer-based models: BERT; the multilingual BERT (M-BERT) (Devlin et al., 2018), which was pretrained on the concatenation of monolingual Wikipedia datasets from 104 languages (Wang et al., 2019; Pires et al., 2019); and XLM-RoBERTa, which was pretrained on 2.5TB of newly created clean CommonCrawl data in 100 languages (Cañete et al., 2020).

### 3 Experiments

We used the BuzzedFeed-Webis Fake News Corpus 2016 collected by (Potthast et al., 2018) whose articles were labeled with respect to three political orientations: mainstream, left-wing, and right-wing (see Table 2). Each article was taken from one of 9 publishers known as hyperpartisan left/right or mainstream in a period close to the US presidential elections of 2016. Therefore, the content of all the articles is related to the same topic. During initial data analysis and prototyping we identified a variety of issues with the original dataset: we cleaned the data excluding articles with empty or bogus texts, duplicates. As a result, we obtained a new dataset with 1555 articles out of 1627.1 Following the settings of (Potthast et al., 2018), we balanced the training set using random duplicate oversampling.

#### 3.1 Masking Content vs. Style in Hyperpartisan News

In this section, we reported the results of the masking technique from two different perspectives. In one setting, we masked topic-related information in order to maintain the predominant writing style used in each orientation. We call this approach a style-based model. With that intention we selected the \( k \) most frequent words from the target language, and then we transformed the texts by masking the occurrences of the rest of the words. In another setting, we masked style-related information to allow the system to focus only on the topic-related differences between the orientations. We call this a topic-based model. For this, we masked the \( k \) most frequent words and maintained intact the rest.

\[^1\text{The dataset will be available to the research community upon acceptance.}\]

After the text transformation by the masking process in both the training and test sets, we represented the documents with character n-grams and compared the results obtained with the style-based and the topic-related models.

3.2 Experimental Setup

Text Transformation: We evaluated different values of \( k \) \((k \in \{100, 200, ..., 5000\})\) for extracting the \( k \) most frequent words from English\(^2\). For the comparison of the results obtained by each model with the ones of the state of the art, we only showed the results fixing \( k = 500 \).

Text Representation: We used a standard bag-of-words representation with \( tf \) weighting and extracted character 5-grams with a frequency lower than 50.

Classifiers: We compared the results obtained with Naïve Bayes (NB), Support Vector Machine (SVM) and Random Forest (RF); for the three classifiers we used the versions implemented in `sklearn` with the parameters set by default.

Transformers: We approached the hyperparameter tuning by grid search. The best results were obtained with: \( learning\ rate = 3e^{-5}; \) the \( batch\ size = 16; \) and the \( adam\) optimizer. Moreover, we applied a dropout value of 0.3 to the last dense layer. We have selected a value of 200 for the \( max\_length\) hyperparameter.

Evaluation: We performed 3-fold cross-validation with the same configuration used in (Potthast et al., 2018). Therefore, each fold comprised one publisher from each orientation (the classifiers did not learn a publisher’s style). We used macro \( F_1 \) as the evaluation measure since the test set is unbalanced with respect to the three classes. In order to compare our results with those reported in (Potthast et al., 2018), we also used accuracy, precision, and recall.

Baseline: Our baseline method is based on the same text representation with the character n-grams features, but without masking any word.

4 Results and Discussion

Table 3 shows the results of the proposed method and the system from (Potthast et al., 2018)\(^3\) in our cleaned dataset (Section 3), both considering topic and style-based methods. In order to compare our results with those reported in (Potthast et al., 2018), we report the same measures the authors used. We also include the macro \( F_1 \) score because of the unbalance test set. For these experiments we extract the character 5-grams from the transformed texts, taking into account that as more narrow is the domain more sense has the use of longer n-grams. We follow the steps of (Stamatatos, 2017b) and set \( k = 500 \) for this comparison results.

Similar to (Potthast et al., 2018), the topic-based model achieves better results than the style-related model. However, the differences between the results of the two evaluated approaches are much higher (0.66 vs. 0.57 according to Macro \( F_1 \)) than those obtained from the system of (Potthast et al., 2018) (0.63 vs. 0.61). The highest scores of the masking technique were consistently achieved

\(^2\)We use the BNC corpus (https://www.kilgarriff.co.uk/bnc-readme.html) for the extraction of the most frequent words as in (Stamatatos, 2017a).

\(^3\)https://github.com/webis-de/ACL-18
using the SVM classifier and masking the style-related information (i.e., applying the topic-related model). This could be explained with the fact that all the articles are about the same political event in a very limited period of time. In line with what was already pointed out in Potthast et al. (2018), the left-wing orientation is harder to predict, possibly because this class is represented with fewer examples in the dataset.

Another reason why our masking approach achieves better results than the system from Potthast et al. (2018), could be that we use a higher length of character n-grams. In fact, comparing their results against our baseline model, it is possible to note that even without masking any word, the classifier obtains better results. This suggests that the good results are due to the length of the character n-grams rather than the use of the masking technique.

The last three rows of Table 3 show the results of the transformer-based models. As we can see, these models achieved the highest results, in particular the BERT model, with a Macro $F_1$ = 0.86. These models are known for their ability to capture complex syntactic and semantic patterns, therefore, these results are somehow justified to be the highest compared to the masking approach. However, what is interesting at this point is the effectiveness of the models at predicting the correct orientation using just the beginning of the news (max Length = 200). This is aligned to the work of Ghanem et al. (2021) that focused on analyzing the initial part of false news articles. The authors as-

Table 4: Most relevant features to each class.

Table 4 shows the features with the highest weights from the SVM (we used scikit-learn’s method to collect feature weights). It is possible to note that the mention of cnn was learned as a discriminative feature when the news from that publisher were used in the training (in the topic-based model). However, this feature is infrequent in the test set where no news from CNN publisher was included.

The features related to Donald Trump (donal and onal), and Hillary Clinton (illary and illary) are more frequent in one of the hyperpartisan orientation, and none of them occurs frequently in the
main
Obama proposed a plan which his son pretty much confirmed in a foolish statement. The content of those tax returns has been the subject of much speculation, but given Trump’s long history of tax evasion and political bribery, it doesn’t take much imagination to assume he’s committing some kind of fraud.

right
The media, which had started by March 16, 2011, and shared with POLITICO, reads: Jim, on Kenya your person in the field might look into the impact there of Obama’s public comments about his father. I’m told by State Dept officials that Obama publicly derided his father on ( ...). Blumenthal, a longtime confidant of both Bill and Hillary Clinton, emerged as a frequent correspondent in the former secretary of ( ...).

Table 5: Fragments of original texts and their transformation by masking the k most frequent terms. Some of the features from Table 4 using the topic-related model are highlighted.

4.2 Features with the Highest Attention Scores
Transformer-based models allow us to visualize different parts of the news according to the scores they received to obtain the final prediction. In Figure 1 we show examples of news predicted correctly by BERT (the model with the highest $F_1$ score). Due to space limitations, we provide fragments of six news, two per orientation. The more intense the color, the greater is the weight of attention given by the model.

In the examples from 1a, the left-wing orientation remarks the names of the opposite politicians, and it is possible to see which of them is the favourite of the journalist. In particular, the leader of the right-wing (i.e., Trump) is referred in a negative way (he does not know his own words) while Hillary Clinton, the representative of the left-wing, is favored by the news. Similar to this, examples 1c do the same but in the opposite direction; i.e., Hillary Clinton is put as a very negative “character” who loves taxes and is the most despicable liar ever. However, examples from 1c offer a comparison in which keep the reader in a neutral position. Moreover, in the second mainstream news, Trump’s campaign is mentioned without describing the stance of the author whether Trump did well or not in his topic selection. This suggests that the style used to speak about the leaders can differ from the more biased (hyperpartisan) news to the less biased (mainstream).

We can conclude that the attention mechanism of the transformers not only help in doing effective predictions, but offer some extra information that could be useful to understand some insights about hyperpartisanship. For example, the words with the highest scores can be used in other strategies to confirm the previous results that topic-based models outperform a style-based one at distinguishing left, right and mainstream orientations (Potthast et al., 2018).

5 Conclusions
In this paper we presented initial experiments on the task of hyperpartisan news detection. In particular, we aimed to explore the trade-off between performance and transparency, and proposed a comparison of two different approaches. First, we explored the use of masking techniques to boost the performance of a lexicalized classifier. Our results corroborate previous research on the importance of content features to detect extreme content: masking, in addition, shows the benefits of reducing data sparsity for this task comparing our results with the state of the art. We evaluated different values of the parameters and see that finally our baseline model, in which we extract character 5-grams without applying any masking process, achieves the better results. This seems to indicate a strong lexical overlap between different sources with the same orientation, which, in turn, calls for more challenging datasets and task formulations to encourage the development of models covering more subtle, i.e., implicit, forms of bias. Future datasets could consider more topics and different time spans to avoid the models learn from the topic, rather than the target classes.

Second, we used three transformer-based models (BERT, M-BERT, and XLM-RoBERTa) that are resource-hungrier than the masking technique, and achieved the highest results. We also presented some examples of how these models, through their attention scores, provide additional information about the relevant parts of the text for distinguishing their political orientation. Considering the high effectiveness of these models, and that they only observe the first part of the news, we will evaluate as future work how necessary is to use all the
Hyperpartisan (left-wing) news.

Hyperpartisan (right-wing) news.

Non-hyperpartisan (mainstream orientation) news.

News (and not only the beginning), e.g., with the Transformer-XL model (Dai et al., 2019). Moreover, we are motivated to take advantage of the attention scores to study in more detail the style used in hyperpartisan news in order to improve the predictions.

Acknowledgments

The work of the authors from the Universitat Politècnica de València was funded by the Spanish Ministry of Science and Innovation under the research project MISMIS-FAKEnHATE on MIS-information and MIScommunication in social media: FAKE news and HATE speech (PGC2018-096212-B-C31). Experiments were carried out on the GPU cluster at PRHLT thanks to the PROMETEO/2019/121 (DeepPattern) research project funded by the Generalitat Valenciana.

Abstract

In this work, we present a Serbian literary corpus that is being developed under the umbrella of the “Distant Reading for European Literary History” COST Action CA16204. Using this corpus of novels written more than a century ago, we have developed and made publicly available a Named Entity Recognizer (NER) trained to recognize 7 different named entity types, with a Convolutional Neural Network (CNN) architecture, having $F_1$ score of $≈91\%$ on the test dataset. This model has been further assessed on a separate evaluation dataset. We wrap up with comparison of the developed model with the existing one, followed by a discussion of pros and cons of the both models.

1 Introduction

The “Distant Reading for European Literary History”\(^1\) (COST Action CA16204) has started in 2017 with the purpose of using computational methods to analyse large collections of literary texts (Stanković et al., 2019; Frontini et al., 2020). The main goal of this ongoing action is to compile a multilingual open-source collection, named European Literary Text Collection (ELTeC), containing linguistically annotated sub-collections of 100 novels per language written more than 100 years ago.

In this paper, we present a collection of Serbian texts in this corpus, named SrPTELTeC. Alongside, we describe our efforts in developing its Named Entity (NE) layer, defined previously as one of the main action’s deliverables.

For this purpose, we adjusted and used the existing rule-based NE recognizer for Serbian, dubbed SrPNER, that we will describe in Section 2 together with some approaches to NE recognition in literary texts. This SrPNER model was applied to the raw version of the selected texts from SrPTELTeC collection, presented in Section 3. Based on the specifically tailored guidelines, different evaluators performed careful checks and corrections, yielding a gold standard (SrPTELTeC-GOLD). This enabled us to train a CNN-based NE recognizer, named SrPCNNER, presented in Section 4. Having the gold dataset, prepared as described in Subsection 4.1, we trained (Subsection 4.2) and evaluated the model in two different settings: first, we discussed our model’s performance on the SrPTELTeC-GOLD test subset, as shown in Subsection 4.3. Afterwards we carried out a detailed evaluation on a collection of novels that were not present in the gold standard, named SrPTELTeC-EVAL, with the findings and a thorough discussion given in Section 5. Finally, conclusions and plans for the future work were stated in Section 6.

2 Related Work

The existence of large-scale lexical resources for Serbian, e-dictionaries in particular (Krstev, 2008), coupled with local grammars in the form of finite-state transducers (Vitas and Krstev, 2012), enabled the development of a comprehensive rule-based system for NER SrPNER. This system presented by Krstev et al. (2014) targeted 11 classes of NEs: dates and time (moments and periods), money and measurement expressions, geopolitical names (countries, settlements, oronyms and hydronyms), and personal names (one or more last names with or without first names and nicknames). The system was developed to recognize NEs in

https://doi.org/10.26615/978-954-452-072-4_142
newspapers and similar texts. It was manually evaluated on a sample of unseen newspaper texts. The overall $F_1$ score of the model was $\approx 96\%$. To the best of our knowledge, so far there were no attempts to produce a NER system for Serbian literary texts.

The enhanced version of SrPNER was later utilized by Šandrih et al. (2019) for the preparation of a gold standard annotated with personal names, which was used for building training sets for 4 different levels of annotation, on which two ML-based NE recognizers were trained and evaluated (SpaCy and Stanford). As a support for the developed NER models, Šandrih et al. (2019) joined several existing tools and developed various new tools, combined into a web platform NER&Beyond.\(^2\)

Although NER systems in general were developed mostly for newspaper and similar texts, there were some endeavours to produce functional systems for literary texts as well. Enrichment of French Renaissance texts with proper names (Maurel et al., 2014) faced two challenges: text diversity due to various spellings of words, and need to deal with numerous XML-TEI tags used to preserve the format of original editions. Authors’ solution was based on the cascades of finite-state automata and both general dictionaries and those built specifically for the project. The evaluation showed that the slot error rate of name tagging was 6.1%.

A dataset of literary entities comprising 210,532 tokens evenly drawn from 100 different English literary texts annotated with ACE entity categories (person, location, geo-political entity, facility, organization, and vehicle)\(^3\) was published in (Bamman et al., 2019). The authors’ main motivation was to asses NER models’ performance on different types of texts. Their conclusion was that recognition improved for almost all entity types when literary texts were used for the both training and evaluation (on average $P = 75.1\%$, $R = 62.6\%$ and $F_1 = 68.3\%$), whilst for training on general texts, such as news data, and testing on literary texts the results were much poorer (on average $P = 57.8\%$, $R = 37.7\%$ and $F_1 = 45.7\%$).

SHINRA2020-ML shared-task (Sekine et al., 2020) targeted the categorization of Wikipedia entities using the Extended Named Entity (ENE) hierarchy in 30 languages (Serbian was not one of them). ENE included about 220 fine-grained categories of NEs in a hierarchy of up to four layers. Some traditional NE types such as location were specified as either geopolitical location (“city”, “province”, “country”, etc.) or geological region (“mountain”, “river”, “lake”, etc.). ENE also included some new NE types like “products”, “event”, “position”, etc.

Dekker et al. (2019) experimented with different off-the-shelf NER tools for the extraction of social network graphs from classic and modern English fiction novels. The authors wanted to find out to what extent are these tools suitable for identifying fictional characters in novels, and what are differences and similarities that can be discovered between social networks extracted for different novels.

Distant Reading Training School for Named Entity Recognition and Geo-Tagging for Literary Analysis organized within the COST Action 16204\(^4\) covered NER approaches in general, annotation campaigns, practical work with NER tools, annotating NER in TEI, analyzing NER annotation for literary characters and place names and NER data analysis. Different types of NER systems were tested for several languages, some based on symbolic methods, relying on rules developed by experts and dictionaries (gazetteers), others using statistical and data-driven approach.

The NE layer of ELTeC corpus has presently been produced for three languages: Hungarian, Portuguese, Slovene. Santos et al. (2020) reported on the NER annotation of the Portuguese sub-collection of the ELTeC corpus. Authors used the PALAVRAS-NER parser, a Constraint Grammar (CG) system, in which NER is an integrated task of grammatical tagging, implemented with the basic tagset of 6 NE categories (person, organization, place, event, semantic products and objects) with about 20 subcategories at three levels, disambiguated by CG-rules: known lexical entries and gazetteer lists, pattern-based name type prediction and context-based name type inference for unkno-

\(^4\)Materials for the NER Training School, \url{https://github.com/distantreading/WG2/tree/master/NER_TS}
This system was applied to eight novels that were fully human revised. Evaluation results varied for precision from 64.6% to 80.8%, and recall from 64.3% to 82.0%.

At the mentioned Distant reading training school it was concluded that spaCy module\(^5\) for Python was used for training NER models for many involved languages, already having tagsets that could be mapped to the ELTeC annotation scheme, elaborated later in Section 3. Partalidou et al. (2019) developed a POS-tagger and a NER for Greek using spaCy, based on newspaper articles and Wikipedia dataset, able to recognize the following entity types: location, organization, person and facility. Jabbari et al. (2020) created a corpus consisting of news articles in French, which served as a dataset for training and evaluation of a NER and a relation extraction algorithms using spaCy. Modrzejewski et al. (2020) incorporated NER trained in spaCy into an English/German Machine Translation system, with the aim to improve NE translation.

Moreover, Jiang et al. (2016) conducted a comparative evaluation of different publicly available NER tools. Based on different criteria, authors concluded that spaCy was among best performing across all tested datasets. Having all this in mind, we decided for spaCy as a framework for developing a Serbian NER model on a collection old literary texts.

### 3 Serbian Collection in the ELTeC

As described earlier in Section 1, the focus of the COST Action CA16204 is to compile the ELTeC corpus containing collections of old European novels published between 1840 and 1920 in various languages. In order to make these sub-collections decent representatives of their corresponding languages, the novels were selected to evenly represent a) novels of various sizes: short, medium, long; b) four twenty-year time periods within the examined time span, c) canonical novels as well as those not known to wider audience or completely forgotten, as judged by the number of reprints, and d) female and male authors (Frontini et al., 2020).

The last version of the ELTeC (v. 1.1.0) was released in April 2021.\(^6\) It contained 14 language sub-collections each with at least 50 novels, while 8 collections contained targeted 100 novels per language.

The SrpELTeC corpus\(^7\) in the latest ELTeC release has 90 novels. The work on this collection is still in progress with the aim to obtain the complete collection by the end of the project. Contrary to a number of other European languages involved in this action, the Serbian corpus is being produced from scratch, because the vast majority of novels from the selected time period were not digitized before, they were not digitized in the proper manner or were not available (Krstev et al., 2019).

This preparation procedure involved several steps: selection of novels, retrieval of hard copies, scanning, OCR, automatic correction of OCR errors (for which a specialized tool based on the Serbian morphological dictionaries was produced (Krstev and Stanković, 2020)), correction of remaining errors by a number of volunteer readers, and production of metadata.

One of the important aspects of this ELTeC collection is to feature annotations of certain named entities. At this moment, annotation of named entities is carried out for nine languages, including Serbian. According to the guidelines, the common NER tagset includes the following 7 categories: demonyms (DEMO), professions and titles (ROLE), works of art (WORK), person names (PERS), places (LOC), events (EVENT) and organizations (ORG).\(^8\)

### 4 SrpCNNER Model for Serbian

In this section we first explain how we have turned the SrpELTeC corpus into a dataset for NER. Afterwards, we describe the training of the NER model SrpCNNER, followed by a detailed evaluation. Web users can navigate to http://ner.jerteh.rs/ in order to apply the SrpCNNER model directly on input text. The model can also be applied to a custom-size collection of text files using the previously mentioned NER&Beyond web platform.

8ELTeC Collections with NE-annotations, http://brat.jerteh.rs/index.xhtml#/eltec/
4.1 Gold Standard: SrpELTeC-gold

The SrpNER system for Serbian introduced in Section 2 was used in the first stage of the gold standard preparation (dubbed SrpELTeC-gold) in order to automatically annotate Sr- pELTeC collection. The tagset used by SrpNER differed from the simplified tagset used in the ELTeC project – the tags are more refined, e.g. toponyms are classified as oronyms, hydronyms, settlements etc., and nesting of tags is allowed. Thus, the tags produced by SrpNER had to be mapped to ElTeC tags as illustrated in Figure 1:

![Figure 1](image)

Before text annotation, we used the advantage of rule-based NER systems and adjusted SrpNER to these specific texts that differ significantly from newspaper texts for which SrpNER was primarily developed in order to improve its performance and facilitate the work of evaluators. Some modifications of rules and used lexicons were done for the whole collection (e.g. Danas ‘today’ cannot be the name of an organization since this publishing house was established 20 years ago), while others were novel-specific (e.g. Una can be the first name or the name of the river – we retained only the possibility appropriate to the particular novel).

The EVENT named entity is somewhat special: SrpNER does not recognize this entity, so the evaluators were asked to identify and annotate them when they occur in text. SrpNER does not recognize WORK entity either, but these annotations were in many cases added by volunteer readers during text correction.

Afterwards, students were given different novel chapters along with the annotation guidelines presented briefly in Table 1. Following these instructions and under constant supervision of their professors, students manually corrected the automatically annotated chapters.

The evaluators were divided into two groups: the first group performed corrections using the BRAT annotation tool,\(^9\) while the second group used the INCEpTION.\(^10\) We wanted to receive user feedback on both platforms for the sake of creating the annotation process as comfortable and efficient as possible in the future, but also to provide choice to annotators. The fundamental difference was the input format these platforms needed: BRAT tool uses the standoff format, whilst INCEpTION relies on the CoNLL-2002 verticalized format.\(^11\) In order to convert from one format into another, we used the NERBeyond web application.

Table 2 displays distribution of different entity types over SrpELTeC-gold novels. The first four digits of text identifiers represent the year of the first publication of a novel. For some novels, NER was not performed on the whole text, but rather on randomly selected chapters. These annotated samples were also included in the gold standard. The cumulative values of entities on all samples are indicated in the first row (ID “sample”). Column $\sum_{tok}$ indicates a novel’s size in terms of tokens.

4.2 Training

We trained our SrPCNNER model on the SrpELTEC-gold corpus using the spaCy Python module, version 3.0. In order to prepare the dataset for training, we first segmented texts into sentences, ending up with 43,129 sentences in total, including sentences that did not contain named entities. Afterwards, we randomly shuffled and split these sentences into training, test and development sets with the ratio of 8:1:1, i.e. 34,503 sentences in the train set, and the same number of sentences, 4,313, in the test and development sets, respectively. These sentences were prepared as Python list-objects containing tuples as elements. An example of such tuple is the following:

```
"Hadži-era je za vreme ušao u sobu agama, da im nazove dobro jutro, a manastir-
```

\(^10\)INCEpTION annotation tool, [https://inception-project.github.io/](https://inception-project.github.io/)

\(^11\)Among other CoNLL and XML variants that this tool supports.
Entity | Explanation
--- | ---
PERS | Personal names First names, surnames, nicknames and their combinations (of real people and fictional characters, including gods and saints). Possessive adjectives from personal names should not be annotated.
ROLE | Occupations and titles Occupations, titles and responsibilities: doctor, teacher; king; director.
LOC | Locations Continents, countries, regions, populated places, onyms, water surfaces, names of celestial bodies, city locations.
DEMO | Origin or residence Residents of states, cities, regions, or ethnic groups; adjectives derived from the names of locations.
ORG | Organizations, institutions, societies Company names, politic parties, educational institutions, sport teams, hospitals, museums, libraries, hotels, cafes, churches and shrines.
WORK | Art works Titles of books, plays, poems, paintings, sculptures, newspapers.
EVENT | Events Names of events that are repeated regularly or have happened once but have their own name: natural disasters, revolutions, battles, wars.

the architecture (architecture) to HashEmbedCNN\(^\text{14}\) having width of the input and the output equal to 300 (width), with 8 convolutional layers (depth), 10,000 rows in the hash embedding tables (embed_size), with the recommended 1 token on either side to concatenate during the convolutions (window_size), without pretrained static vectors (pretrained_vectors = null).

Model training ended up after 11 epochs (the number of epochs is automatically generated), having 93.33\%, 90.14\% and 91.71\% F\(_1\) score, precision and recall, on the development set, respectively.

### 4.3 Evaluation

Afterwards, we examined our model’s performance on the test set. We run the previously trained model on raw, non-annotated sentences from the SrpELTeC. After comparing the obtained annotations with the ones given in the test subset of the SrpELTeC-GOLD, we obtained the precision (P), recall (R) and F\(_1\) scores displayed in Table 3.

<table>

Table 3: SrpCNNER on the test set.

The normalized confusion matrix is given in Figure 2 (‘O’ represents tokens that are not NE). One can observe that WORK and EVENT were frequently missed or confused with PERS.

### 5 Separate Evaluation Set

Despite the encouraging results obtained on the SrpELTeC-GOLD, shown in Subsection 4.3, we wanted to further assess our model’s performance. For this purpose, we prepared an independent evaluation set, dubbed SrpELTeC-EVAL, containing corrected annotated chapters from three novels that were not included in the training procedure. Table 4 displays entity distribution over SrpELTeC-EVAL. Named entities are represented by their first letter (e.g. P represents PERS). It should be noted that the EVENT type did not occur in this dataset.

Table 4: SrpELTeC-EVAL NE distribution.

We applied the same evaluation procedure for the both recognizers. After running a them on SrpELTeC-EVAL, we took the strictest approach and differentiated between the following three situations:

- **[TP]** an entity is recognized exactly as it should, comparing to the gold standard (the text and the named entity types match – true positives);
- **[FP]** there are three cases here: 1) an entity is recognized, but not with the correct type (e.g. PERS mistaken for a ROLE); 2) an entity is recognized as a correct type but the scope is not correct (e.g only a first name is recognized as PERS, although a full name is given); or 3) model annotated something that is not present in the gold standard – false positives;
[FN] an entity present in the gold standard was not recognized – false negatives.

In the subsections that follow, we analyze the performances of our newly trained model SrpCNNER and the adjusted SrpNER on the SrpELTeC-EVAL corpus. Finally, we discuss their strengths and weaknesses and make certain statements about their applicability in different contexts and situations.

5.1 SrpCNNER vs. SrpELTeC-EVAL

The overall results for the SrpCNNER are displayed in the upper part of Table 5. As previously explained, for the case of FP, there is a specific situation that something was recognized, but not with the correct entity type. Such cases are indicated by the number in parentheses of the FP column (therefore, numbers TP, FN and the one given in parentheses from the FP column sum up to the total number of entities given in the \( \sum \) column in Table 4).

Table 5: Evaluation results SrpELTeC-EVAL.

Values of precision (\( P \)), recall (\( R \)) and \( F_1 \) scores over each entity are shown in the upper part of Figure 3.

5.2 SrpNER vs. SrpELTeC-eval

The overall results for the SrpNER are displayed in the lower part of Table 5. Values of precision (\( P \)), recall (\( R \)) and \( F_1 \) scores over each entity are shown in the lower part of Figure 3.

From the obtained results it is obvious that SrpNER was not nearly as successful as when applied to newspaper texts. This could well be expected since each novel has its own specifics, and one cannot say that novels in general share some common language features, as newspapers do. Also, one can observe that results are very different for each of three samples; however, we cannot draw some firm conclusions, since the used samples were rather small.

5.3 Discussion

Based on the results shown in Figure 3 (upper part) and Table 5, it becomes obvious that SrpCNNER does not perform so well on unseen texts. In order to understand the reasons for that, we observed each and single case in isolation, which brought us to certain findings.

SrpCNNER performed rather well in recognizing personal names (e.g. Ana, Nikola, Gavrakovici, Ismail), roles and titles (e.g. car ‘tsar’, sultan, princeza ‘princess’, sveštenik ‘priest’), locations (e.g. Beograd, Paris, Niš), and demonyms (e.g. Švaba ‘German’ (pejorative), ruskom ‘Russian’, francuskom ‘French’). However, the number of FP cases was intriguing, due to the ambiguity of use. For example, the model recognized all occurrences of the word otac ‘father’ as a ROLE, although it can represent both a male parent (which according to the guidelines should not be annotated) and a priest (which should be annotated). Similar is the case with čika ‘uncle’, which in Serbian, when used before a personal name, has the meaning of mister/sir (familiarly). Both words are used rather frequently, and out of 33 false positives for the novel 19180, 13 were occurrences of exactly these two words.

The novel 19070 revealed some new weak points. For example, occurrences such as Fatiseultan, Ismail-beg and Ahmed-hafuz are specific to this novel and they represent a combination of a PERS-ROLE entities, a construction that is not usual in Serbian – ROLE PERS order is preferred. SrpCNNER recognized these two entities as a single PERS, WORK or LOC entity (among 43 false positives for the 19070, 7 were these names in various inflected forms), or did not recognize them at all (14 times).

We also noticed that some false positives were due to specific characteristics of texts. Namely, the orthography in the old novels was not stable, leading to incorrect occurrences (according to contemporary usage); for instance, the word gospode ‘god’ was considered, according to the decision of the evaluator, FP because written with the lower-case G, while the same word written with the upper-case G Gospode ‘God’ was found among the true positives.

It should be noted that in literary texts it is not always easy to decide what is the right type of an NE. For instance, in a sentence from...
19180: Sa Tolstojem sam se pomirila i obožavam ga za Anu Karenjinu ‘I reconciled with Tolstoy and I adore him for Anna Karenina’, *Ana Karenjina* can refer to the novel (WORK) or to its main character (PERS), and it is open to interpretation. Similarly, the names of saints (PERS) were sometimes difficult to distinguish from festivities that celebrate them (EVENT). One such example from 18950 is: *Mi slavimo Svetog Nikolu, ovog letnjeg.* ‘We celebrate Saint Nicolas, the one that comes in summer.’

Finally, we have noticed that our gold standard has flaws, introduced by evaluators, especially when facing some of the tricky cases mentioned before. It would have certainly been better if we could engage two evaluators for each text, but our human resources were limited.

Overall conclusion is that SrpCNNER performs satisfactorily on similar texts, which can be seen from the model’s performance on the test set displayed in Table 3. Since this collection of novels contains very diverse texts, both lexically and syntactically, SrpCNNER did not generalize that well on unseen texts.

6 Conclusions and Future Work

We presented the corpus of old Serbian novels, which served as a basis for training a CNN-based NER model SrpCNNER using the spaCy module’s framework for Python. After comparing this newly developed model for Serbian with the existing rule-based SrpNER, we came to the conclusion that the previously developed one performs better on this type of texts, due to its adaptability. However, it is not easy to set it up and use it, while the model trained in spaCy can be easily and efficiently applied to the large text collections, and there is still a lot of room for improvement. First of all we need to remove observed flaws from SrpELTeC-gold. Moreover, in the future we intend to use the pre-trained word embedding vectors instead of the default *tok2vec* layer.

The integration of POS-tagging and lemmatization with NER into TEI ELTeC level 2 schema\(^{15}\) is an ongoing activity, where a pipeline starts with SrpNER annotation, followed by POS-tagging and lemmatization by a TreeTagger (Schmid, 1999; Stanković et al., 2020). As a result, first 16 novels from SrpELTeC collection were annotated with POS, lemmas, and NE in a format agreed by the COST action.

Acknowledgments

This research was done in the scope of the COST action CA16204 “Distant Reading for European Literary History”. We thank the students of the Department of Library and Information Sciences, Faculty of Philology, master students of Social Sciences and Computing at Multidisciplinary Graduate Studies and PhD students of Intelligent systems program (University of Belgrade) for their help in evaluating the data.

Abstract

Toxic comments contain forms of non-acceptable language targeted towards groups or individuals. These types of comments become a serious concern for government organizations, online communities, and social media platforms. Although there are some approaches to handle non-acceptable language, most of them focus on supervised learning and the English language. In this paper, we deal with toxic comment detection as a semi-supervised strategy over a heterogeneous graph. We evaluate the approach on a toxic dataset of the Portuguese language, outperforming several graph-based methods and achieving competitive results compared to transformer architectures.

1 Introduction

Toxic comments, posts, and other types of content became more common in social media nowadays. They contain forms of non-acceptable language (profanity), which may be concealed or explicit, including insults and threats directed to a group or individual (Zampieri et al., 2019). These comments spread rapidly on the internet, especially on social networks where they find acceptance, and may culminate in several threats to individuals, becoming a serious concern for government organizations, online communities, and social media platforms.

The term toxic comment is commonly found in literature as harmful speech, hate speech, or offensive language. Toxic comment may be viewed as negative online behaviors, i.e., comments that are rude, disrespectful, may contain hate speech, or otherwise likely to make someone leave a discussion1. Schmidt and Wiegand (2017) define hate speech as any communication that disparages a person or a group based on some characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, religion, or other characteristics. Also, it may occur with different linguistic styles, even in subtle forms or when humour is used (Fortuna and Nunes, 2018). It is important to highlight that fighting these types of comments is of utmost importance since they are a crime in several countries.

To deal with toxic comments, most approaches adopt supervised-machine learning techniques and are mainly focused on the English language (Poletto et al., 2020). These approaches range from surface-level features, as Bag-Of-Words (Paiva et al., 2019), linguistics features, as Part-Of-Speech information (Chen et al., 2012), deep neural networks, as Long Short-Term Memory (LSTM) (Fortuna et al., 2019) and Convolutional Neural Networks (CNN) (Badjatiya et al., 2017) to Transformer architectures (Leite et al., 2020). Despite interesting results achieved by Transformer architectures, there are still several rooms to be explored in this research area.

In this paper, we developed a semi-supervised strategy to detect toxic comments in the Brazilian Portuguese language. Semi-supervision is the problem of learning from labeled and unlabeled data (Abney, 2007; Subramanya and Talukdar, 2014), in which given a point set $X = \{x_1, \ldots, x_l, x_{l+1}, \ldots, x_n\}$ and a label set $L = \{1, \ldots, c\}$, the first $l$ points have labels $\{y_1, \ldots, y_l\} \in L$ and the remaining points are unlabeled (Zhou et al., 2004).

We modeled that problem as a heterogeneous network. The structure of our graph was inspired by de Sousa et al. (2020) and Anchiêta et al. (2020). These authors modeled the tasks of helpfulness prediction and paraphrase identification as a heterogeneous network, respectively. For that, they defined an undirected unweighted graph with two node types: sentence and token. However, we have

1https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge/overview
created a weighted graph based on pre-trained word embeddings. The weight between sentence and token nodes is the average of the embedding values for that token. Figure 1 depicts an example of a sentence modeled as a graph. From this figure, we may see two node types: token and sentence, and an undirected and weighted edges between the sentence and tokens nodes.

Figure 1: Example of a graph model for the sentence “Holy shit, I miss playing midnight club”.

To extract features from the graph structure, we used a regularization algorithm that propagates labels from a small set of labeled nodes to the entire graph.

We evaluated the approach using the ToLD-Br corpus (Leite et al., 2020). It has twenty-one thousand annotated tweets as either toxic or non-toxic language. Also, we compared our strategy with different graph-based methods and with transformer-based methods. Our method outperformed all graph-based approaches and achieved competitive results compared to transformer-based methods, using only 10% of labeled nodes.

The reminder of this paper is structured as follows: Section 2 briefly presents related work. In Section 3, we show the used corpora. Section 4 details our developed approach. In Section 5, we analyze the conducted experiments. Finally, Section 6 concludes the paper, presenting future directions.

2 Related Word

As aforementioned, the main approaches to detect toxic comments are based on supervised machine learning. Here, we briefly present the main works.

Most of the works that study this task commonly point first to surface-level features, such as bag of words and lexicon-based approaches, with negative words as features (Gitari et al., 2015; Waseem and Hovy, 2016; Waseem et al., 2017; Schmidt and Wiegand, 2017).

More recently, neural networks-based strategies and transformer-based architectures has been applied to hate speech detection due to the good results achieved in various tasks. Banerjee et al. (2020) evaluated pre-trained word embeddings with CNN networks to hate speech detection for the Indian language. Rizwan et al. (2020) explored transfer-learning of embeddings models to Roman Urdu and developed a CNN-gram network to hate speech classification for that language. Duwairi et al. (2021) investigated the ability of CNN, CNN-LSTM, and BiLSTM-CNN to classify hate speech in Arabic. Plaza-del Arco et al. (2021) compared two pre-trained language models, such as BERT (Devlin et al., 2019) and XLM (Conneau and Lample, 2019) trained to detect hate speech in the Spanish language.

For the Portuguese language, most of the works follow the trend of supervised approaches. de Pelle and Moreira (2017) created a dataset consist of 1,250 offensive comments and developed a baseline method based on n-gram features to classify offensive comments in their dataset. Fortuna et al. (2019) created a hate speech dataset composed of 5,668 tweets and developed a baseline classification using pre-trained word embeddings and LSTM in their dataset. Coutinho and Malheiros (2020) trained a logistic regression using superficial features for sentiment analysis. Then, they evaluated that model into a homophobia corpus to detect homophobic posts.

Although there are some efforts to detect non-acceptable language in Portuguese, they evaluate the developed approach in their own corpus, making a fair comparison among the models difficult. Moreover, these corpora are much smaller when compared to corpora of other languages (Poletto et al., 2020) and than the ToLD-Br corpus. This fact makes the development of robust strategies to handle toxic comments difficult, as they usually require a large corpus.

3 ToLD-Br Corpus

Toxic Language Dataset for Brazilian Portuguese (ToLD-Br) (Leite et al., 2020) is a very recent dataset with Twitter posts in the Brazilian Portuguese language. It has 21K tweets manually annotated into seven categories: non-toxic, LGBTQ+phobia, obscene, insult, racism, misogyny, and xenophobia. The corpus is the largest dataset available for toxic data analysis in social
media for Portuguese and the first dataset with demographic information about annotators.

Besides seven categories, the authors released a binary version of the corpus for the binary classification task, as shown in Table 1.
